MACHINING AUTOMATIC CHUCKING MACHINE AND LATHE TURRETS

SPECIAL BORING AND PLANER FIXTURES FOR INSURING HIGHLY ACCURATE INDEXING

BY C. M. CONRADSON*

IN boring the spindle bearings of the turret for the automatic chucking machine shown in Figs. 1 and 2, it was necessary to attain a degree of accuracy seldom required in machine work of this size. The holes had to be perfectly round, accurately spaced tangentially and radially, and the axes of the holes had to be exactly parallel with the axis of the central bearing of the turret. When it is known that the limit of tolerance was 0.0005 inch, it will be readily understood that this job required more than ordinary care.

In order to index the work for boring the six bearings, a special fixture was constructed which, so far as the writer knows, operates on a new principle. Referring to the illustrations, it will be seen that this fixture is mounted on a surface plate, the work being carried on an arbor supported in V-blocks. The supports which carry these V-blocks are firmly bolted and doweled to the surface plate and carefully

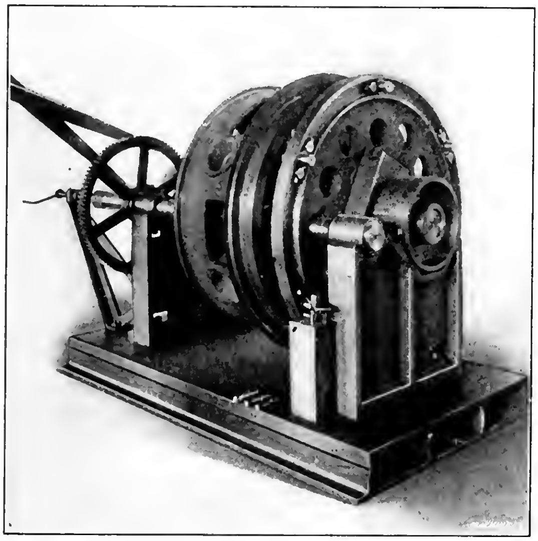

Fig. 1. End View of Fixture showing V-blocks and Indexing Mechanism

finished to bring the axis of the spindle carrier at exactly the required distance from the boring-bar which machines the six bearings.

The boring-bar is also supported in bushings which are carried in V-blocks, the bar being provided with double-ended boring cutters. The method of driving the boring-bar and feeding it up to the work is clearly shown.

The method of indexing used on this fixture constitutes the most interesting part of the work. The index wheel is a heavy plate casting which is clamped to the arbor by means of a split hub. It will be seen that there is an annular groove in the plate close to the periphery, and the index plugs are carried in holes bored through the casting in this groove. The plugs were very carefully ground and lapped after hardening and were brought to a perfect fit in the annular groove. A test-bar adapted to swing on one of the index plugs was equipped with a delicate test indicator at the opposite end. This indicator was used for adjusting the plugs until each plug was located at exactly the same distance from adjacent plugs. Similar tests were made to prove that the distance of each plug from the center of the fixture was exactly the same. The method of indexing is rudimentary in its simplicity, but it possesses the valuable feature of eliminating lost motion entirely. The index plug is strapped down on a hardened and ground steel plate which is carried on the top of a cast-iron block fastened to the surface plate. The operation of the fixture and the resulting accuracy of the work produced on it left nothing to be desired. The total time required for boring the piece was sixteen hours, and as this was the first piece to be machined in this fixture, it is felt that subsequent pieces can be machined in a much shorter time. Five of the bearings were located in exactly the required position, while the sixth one was 0.0005 inch out of the way.

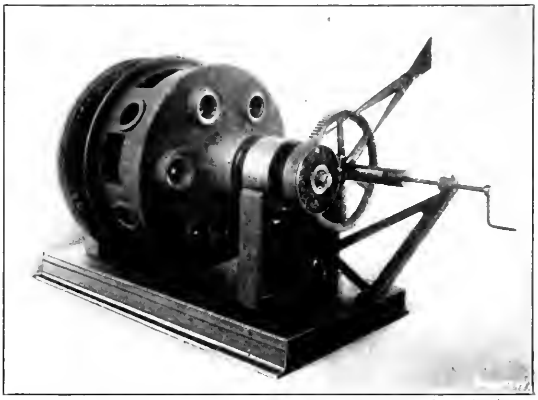

Fig. 2. Opposite End of Fixture showing Drive and Feed Mechanism

Fig. 3. Final Test of Location of Index Plugs with Dial Test Indicator

The question has been asked why some simple form of power feed was not used instead of relying upon the rather crude hand feed. It was felt that a workman who was competent to do this work satisfactorily could produce the desired results with the hand feeding device shown in the illustrations, and experience has shown that this assumption was correct. The accuracy and rapidity with which the work was done entirely fulfilled expectations. The fixture was designed and built by the writer, with the assistance of Mr. C. F. Larzelere, superintendent of Giddings & Lewis Mfg. Co., Fond du Lac, Wis.

*Address: Madison, Wis.

Planing Turret and Slide of Semi-automatic Turret Lathe

Figs. 3 to 8 show the methods used in machining a turret and turret slide for a semi-automatic turret lathe which is being built for the writer by the Phoenix Mfg. Co., Eau Claire, Wis.

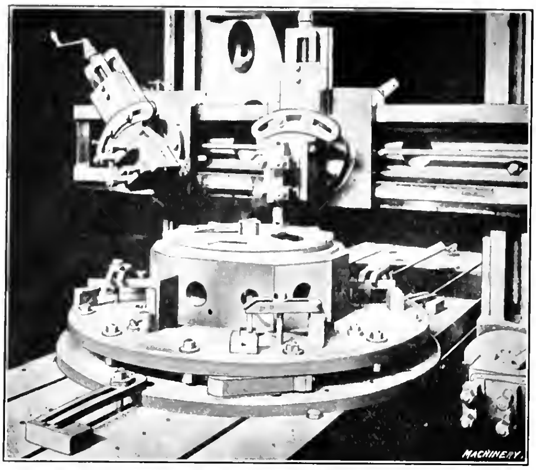

Fig. 4. Planing Teeth of Turret of Semi-automatic Lathe

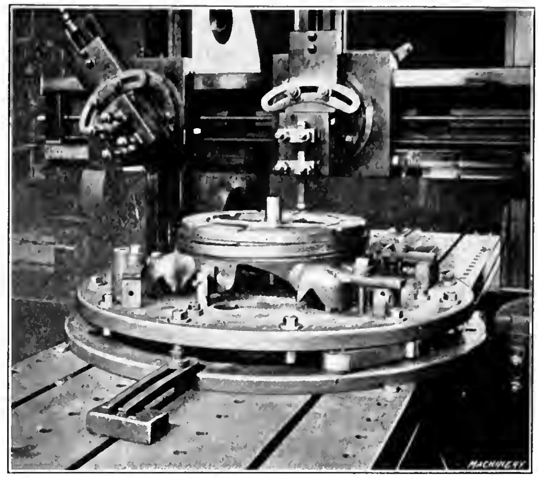

Fig. 5. Planing Spaces in Turret Slide to receive Turret Teeth

The turret of this semi-automatic turret lathe is provided with twelve holes and after it has been indexed to bring the required tool into the operating position, it is locked to the turret slide by means of the twelve teeth and spaces shown in the illustrations. The fixture shown in Fig. 6 was designed for indexing the work in order to plane these teeth and spaces. These operations are unusual, in that it is necessary to finish the work within very close limits in order to have the teeth on the turret engage properly with the spaces on the turret slide.

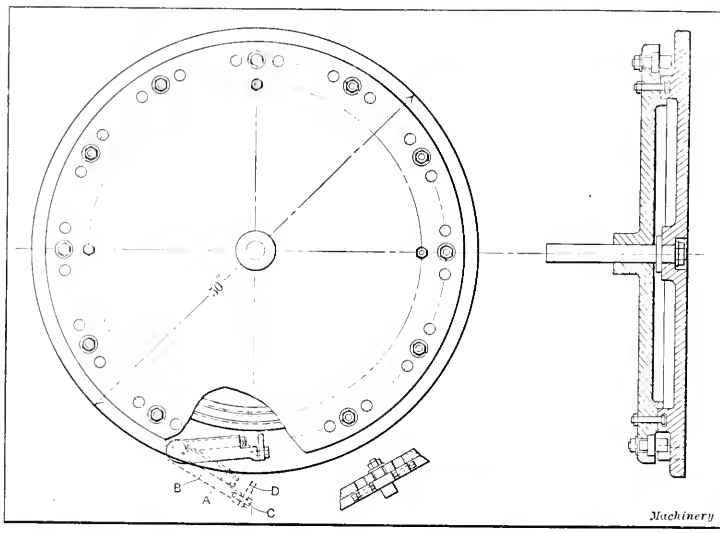

Fig. 6. Design of the Planer Indexing Fixture used to plane the Turret and Turret Slide

It will be seen that the fixture consists of two plates, the lower plate being bolted to the planer table, while the upper plate is carried on an arbor upon which it can be rotated in relation to the lower plate. The upper plate has twelve plugs mounted on its lower side. These plugs are made of steel and were ground and lapped after hardening to insure having them of exactly the same size; they were then carefully spaced around the diameter of the plate by means of a vernier caliper, the final adjustment being made with a dial test indicator as shown in Fig. 3.

In using this fixture to index for the twelve teeth on the turret or spaces on the turret slide, successive plugs on the index plate are brought up against the hardened steel plug *A* of the lock mechanism *B*. The bolt *C* is then tightened to clamp the plug *D* over the index plug. In this way the fixture is held securely in position and the planing operation can then be carried on. Fig. 4 shows the teeth being planed in the turret and Fig. 5 shows the operation of

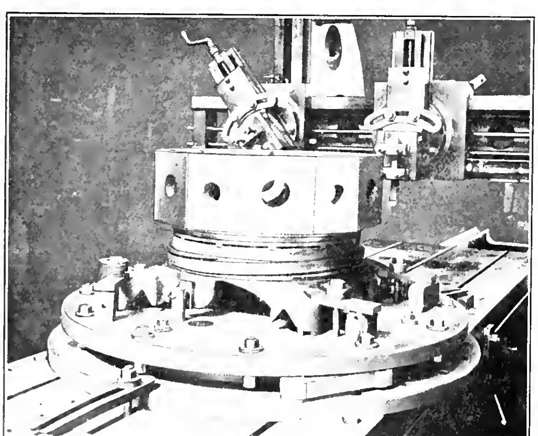

Fig. 7. Testing Accuracy of Teeth and Spaces of Turret and Slide

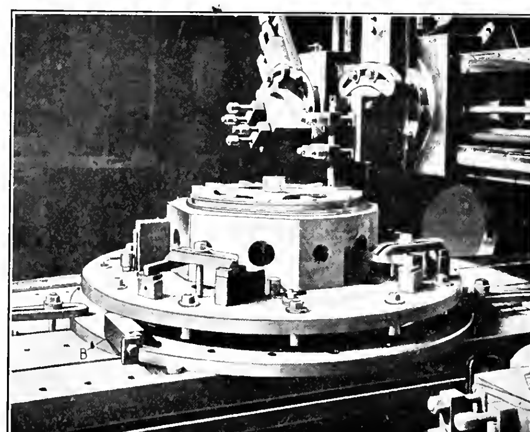

Fig. 8. Planer Indexing Fixture with the Lock Mechanism B swung back

planing the spaces in the turret slide. After these operations were completed, the table of the planer was run out sufficiently to allow the turret to be placed in position on the turret slide as shown in Fig. 7, in order to test the accuracy of the teeth and spaces.

This index plate was made in the shops of the Phoenix Mfg. Co., Eau Claire, Wis., under the direction of Mr. Neys, superintendent of the company. The operation of planing the turret and turret slide was also conducted in these shops and as previously stated, the work was finished within very close limits.

* * *

A CASE OF DEFLATION

BY GEORGE WILSON*

It is an idiosyncrasy of human nature to derive considerable satisfaction from the discomfiture of a performer who is putting on frills in an effort to aggrandize himself in the eyes of the audience—in plain English, "playing to the grandstand."

Bill and I were making the rounds of the machinery section of a state fair. A crowd that was gathered around the exhibit of a carriage-maker drew our attention, and on edging our way to the front we found the attraction to be several blacksmiths at their forges producing the various iron parts that went into that particular make of buggy. The *piece de resistance* of the exhibit proved to be a young fellow of perhaps twenty-five years of age, and it was quite evident that if there was any applause lying around loose he meant to have it.

He was a typical melodramatic smith, tall, broad-shouldered and a "good looker" generally. His hair was carefully arranged; his blue flannel shirt was open at the throat, disclosing a section of manly chest, and his sleeves were rolled rather higher than was necessary to give play to biceps that knotted and swelled just a little more than the job warranted. His get-up was one of "studied indifference" as the novelists say. But his action! Chesterfield and the Apollo rolled into one had nothing on him. Grace incarnate. The poetry of motion. The methodical plodding of the veterans at the other anvils was only cheap newspaper prose compared to his easy grace.

"My, ain't he grand!" breathed a callow damsel ecstatically through a mouthful of popcorn.

His pride was partly excusable, for he was really a good workman. With a few deft blows he would have a rod welded and bent into a graceful scroll. Then to prove the merit of the weld and the quality of the material he would bend and twist the cold piece over the anvil.

One of the duties of the smiths was to pass out souvenirs in the form of pewter facsimiles of a medal the carriage concern had won at some exhibition. This the Apollo did with a fine condescension.

"That guy is all right, but he ought to take something for his head," muttered Bill. Then to the Apollo, timidly, "Don't you ever get a bum weld?"

If a look could have killed, Bill's demise would have been swift and terrible. Chastened and contrite, Bill slunk back as Apollo flourished his irons from the fire and struck the uniting blow. Amazed he looked at the glowing ends. They had not stuck! Back to the fire. Another trial. Nothing doing. Some of the crowd tittered. The veterans at the other anvils grinned appreciatively and the Apollo's face got red. There were no flourishes when he grabbed some new irons and brought them to a heat. Biff! Bang! Swat! The pieces stuck about as nicely as a couple of pieces of brass would have done.

Apollo ceased his effort and mopped his classic brow. The hauteur had all oozed out. The snickers became general and included a few uncomplimentary remarks.

"Let's get out of here," muttered Bill. As we turned to leave the Apollo started to heave out his fire. Outside the crowd, Bill exploded and a suspicion dawned in my mind.

"Bill," I demanded, "what did you do to that fellow's fire?"

"Nothing much," grinned Bill, "just dropped a couple of his medals into it."

* Address: Madelia, Minn.

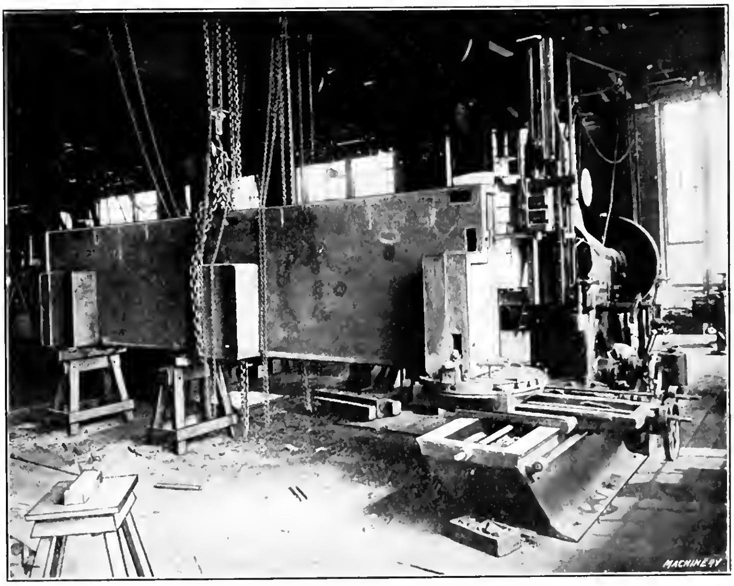
A LARGE SLOTTER JOB

In building a large special drilling machine at Edwin Harrington Son & Co.'s shops, at Philadelphia, Pa., the bed was constructed in quarter sections, and to join these sections properly it was necessary to machine the sides and ends. The sides were readily finished by planing, but the machining of the ends presented unusual difficulties because of the great size and weight of the work.

The halftone shows how the parts were machined on a Dill slotter. The casting was supported from a ten-ton crane and located with one end resting on the slotter table. As the length of the cut measured 51 inches and the full stroke of the slotter was only 20 inches, it is evident that the surface had to be finished in three cuts. In order to get up high enough to start the first cut a special offset slotting tool was forged, and this was clamped at the extreme top of the tool-holder. This tool being properly set, the casting was machined as far as the offset portion which is shown in the illustration. Of course the feeding across the work, which was a distance of twelve inches, was accomplished by using the traveling head, which is a distinguishing feature of the Dill slotter. After this section had been surfaced, a straight slotting tool was mounted in the tool-post and a second cut taken, leaving the stroke of the ram still at its highest position. The stroke was next transferred to the lower section of the work and the remaining part of the work thus completed. C. L. L.



Facing an 11,500-pound Casting on a Dill Slotter

* * *

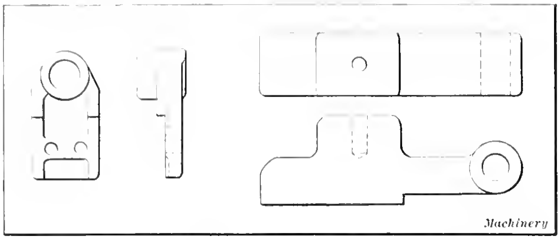
Reaming is commonly regarded as an internal cutting operation—that is, as enlarging a hole. But reaming is both internal and external. Box-tools are examples of external reamers. These usually ream or turn straight or cylindrical parts but they are also successfully used for taper work up to lengths of eighteen inches and diameters of 1½ inch or more. A prominent example is the locomotive taper turning tools used on special vertical machines in locomotive building and repair shops. The speed with which taper bolts are turned or reamed to exact sizes would astonish one not familiar with this work.

A UNIVERSAL DRILL JIG

A DESIGN PRIMARILY INTENDED TO HANDLE CASTINGS HAVING A ROUND BOSS ON ONE SIDE

BY CHRISTIAN F. MEYER*

The universal drill jig described and illustrated in the following was designed for drilling parts which are quite different in shape but which all have a round boss on one side.



Figs. 1 and 2. Two Classes of Work for which the Jig was designed

Figs. 1 and 2 show two typical examples of the class of work for which this jig was designed, and with slight modifications which will be explained later, the jig could be adapted for both drilling and boring operations on a great variety of work.

Referring to Figs. 3 to 6, it will be seen that the jig consists of a cast-iron baseplate *A*, which is provided with a dovetail slot in which three slides *D*, *G* and *K* are held, so that they may be moved longitudinally by screws and operating keys. A cast-iron guide piece *V* is also held in the dovetail slot in the base of the jig, and this guide carries the lower bushing *W*. This construction will be readily understood by referring to Figs. 4 and 5.

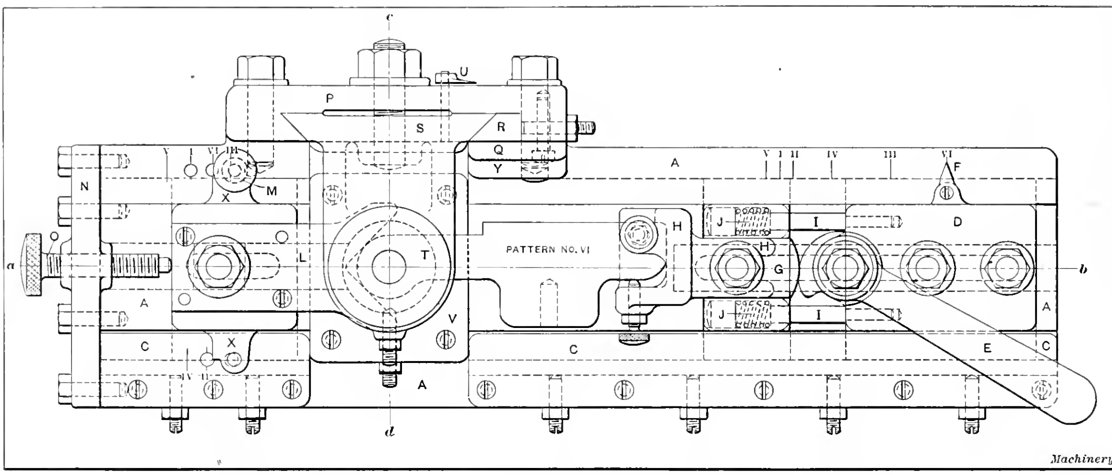


Fig. 3. Plan View of the Jig, showing Adjustable Slides for holding Different Kinds of Work

The slide *D* is provided with two bolts which slide with their heads in a suitable slot in the base *A*, and handle *E* is fastened to this slide, the hub of the handle being cam-shaped, as shown in Fig. 3. The cam forces the slide *G* forward when handle *E* is turned in the proper direction. Slide *G* is loose in the slot in casting *A*, and is connected to the slide *D* by means of two studs *I*. Each stud is provided with a spring *J* which draws slide *G* toward slide *D*. The top of slide *G* is cut away to receive the guide pieces *H*, a different form of guide piece being required for each class of work which is drilled in the jig. In order to explain the operation of this jig, it has been assumed that it was designed for drilling six classes of work, known as Patterns I to VI. Pattern No. VI is shown in detail in Fig. 2, and the same piece is shown mounted in the jig shown in the illustrations. It will be seen that the guide piece *H* for this particular piece is designed in such a way that the work is held by means of two screws with knurled heads. The guide piece is held on slide *G* by means of a washer and nut, which fit a stud in the slide. Slide *K* is also cut away for the V-block *L*, which receives the end of the piece to be drilled.

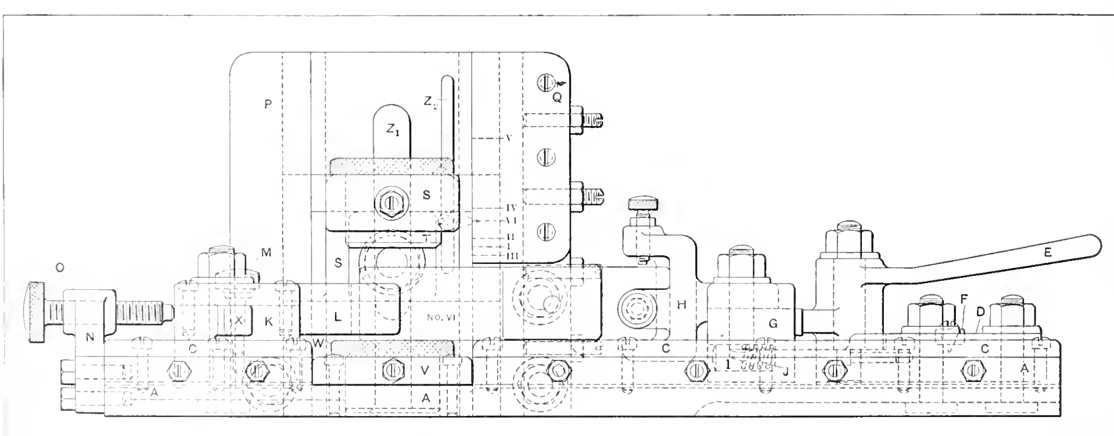

Fig. 4. Front View of the Jig showing Bushings and Drill Guide Supports

Referring to Fig. 3, it will be seen that slide *D* is provided with a pointer *F*. In adjusting the jig for any particular class of work, the bolts which hold the slide are loosened; the slide is then moved along the slot in the casting to bring the pointer

* Address: Wyomissing, Pa.

F to the graduation which indicates the class of work which is to be machined. The bolts are then tightened to secure the slide in this position. As shown, at the other end of the jig there are similar graduations which provide for setting slide *K* and V-block *L* in the required position, the method of adjustment being similar to that described for slide *D*. It will be seen that an adjusting screw *O*, carried by the piece *N*, provides for adjusting the position of slide *K*. This slide has a pointer *X*, which is brought up to the graduation that indicates the class of work to be drilled. A taper pin *M*, fitting into corresponding holes in the top of base *A* and cover *C*, serves to locate slide *K* and V-block *L* in exactly the required position, thus insuring an accurate location of the work.

The guide *V* is fastened to base *A* and receives a hardened steel bushing *W* which is held in place by a pointed set-screw. In a similar manner, the bushing *T* is held in the arm of the slide *S*. Both bushings are provided with a knurled flange and may be easily removed to be replaced by different bushings for another kind of work. The outside diameter of all of the bushings is made alike, however, so that they all fit the same holes.

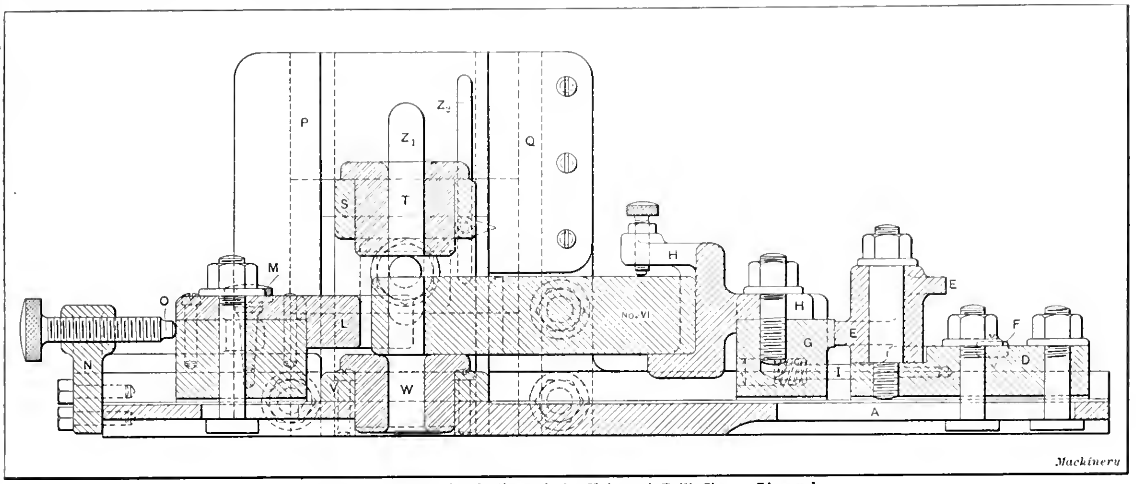

Fig. 5. Cross-sectional View of the Universal Drill Jig on Line a–b

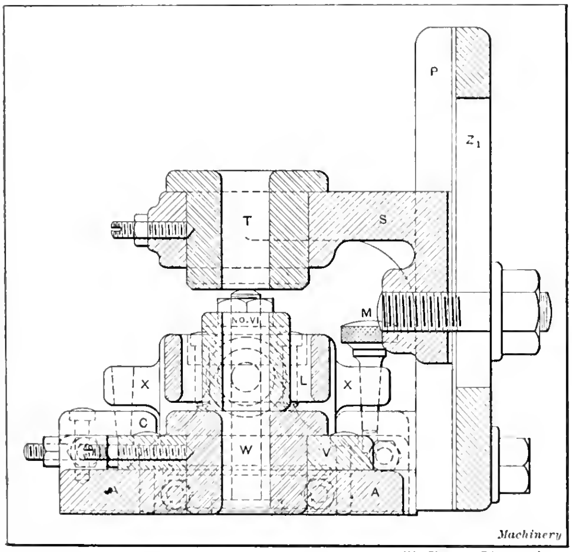

Fig. 6. Cross-sectional View of the Universal Drill Jig on Line c–d

The slide *S* is carried in a dovetail slot in the support *P*. The cover *Q* and key *R* are used to adjust the position of slide *S*. The support *P* is fastened to an extension on base *A* by means of bolts, the construction being clearly shown in Figs. 3 and 6. Slide *S* is held in the support *P* by a strong stud, washer and nut, and may be fastened in any desired position, the stud moving in the slot Z_1. A narrow slot Z_2 guides a smaller stud which has a pointer *U* fastened to it. This pointer slides over a scale graduated on the back of the support *P*, which indicates the correct position of slide *S* for different classes of work which are being drilled in the jig.

After the three slides *D*, *K* and *S* have been set, the jig is ready for use. The quick-acting cam lever *E*, in connection with the automatic releasing slide *G* and guide piece *H*, works very efficiently, and the guide pieces *H* and *L* locate the work with great accuracy. Although this jig was only constructed for work with a round boss—as shown in Figs. 1 and 2—it will be readily seen that it could be adapted for almost any shape of work by replacing the V-block *L* by a member somewhat similar to the guide piece *H* on the slide *G*. This jig might also be arranged upon the faceplate of a lathe or boring mill. The drill guide would then be unnecessary and the bushing *W* would be made in such a way that the pilot of the cutter would enter the bushing before the cutting operation began. This would provide for an accurate cut.

The operation of the jig is so simple that any boy can handle it. In addition, the jig is "fool-proof," as the special guide piece and setting of the slides will not suit any class of work except the one for which it is designed. The use of a universal jig of this kind saves the expense of making individual jigs for each class of work and also means a considerable saving of space in the tool-room.

* * *

USELESS LABOR IS THE ONLY UNPRODUCTIVE LABOR

"If a lot of capital is***spent in unproductive ways, there will be not only less for other uses, but the natural growth of capital will be arrested in proportion as the uses to which it is devoted are unproductive. When you put $10,000,000 of capital into an industry or a railroad it multiplies itself; when you put capital into armament, meaning warship and standing armies, as has been done on so vast a scale in Europe, or when you spend it on monuments which in themselves have no earning power, as has been done widely in this country, the capital is, in the economic sense, lost. It cannot multiply. The enormous expenditure of capital all over the world in unproductive ways is the fundamental explanation of the present scarcity of capital."—*New York Evening Sun.*

[The statement above would have been equally, or, perhaps, even more directly applicable and true if the writer had referred to labor spent in unproductive ways. In the last analysis, capital spent in unproductive ways is really labor thus spent, and the enormous expenditure of labor all over the world in unproductive ways is without question a fundamental reason for many of our financial, economic and social difficulties. EDITOR.]

PHOTOGRAPHIC DEPARTMENT OF THE NATIONAL-ACME MFG. CO.*

THE EQUIPMENT AND FUNCTIONS OF AN INDISPENSABLE FACTOR IN MODERN ADVERTISING AND SELLING

BY F. SLUKA, JR.†

The National-Acme Mfg. Co., of Cleveland, Ohio, in common with many other manufacturing companies, had a great deal of difficulty in getting suitable photographs from outside photographers, due to their lack of special training in photographing mechanical subjects, and to the fact that they were forced to work under difficulties, such as lack of a suitable place to take the pictures and conveniences for preparing the subjects to be photographed. The company therefore established its own photographic department, as a branch of the advertising department, during the month of August, 1910, as an experiment toward getting better photographs at less cost. In three years' time the photographic department has made itself practically self-sustaining, and it is doing so much better work in its line than the company was able to get previously that it has come to be regarded as a valuable adjunct to the advertising and sales divisions of the business.

The extent of the work carried on by the photographic department can be judged from the fact that during the past year the builders of the Acme automatic multiple-spindle screw machine used about 850 photographs per month for advertising and sales purposes, which means the use of over 10,000 photographic prints during the year. If outside photographers had been employed as required to get these pictures, a member of the sales or advertising force would have had to be with the photographer on each occasion, to see that he got the view of the machine desired, that the subject was prepared properly, and that the proper parts of the mechanism were brought out according to the requirements. An outside photographer, lacking familiarity with machinery in general and with the Acme automatic in particular, could not be expected to get this without supervision. With his own department, however, the advertising manager tells the head of the photography branch just what he wants, and then forgets about it until the photographic department shows him the finished prints that he ordered. The sales department puts in an emergency call at any time for any special photograph and the photographic department has it ready in a day or so without further attention from the sales department. This is a very great convenience to the heads of the sales and advertising departments, and it soon saves a lot of time and expense to the company. The National-Acme Mfg. Co. uses photographs in the following ways:

Fig. 1. Section of National-Acme Mfg. Co.'s Photographic Department

1. *For Records.*—The advertising department has all sorts of views of machines, parts, and tools taken at different times for many purposes. Every time a new photograph is made for any purpose whatever, the necessary working prints, for retouching, mailing, or other use, are made from the negative and at the same time one record print. The negative is then filed away in the racks provided for that purpose, the working prints are used or sent out as required, and the record print goes into one of the record binders, according to its classification. The record photographs are separated into twelve different classifications and each is kept in substantial binders and properly labeled for reference at any time. These record photographs are also listed in a card index, and the number on the negative also appears on the record print and on the

* For articles on shop photography previously published in MACHINERY see: "Shop Photography," January, 1910, and the other articles there referred to.
† Address: National Acme Mfg. Co., Cleveland, Ohio.

proper card in the card index. Needless to say, this library of record photographs is extremely useful and valuable. It is in many ways, a history of different experiments and developments in building the Acme automatic multiple-spindle screw machine during the period that the photographic department has been in existence.

2. *Photographs for answering Inquiries and for Sales Promotion Work.*—When inquiries about the machines, their work, their parts or their product are received, a very clear answer can be given the inquirer by sending him a photograph and a brief letter of explanation. The sales promotion department finds these photographs very effective as auxiliaries to the promotion letters. The photographs establish a bond of interest with the prospect and illustrate the truth of the points brought out in the letters. One of the big advantages of a photographic department for the business comes in right here. The men in the photographic department, through familiarity with the machines and their uses, develop the sense of mechanical values which is so necessary in order to get the real sales force into the photographs. By specializing, so to speak, on the Acme machines, they know how to bring out certain parts of the machines or features of their use, according to the requirements, and thus get pictures that have real educational and sales value, as well as artistic beauty. Some of these pictures are printed on black backgrounds with soft gray tones for the masses and high lights for the details of the machines. This treatment, besides being distinctively original, subdues the non-essentials and brings out the essential parts of the machines. Other pictures of machines have the background left in purposely, while on others it is painted out on the negative.

Fig. 2. Photographing Machine in Perspective for Line Drawing Copy

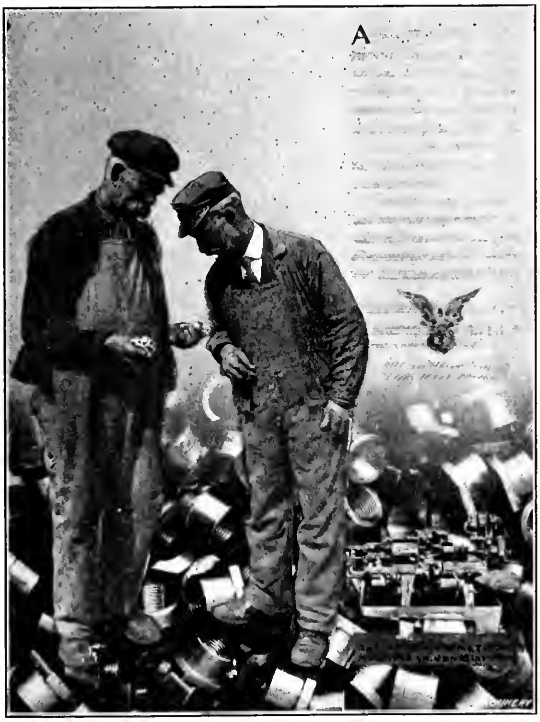

Fig. 3. Advertising Illustration composed from Shop Photograph

3. *Photographs for Retouching.*—Retouching photographs is at best an expensive process because it means hand painting by high-priced craftsmen. The cost of retouching can be minimized by the use of fine photographs, or magnified by the use of poor ones. It is a question of the amount of the artist's time required to fit the photograph for engraving. As a photograph of a simple object will cost only about $1.50 to $2.50, while the retouching necessary may cost anywhere from $5 to $50, according to the photograph, it seems wise to take more time for the photographing and save the more expensive time of retouching. The National-Acme idea is to spend a little more time and money on the photographs and save a lot on the retouching. The photographic department, in getting photographs which are later to be made into engravings, is very careful to get the clearest possible pictures to bring out the salient parts of the machine, which should be strong in the printing.

Fig. 4. The "Skyscraper" Camera photographing a Group of Screws

4. *Photographs for Line Drawing, or for Poses of Individuals for Advertising Purposes.*—Fig. 2 shows that when line drawings of machine parts are wanted, it is quite a simple matter to go into the shop and make a quick photograph from the proper angle, from which it is easy to make a pen-and-ink drawing. Such photographs do not need to have the light and shade contrast that the better photographs must have, but they should show as much detail as will be required in getting material for the artists to work on, so as not to waste the artists' time. A camera is often taken into the shop to get a quick photograph of a man or group of men in some characteristic pose to illustrate an idea for an advertisement. (See Fig. 3.) Sometimes line drawings for engravings are made from these pictures, and sometimes the photographs are used as copy for halftones with a background of machines or some other effect sketched in.

5. *Photographs to be enlarged for Advertisements or for Framing.* Magazine pages are in some cases larger than 8 by 10 inches the usual size of the photograph and in making the engravings for printing, as it is always advisable to reduce from the photograph, they are frequently thrown up to a much larger size, retouched if necessary, or perhaps lettered, and then sent to the engraver, who photographs them in reduced size to the proper size for the plate. This gives more detail in the finished cut. Enlargements of the Acme automatic machine and views of the factory are also made for framing. These pictures are sent to the branch offices and to other companies interested in having them on their office walls. These pictures are often made with the black background treatment referred to above.

The National-Acme photographic department has a well-equipped studio for taking pictures, a section of which is shown in Fig. 1. It is located on the top floor of one of the three bridges which connect two wings of the plant—an ideal place for photographic work, as an abundance of light is available from both sides and above, and the vibration common to large manufacturing plants is not felt in the suspended bridge. The studio is equipped with two 8 by 10 Century cameras, one for copying work and enlarging, and the other for general photographing; one 11 by 14 Century camera which is chiefly used for catalogue work; and a 5 by 7 Graflex which is used on special work. Four lenses are in use, *viz.*, one 19-inch, one 12-inch, one 8-inch Dagor, and one Bausch & Lomb Zeiss-Protor, Series V for extremely wide angle work.

When one of the Acme automatics is to be photographed it is brought into the studio from the elevator on a portable crane, and placed on a turntable by means of which the photographer can turn the machine easily to get any view desired. This is shown in Fig. 5. The turntable allows him to take advantage of the best lighting available at the time, and this is a particularly important feature in obtaining the best results. Artificial light is often used in photographing sections of the machines where the daylight fails to penetrate, and for this purpose a Cooper-Hewitt light is used as an auxiliary to the daylight in the studio.

Before photographing the machine, it is usually prepared by painting to avoid excessive retouching and to get a smooth effect in the engraving. The paint used by most photographers is made of lampblack and gasoline. The objection to this is that it is very quick-drying and requires care to apply it without getting a streaky effect. The lampblack must then be scraped off before finish-painting the machine for shipment. The National-Acme Mfg. Co. prepares the machines by wiping off all oil and grease, and then applying an oil paint that is a flat but not a dead black. (See Fig. 6.) This paint dries smoothly and with just enough luster to give the image a little snap. A picture of the machine prepared for photographing in this way will reproduce much better than one treated with the lampblack coating. The oil paint will not rub off, and a finishing coat of gloss paint, applied after photographing, makes the machine ready for shipment.

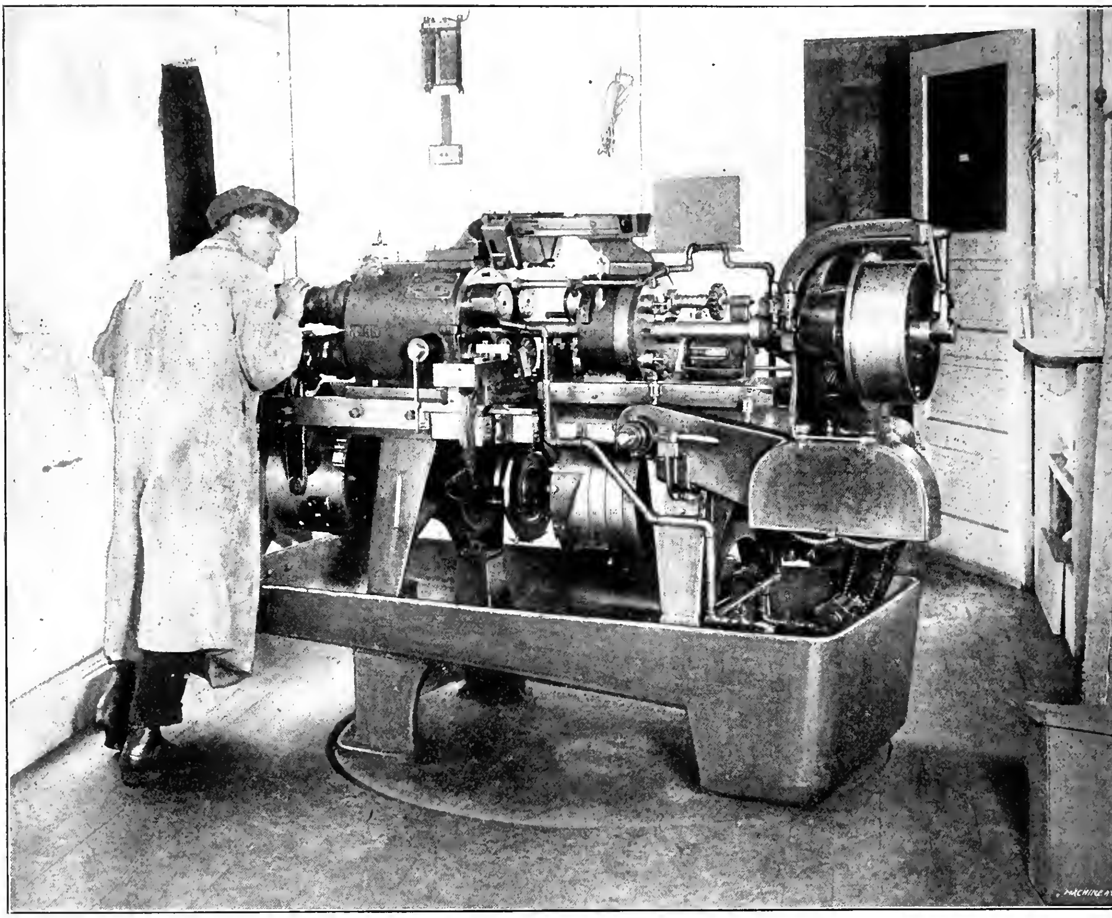

Fig. 5. Acme Screw Machine being posed on Turntable for photographing

A large part of the work of the photograph department consists of making pictures of screws and small parts which are the product of the machines. It has been found desirable to photograph these groups of parts in a horizontal position to avoid the trouble of nailing or wiring them to a board. Such photographs are taken with what is called the "skyscraper" camera, which is shown in Fig. 4, and this method is particularly advantageous when the parts are being photographed for reproduction, as no time is lost in working out the nails or wires from the print. The skyscraper camera, as arranged to take objects at an angle or straight down, is bolted to the top of the stand, and as one end is hinged it is

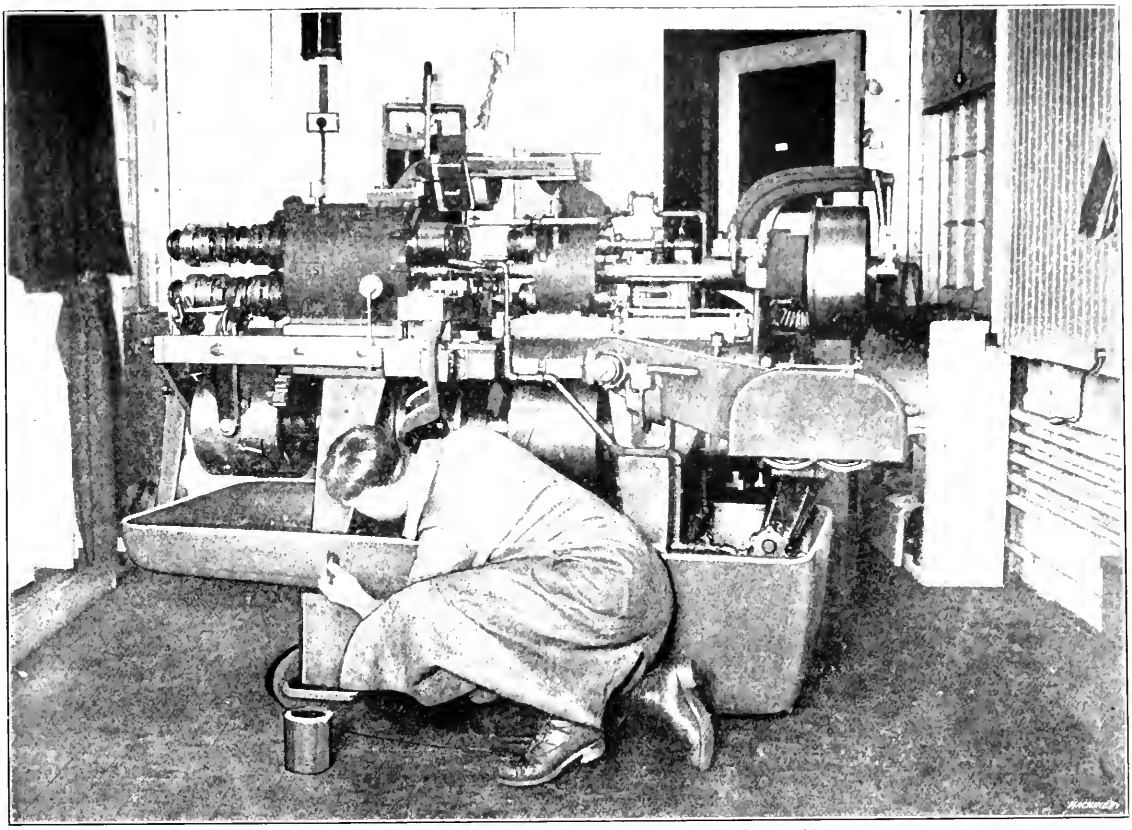

Fig. 6. Painting a Machine with a Flat Oil Paint before photographing

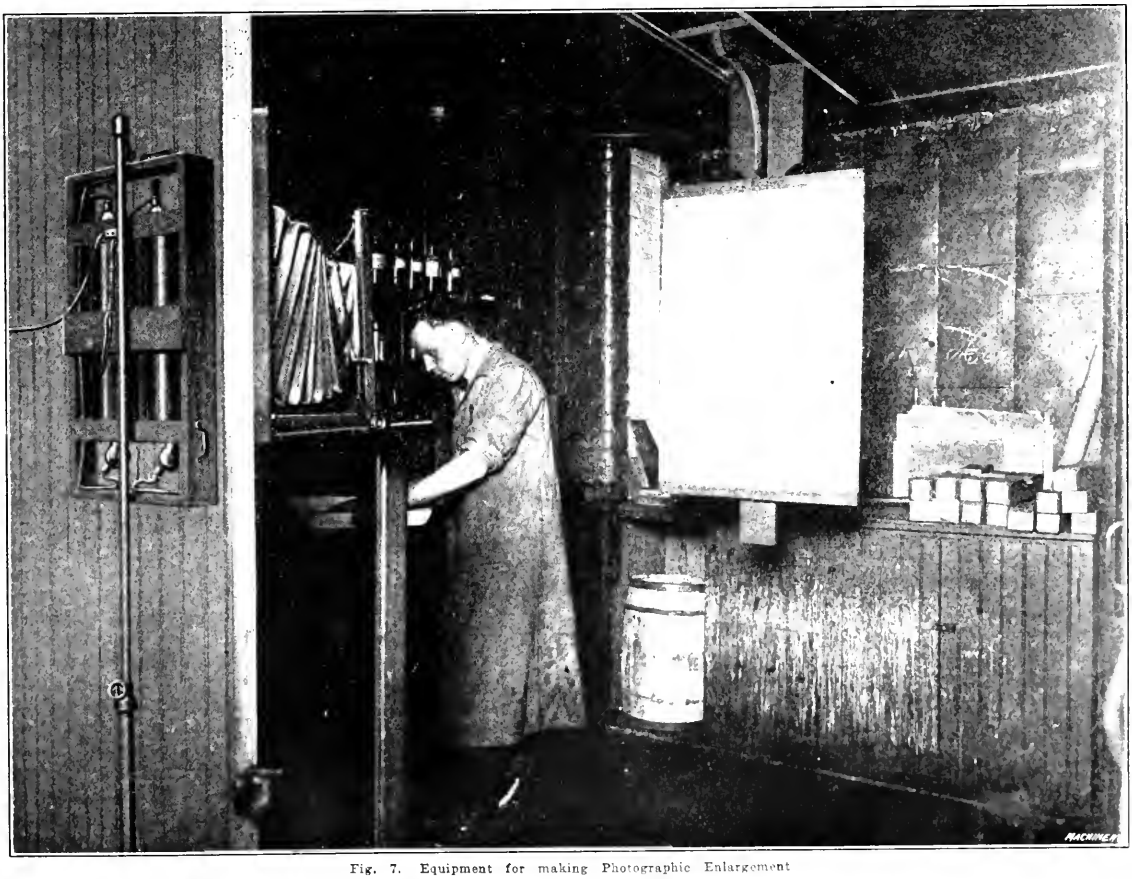

Fig. 7. Equipment for making Photographic Enlargement

possible to tilt the camera to any desired angle. The top is held in position by means of braces which are clearly shown in Fig. 4. In photographing screws or small parts when it is desirable to have the pieces cast a shadow for a natural effect, the group is laid on a sheet of clean white paper and the lighting arranged to strike the group at an angle of 45 degrees. When a pure white surface is desired, to show that the pieces are accurate, a piece of glass is used upon which the pieces are placed as is shown in Fig. 4. The objection that photographers have to using glass for this purpose is that it is impossible to hold the pieces in the position desired. This can be overcome by the use of small pieces of putty, which are placed under the parts to hold them firmly in position. This putty is prepared by heating beeswax and mixing it with vaseline, two parts of wax being mixed with one part of vaseline.

The National-Acme Mfg. Co. uses quite a good many enlargements. These are made in a dark room by means of a Cooper-Hewitt light and the regular 8 by 10 Century camera. One of the walls in the dark room has an opening about twenty inches square, through which the light enters. (See Fig. 7.) Over this opening, inside the dark room, a frame is built in which the plate to be enlarged is held. The Century camera, with the ground glass carrier detached, is fastened to this frame in front of the plate. Then the Cooper-Hewitt light is placed outside and close to the opening in the dark room wall and the light is thrown through the plate and lens onto a board. This board is fastened to a sliding frame suspended from the track in the ceiling. The overhead track runs the full length of the room, and the board can be adjusted toward or from the camera, according to the degree of enlargement required. (Fig. 7 shows this arrangement clearly.) Of course, the farther the board is from the camera the larger the image.

For developing plates, different kinds of developers are used to get different effects—usually metol-pyro for soft effects and hydroquinone for contrasting effects. The standard formulas published by plate and paper makers are used in this department because they have been found to give the best results claimed from the use of the different plates and papers. For most purposes metol-pyro is found to be a very good universal developer, as it produces soft effects and good transparent blacks. Wooden trays, about three feet by four feet, lined with oilcloth, are used for developing the enlargements. Separate rooms are provided in the advertising department for developing and printing from the negatives taken in the studio in the factory bridge. An unusually complete filing system is intact for both negatives and record prints for reference.

* * *

What is to be done with the fresh-air crank in the drafting-room and the equally absurd creature who is afraid of death if a whiff of fresh air touches him? Many disagreeable scenes are enacted in offices and other quarters where men and women work. Some are constitutionally unable to work unless the air is cool and fresh while others thrive best, in their own opinions at least, with all windows closed in winter and the temperature at 75 degrees F. The remedy is to provide in modern structures a heating and ventilating system that insures an equable temperature and air condition in all parts of an office or work room without requiring local ventilation by windows, doors or registers. Then control is removed from individuals who must perforce be contented with the conditions, or get out.

* * *

Up to the present some $7,000,000 has been earned by the United States Patent Office by fees, and turned into the treasury of the United States. The present fees provide more than enough income to pay for the cost of examining patent cases. Nevertheless, a bill has been introduced into Congress proposing an increase in the fees for patent applications from $15 to $20. We see no good reason for this increase as long as the letters patent remains merely a license to sue for infringement. The aspect would be different, of course, if the government undertook to protect an inventor directly in his patent rights after a patent had once been granted to him.

FLAT CUTTERS FOR BORING HEADS

BY FRANK H. MAYOH*

Although boring bars with inserted double-edge flat cutters are in general use, few attempts have been made to standardize the dimensions, shapes and angles. The accompanying table gives the dimensions of flat cutters for boring bars that have given satisfaction in use. While the range of 3/8 inch to 2 1/2 inches diameter of bar is perhaps wider in the direction of the smaller sizes than will be generally required, the extent of the table will be helpful in plotting larger sizes than 2 1/8 inches, if required.

The cutter is of the dependable type, fixed in a slot and secured by a wedge, and has ledges that overhang the sides of the bar at one end of the slot. The ledges locate the cutter centrally and prevent change of position. If cutters for bars of intermediate diameters are wanted, use the cutter dimensions of the bar for the next larger diameter. For example, the dimensions of the cutter and parts required for a bar

PEAT POWDER AS A LOCOMOTIVE FUEL

Peat powder has been successfully applied as a locomotive fuel on one of the private railroads in Sweden. About 1 1/2 ton of peat powder is equivalent in steam rising value to one ton of coal. Peat powder is used with a mixture of about 5 per cent of coal. The powder is fed into the furnace by an automatic stoker. No change need be made in the boiler and in the fire-box, except for the mounting and application of the automatic stoker. An incidental advantage of the use of the peat powder is that no cold air can get into the fire-box and no smoke or sparks escape from the smokestack. As Sweden is very rich in peat bogs and has practically no coal deposits the success of the apparatus, which has been worked upon for years by eminent engineers, is of considerable importance. It has been estimated that the cost of peat powder would be only about one-half that of coal.

MACHINE FORGING—5*

DIES AND METHODS EMPLOYED IN THE FORMING, WELDING AND UPSETTING OF MACHINE AND ENGINE PARTS

BY DOUGLAS T. HAMILTON†

The production of the Ford front axle by forging machine methods is an excellent example of the general adaptability of the upsetting and forging machine to the manufacture of miscellaneous parts from carbon and alloy steels. When used in conjunction with a steam hammer or bulldozer, there is practically no limit to the range of work which can be successfully handled. One of the most recent developments in forging-machine methods which should be of unusual interest to many manufacturers is the application of forging machines to the welding of machine and engine parts. This in many cases permits the utilization of scrap metal, thus converting practically valueless material into expensive machine parts. Some interesting forging operations employed in the production of the Ford front axle and other parts, will be described in the following.

Forging the Ford Front Axle

In Fig. 59 is shown a series of interesting operations performed in the 3½-inch "National" forging machine shown in Fig. 60, the work being the front axle for the Ford automobile. In its preliminary stages of production this front axle is made from a vanadium steel bar 1⅝ inch in diameter by 67¾ inches long, as shown at *a* in Fig. 59. The first forging operation consists in forming the two bulges *a* and *b*. Both ends of the bar are formed in this manner, but in separate heats. This operation, which is also indicated at *B* in Fig. 61, shortens up the ends of the bar from a length of 16⅛ inches to 13½ inches, which means that 2⅝ inches of stock is put into the bulges. The forging machine dies for performing this operation are shown in Fig. 62, the bulging being accomplished in the top members. In order to form both bulges at once it is necessary to have the top members of these dies constructed in such a manner that the blocks carrying the impressions are free to slide forward when acted upon by the plunger held in the ram of the machine.

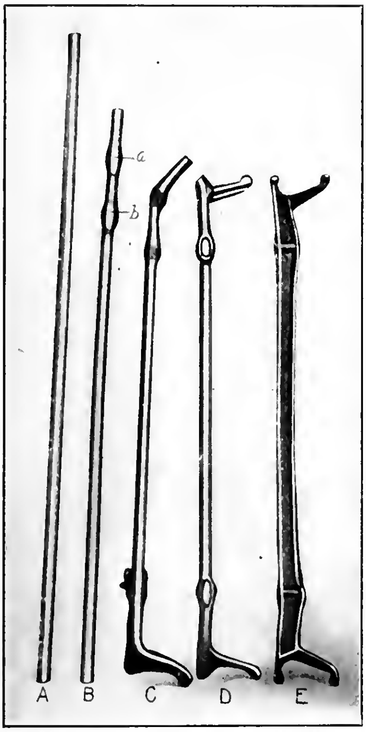

Fig. 59. Sequence of Forging Operations on the Ford Front Axle

As will be seen by referring to this illustration, one-half of the larger bulge is carried in the block *A*, while the other half of the impression is carried in the sliding block *B*. In the opposite end of the sliding block *B* is provided one-half the impression for the smaller bulge, the other half being formed in the sliding block *C*. These sliding blocks *B* and *C* are held by tongue plates *D* to the main body of the top forging die in which they are free to slide, being held in their outward positions by coil springs *E* and *F*. Coil spring *E* is carried on a stud held in sliding block *B*, while coil spring *F* is carried on a stud screwed into block *B* and fitting in a clearance hole in the sliding block *C*. The stock, when heated to the correct temperature, is located in the proper position

Fig. 60. "National" 3½-inch Forging Machine used in accomplishing the Preliminary Operations on the Ford Front Axle

in the dies by the block *G*, which is fastened by cap-screws to the block *C*, and covers the hole in the dies as indicated in the end view. The block *C* is located in its proper "out" position by means of the adjusting screw *H*, which is held in the block *I*, fastened to the top member of the forging die.

In operation, the stock which has been heated for a distance of about 18 or 20 inches is placed in the impressions in the upper members of the stationary gripping dies. The machine is then operated; the gripping dies hold the work rigidly, while plunger *K* advances and forces sliding block *C* forward until it contacts with block *B*. The forward movement of the ram continues until block *B* is forced up against block *A*, when the ram recedes, the dies open, and the forging is removed. It is evident that as the work is held rigidly between the opposing faces of the gripping dies, the advance of these sliding members can only accomplish one result, which is to upset the excess metal allowed and expand it into the impressions provided in the dies, thus forming the bulges.

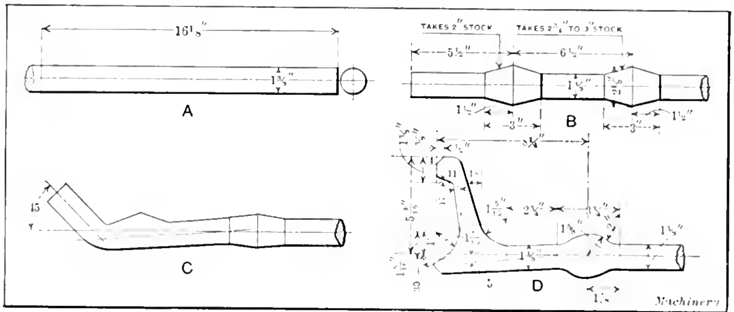

Fig. 61. Sequence of Operations on Ford Front Axle accomplished in "National" 3½-inch Forging Machine

The next operation on the front axle, which is indicated on the top of the axle at *C* in Fig. 59, and also at *C* in Fig. 61, consists in bending the end around in order to locate the material in the required position for forming the knuckles of

* The fourth installment of this series appeared in the July issue.
†Associate Editor of MACHINERY.

the axle. This operation is handled in the dies shown in Fig. 62, that member which accomplishes the work being formed on the top face of the top members of the dies. The bar, which is still in its initial heat, is laid on top of the dies and in contact with the stop gage *L*. The machine is then operated, and as the dies close, the impressions formed on the projection of the top die twist the end of the bar around and form it to the desired shape, offsetting it to an angle of 45 degrees in one direction and 5 degrees in the other.

The bar in this condition is now placed in the furnace and again heated to the proper temperature. Then it is brought to the forging machine and placed in the lower impression in the gripping die shown in Fig. 62. The forging machine is then operated, and as plunger *M* advances, it upsets and forces the work into the impressions in the lower gripping dies *N*, forming the front axle to the shape shown at *D* in Figs. 59 and 61. This completes the operations on the front axle which are handled in the forging machine. After one end of the bars has been formed to the desired shape, the other end of the bars is heated and passed through the operations previously described. Before the front axles are passed on to the final drop-forging operations, the burrs and fins formed in the forging machine dies are removed.

The final forming of the front axles is accomplished under a steam hammer of the type shown in Fig. 63, the dies illustrated in Fig. 64 being used. As was mentioned in regard to the forging machine operations on this axle, only one end is completed at a time; this will be seen by referring to the dies shown in Fig. 64. The axle is heated for a little over one-half its length and is placed on the lower die in the steam hammer. The operator is careful to locate the end of the bar so that the stock to form the knuckles is in the proper position in relation to the impression in the die before the first blow is struck; then ten successive blows are struck and the axle is removed and taken to a punch press holding a shearing die which removes the fins. The axle is then brought back to the steam hammer, given a final blow and laid down to cool off in the sand.

After one end of a batch of front axles has been finished in this manner, the other end is heated and carried through the operations described. The axles are again taken to the furnaces, heated and placed in a fixture held in a punch press, where they are stretched to the exact length—52½ inches. The manner in which work of a similar character—drop-forging of crankshafts—was handled under the steam hammer was illustrated and described in an article entitled "Shop Practice of the Willys-Overland Plant," published in the March, 1913, number of MACHINERY.

Methods used in Welding Parts in the Forging Machine

There are three methods in general use for welding or joining pieces together in a forging machine, the one employed depending largely on the shape of the work and other requirements. The most common method in general use is lap-welding, of which there are several applications. The next method of importance is pin-welding, butt-welding

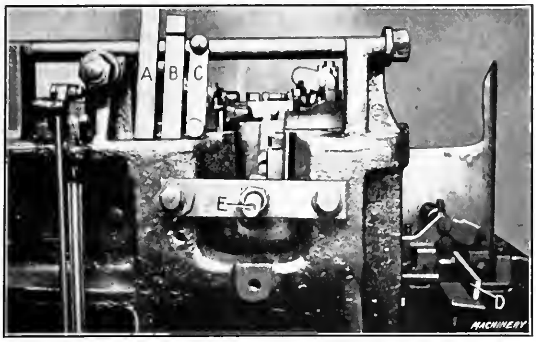

Fig. 65. Making Draw-bar Hangers in a 3-inch Ajax Forging Machine

as a rule being used only where it is impracticable to handle the work in any other way. An example will be given in a future article, however, of this class of welding, which is accomplished in an interesting and satisfactory manner.

In regard to the materials that can be handled, wrought iron can be very readily welded in the forging machine, and when proper care is taken this can be successfully done without resorting to the use of fluxes except in unusual cases. Machine steel does not weld as readily as wrought iron, and usually it is advisable to use a welding compound on the faces of the parts it is intended to join. The following ingredients make a satisfactory flux for steel welds: To one part of salammoniac add twelve parts of crushed borax. Heat slowly in an iron pot until the mixture starts to boil, then remove and reduce to a powder. Then apply the powder to the welding faces of the work shortly before removing from the furnace, putting the work back in the furnace for a short period after applying the flux. Alloy steels, while they can be worked successfully in a forging machine, cannot be welded, especially when great strength of parts is desired. As a rule, parts made from alloy steels can only be worked into shape by upsetting and forming.

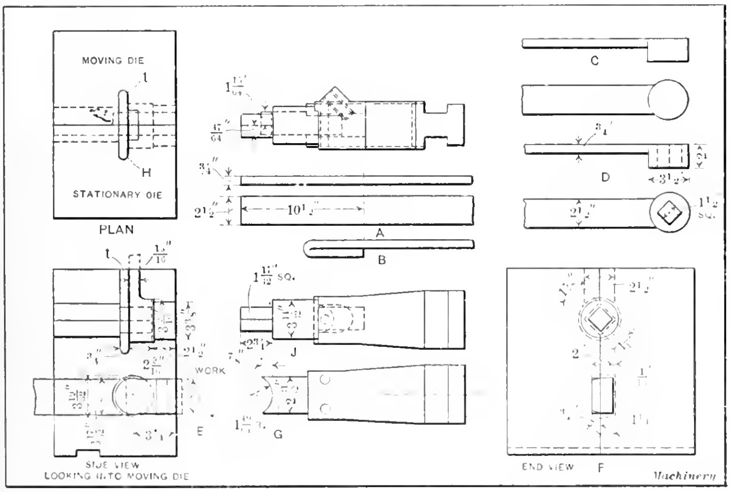

Fig. 66. Dies and Tools used in making a Locomotive Ash-pan Handle

Lap-welding and Forming Operations

A simple example of lap-welding in conjunction with a forming operation is shown in Fig. 65 where the various steps in the production of this part—known as a draw-bar hanger—are illustrated at *A*, *B* and *C*, respectively. The first operation consists in cutting a $2\frac{1}{4}$ by $\frac{3}{4}$-inch bar of wrought iron to a length of $19\frac{3}{4}$ inches—this allowing a sufficient amount of excess material to form the two bosses, one on each end. The bar is then heated in the furnace and placed in the side shear of the machine as shown at *D*. The forging machine is now operated and the tools held on the side shear arrangement partly cut off the bar and bend the nicked end around about one-quarter turn. It is then removed from the machine, placed on an anvil, and the bent end lapped over as shown at *B*, after which it is again put in the furnace and heated to the proper temperature; it is then removed and placed in the lower impressions in the gripping dies, being properly located for length by the back stop *E*. The machine is then operated, completing the weld and forming the upset square boss on one end of the bar in one blow. After performing the operations described on all of the bars, the other end is handled in practically the same manner, using the upper

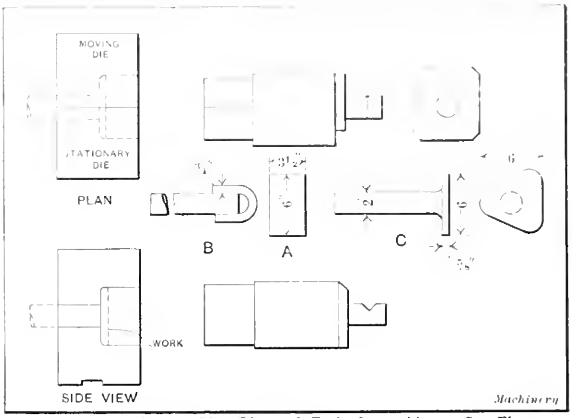

Fig. 67. Forging Machine Dies and Tools for making a Car Float Stanchion Foot

impressions in the gripping dies and subjecting the bar to three heats instead of two.

Dies and Tools for making Locomotive Ash-pan Handle

Fig. 66 shows a steam locomotive part known as an ash-pan handle that is produced in a similar manner to the draw-bar hanger shown in Fig. 65, the operations on this piece being indicated at *A*, *B*, *C* and *D*, respectively. The first operation is to cut off a bar *A* of the required length, as before mentioned, and bend one end over into the shape shown at *B*, putting it into the required condition for welding, forming and piercing in the forging machine. The welding and forming operations which are indicated at *C* are handled in the lower impression of the dies shown to the left of the illustration, the position of the work before forming being indicated by the heavy dotted lines *E*. The lower impression is formed as shown in the end view of the dies at *F*, being provided with a draft in the impression of 1/16 inch on the diameter in order to facilitate the "flow" of the metal and the removal of the forging from the dies. The punch *G* is made with a concave end which forms a portion of the boss and upsets the material into the desired shape at the same time.

After being welded and formed, the work is removed from the lower impressions and placed in a vertical position in the upper impressions in the dies. Here the square hole, as indicated at *D*, is punched. As the gripping dies are made from steel castings, they would not stand up satisfactorily for a piercing operation, so in order to punch a clean hole two steel plates *H* and *I* are inserted in the movable and stationary members of the dies. These are so shaped that a square hole is formed when the dies come together. The hole is pierced by the punch *J*, the construction of which is clearly shown in the illustration. Both punches *G* and *J* are made from steel forgings and hardened.

Dies and Tools for making Car Float Stanchion Foot

Another interesting example of lap-welding which is used for the purpose of enlarging a 2-inch bar to 6 inches in diameter to form the head on a car float stanchion foot is illustrated in Fig. 67. This car part in the initial stages of manufacture as indicated at *A* and *B* is made from a wrought-iron bar 2 inches in diameter, to which a rectangular block *A* 6 by 3½ by ¾ inch is welded. The block *A* is first cut to the required length, and bent into a U-shape in the bulldozer. Then it is placed on the round bar as indicated at *B*, and the two parts are put in the furnace, where they are heated to a welding temperature. The parts are now quickly removed, given a tap to stick them together, placed in the forging machine, and with one blow are formed to the shape shown at *C*. The dies and tools used for this operation, which are also shown in the illustration, are of simple construction, consisting only of two gripping dies and one plunger.

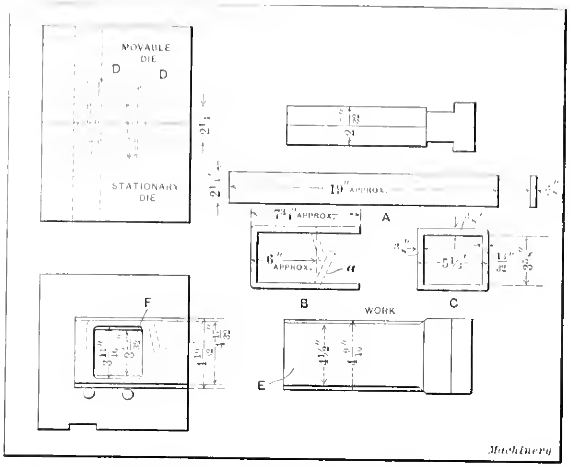

Fig. 68. Forging Machine Dies and Tools for making Locomotive Spring Bands

Dies and Tools for making Locomotive Spring Bands

A lap-welding operation which is handled in a different manner from those previously described is shown in Fig. 68. This piece, which is a spring band for a steam locomotive, is made from a rectangular wrought iron bar 2¼ by ⅜ inch by approximately 19 inches long. It is first bent into a U-shape as indicated by the full lines at *B* in a bulldozer. This part, after being bent in the bulldozer, is again put in the furnace and heated to the proper temperature. It is then removed from the furnace, and by means of bending dies held in the side shear of the forging machine, the ends are bent into the shape shown by the dotted lines *a*—partly overlapping each other. After this operation, the piece is again placed in the furnace, heated to a welding temperature, and quickly removed and placed between the gripping dies shown to the left in Fig. 68. The stationary gripping die, as illustrated, carries two pins *D*, which serve as a means for supporting the work before the dies close on it. The welding and forming operation is accomplished by the plunger *E*, which forms the work around the square impressions *F* in the dies, and at the same time welds the two ends together, forming the spring band into one piece. A particularly interesting feature about this job is the fact that the excess amount of stock formed by the overlapped ends is distributed equally along the front side of the forging, making it 1/32 inch thicker than the original rectangular bar, and thereby increasing its strength at this point.

Dies and Tools for making Extension Handle for Grate Shaking Lever

An interesting example of lap-welding is illustrated in Fig. 69, where the dies and tools used for forming an extension handle for a grate shaking lever are illustrated. This part, as shown at *A* and *B*, is made from two pieces—a rectangular bar of wrought iron 2½ by ¼ inch, which has been sheared to an angular shape on one end—and a loop *B* formed from a piece of ⅝-inch rectangular bar iron bent into a U-shape in the dies illustrated to the left. The trimming of the piece *A* and the bending of the piece *B* is carried on at the same time with special shaped formers held to the top faces of the gripping dies. To do this the operator first places a piece of rectangular stock of the required length in the impressions in the rear member *D* of the stationary gripping die; he then takes the bar *A*, which has been previously cut to the required length, and places it in the impression at the front end of the gripping die. Upon operating the machine, the moving die advances and as it carries a plunger *E* it forces the bar *B* into the suitably shaped impression in the stationary gripping die. At the same time that this operation is being accomplished the shearing plates *F* and *G* carried in the stationary and movable gripping dies, respectively, shear off the end of the bar *A*.

The welding of these two parts is accomplished in the lower impression in the gripping dies which hold the pieces in position while the punch *H* advances and upsets and welds the parts together. The manner in which this operation is accomplished is as follows: The two pieces are placed together and put in the furnace, heated to a welding temperature, then removed and given a tap, so that they are stuck together. They are then put in the lower impression of the gripping dies and the machine operated. Then as the plunger *H* advances it enters the loop in the part *B* expanding it into

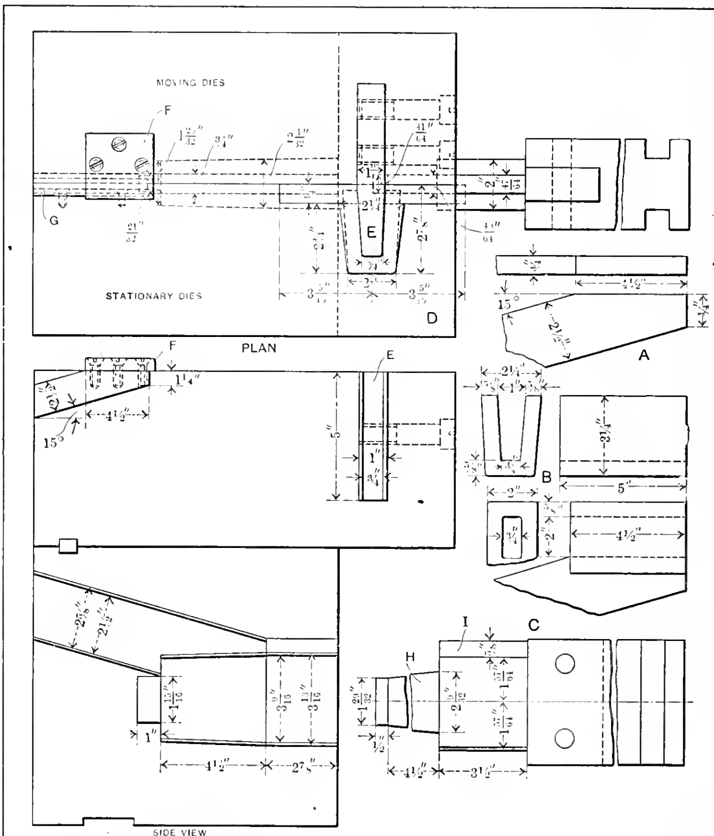

Fig. 69. Forging Machine Dies and Tools for making Extension Handles for Grate Shaking Levers

the impressions in the gripping dies, and at the same time by means of the shoulder on the punch carrying forward the excess stock and distributing it equally throughout the forging, thus joining the two parts and producing a perfectly welded joint. The punch *H* is guided when in operation on the work by a tongue *I*, which slides in a corresponding groove in the gripping dies, and thus prevents any side movement of the punch.

* * *

DON'TS FOR DRAFTSMEN*

BY MAURICE W. FOX†

Don't buy opaque triangles or curves.

Don't try to economize by buying thin tracing paper.

Don't work in an office where you are learning nothing.

Don't use a knife on tracing cloth except for a rough job.

Don't tap into a heavy casting when you can use a through bolt.

Don't draw outlines before you have laid out the center lines.

Don't waste money on cheap drawing instruments—they soon wear out.

Don't use irregular curves when arcs and straight lines will answer.

Don't always ask your neighbor to sharpen your pens—learn how yourself.

Don't design long, light parts that may be broken in shipment or handling.

Don't connect a straight line to a curve except at the point of tangency.

Don't use too hard a pencil—the tracer will have trouble finding the lines.

Don't expose heavy castings to friction—use renewable pieces to take the wear.

Don't use first-angle projection—third-angle projection is now almost universal.

Don't buy a T-square that is not equipped with an adjustable head and transparent edges.

Don't work in an office where you consider yourself superior in ability to the men over you.

Don't buy an irregular curve that does not have a fairly long portion that is almost straight.

Don't put light projections on heavy castings where they are likely to be broken off by accident.

Don't get sore because somebody offers a criticism, or destroy his friendship by an impatient remark.

Don't get mad when asked to make changes—very few drawings are approved in their original form.

Don't make anything elliptical when two halves of circles connected by straight lines will do as well.

Don't think that the concern has employed all the fools or all the experts there are in the business.

Don't detail a lot of special stuff when standard goods can be ordered as well out of a supply catalogue.

Don't make the small gears stronger than the large ones—it is cheaper to replace small ones if they break.

Don't forget elementary principles—they hold good in the greatest structures and most complex machinery.

Don't forget, if you roll up a tracing, it will have an annoying curl in it when you want to lay it out flat again.

Don't draw castings too large or complicated to be easily made or handled—consider dividing the piece and using bolts.

Don't think the chief draftsman incompetent because he does not possess the combined knowledge of all the men under him.

Don't forget that light sections will rust through faster, and cost more to paint, per unit of weight, than heavy sections.

Don't forget that the present tendency is to use nothing but capitals—also to cross-hatch all materials with simple parallel lines.

Don't bear on too hard, or rub too vigorously, or use a sandy eraser in removing ink—with due care the original surface of the cloth can be restored.

* For Don'ts previously published in MACHINERY, see "Don'ts for Drill Grinders," July, 1913, and "Don'ts" there referred to.
† Address: Culebra, Canal Zone, Panama.

Don't think you are an expert just because you once worked for some famous firm—every concern employs men of varying abilities.

Don't tell every newcomer what a dub you are working for—he cannot do his best work without confidence in his employer.

Don't think the professors in your college are the greatest engineers on earth, nor that their books are standards in every nation.

Don't forget that tracing paper is more easily torn and split than tracing cloth, but is cheaper, and lines are more easily erased from it.

Don't think a man is wholly useless because some other man is knocking him—reserve your opinion till you know both sides of the case.

Don't try to design complicated or highly standardized machinery unless you have had wide experience which fully equips you for the task.

Don't try to draw with the point of your ruling pen too close to the triangle—hold the pen vertical, or inclined in the direction of the line you are drawing.

Don't forget you can convert a "right hand" into a "left hand" by tracing the design and the lettering on opposite sides of the cloth or tracing paper.

Don't think that this or that expert produces nothing but perfect designs—check his work with what data you have and don't be afraid to look for improvements.

Don't think you have to have a row with the boss before you resign—leave every job with the good will of the concern and the chance to come back if you wish.

Don't think you are a "draftsman de luxe" because you have a lot of useless drawing instruments and curves or a stack of text-books that you never get time to read.

Don't think that every good designer came from your "neck of the woods"—able men have originated in every part of this country and in every foreign country as well.

Don't forget that nominal diameters and actual diameters of wrought iron pipe are entirely different, and that the actual dimensions can easily be found in catalogues and handbooks.

Don't start extensive erasing on a tracing without considering the method of making a negative and painting out a part with India ink—new lines can be drawn on the positive which is made from the negative.

* * *

POWER FROM DAM BUILT FOR IRRIGATION

The great Assuan Dam in Egypt was begun in 1898 and was completed, as originally planned, in 1902. It was built to impound the waters of the Nile and make them available for irrigation. The original dam impounded 980,000,000 cubic meters. The benefits of the extensive irrigation water supply made available by the dam were so great that in 1905 the government authorities decided to increase the storage capacity by making the dam higher and thicker, thus increasing the storage capacity to 2,500,000,000 cubic meters. The thickening and heightening of the dam was begun in 1907 and was completed in 1912. Plans are now being made for the utilization of power from the waste water flowing through the sluices. This power will be used in part for producing nitrates for fertilizer and will thus additionally contribute in restoring the fertility of the arid fields of ancient Egypt.

SPEED OF EARLY RAILWAY TRAINS

A locomotive steam engine, constructed by Davis and Garther, of York, Pa., commenced her operation on the Baltimore & Ohio Railroad under the most favorable auspices on Tuesday. It started from the Pratt street depot for Ellicott's Mills, with the entire train destined for that place, consisting of 14 loaded cars, carrying, together with the engine tender, a gross weight of 50 tons. The whole went off in fine style and was soon out of sight. A gentleman present says it was out of sight of the depot in about six minutes, and the rapid gliding of the immense train was one of the most imposing and most beautiful spectacles he ever witnessed.—*Extract from the National Gazette, published in the American Railroad Journal of July 28, 1832.*

GRINDING FORMED CUTTERS

Joseph Brown's invention of the formed milling cutter, which can be ground without changing its shape, was a great advance in milling machine practice, and it is safe to state that the milling machine as a factor in interchangeable manufacture would never have become as important as it now is if all formed cutters were to lose their original shape when sharpened. The cost of maintaining cutters would be prohibitive for many classes of work on which they are freely used. The most important of the formed milling cutters are those used for cutting gears, and it is very essential that the original shape be maintained throughout their working life, because slight deviations from the original shape that would pass unnoticed with other formed cutters become very apparent in cut gears. Inaccurate tooth shapes and lack of concentricity of the pitch circle with the mounting shaft are the two chief causes of unsatisfactory action of gears cut with the common gear cutter.

To grind a gear cutter so as to preserve the original shape is not an easy matter unless better means are provided than are found in most machine shops. In the first place the cutting face must be ground truly radial; a pitching of the face ahead or back of the radial line changes the projected shape, and as it is that which defines the outline of the cut, the result, of course, is a departure from the established tooth shape. To grind radial faces with a cutter grinder is comparatively easy, and if this were the only requirement to produce perfect working cutters the problem were easily solved, but the heights of the teeth must be equal. This, too, could be readily accomplished by using an indexing fixture if the cutters were truly round and evenly spaced. These conditions are seldom realized, however. Changes of shape in hardening throw the teeth out of even spacing, and if ground on an accurate indexing fixture some of the teeth will be so short that only a few do the cutting. The result is rough work and heating of the cutter which reduces the quality and quantity of gears cut.

A cutter grinder recently put on the market employs a new principle of indexing—new in the sense that it is unknown to most mechanics. The teeth are indexed by a finger resting on the *back* of the formed part, an indicator being provided which enables the operator to gage the position of each tooth with reference to its own shape as well as to the axis of the cutter, within a thousandth inch or less. Each tooth face is ground truly radial and all the teeth are ground to the same height.

In the operation of this machine, the curious fact has developed that few machinists or toolmakers apparently understand the machine, although it is simple, because they have never taken the trouble to study the fundamental principles of efficient formed cutter action. This condition is hardly creditable to American mechanics, who pride themselves generally on being quick to grasp machine principles and apply them.

IMPROVED MACHINERY AND THE WORKMAN

The boilermakers' union in England is engaged at the present time in a campaign opposing the use of the oxy-acetylene blow-pipe for cutting boiler and ship plates. The union has passed resolutions limiting the number of machines used in proportion to the number of men employed, and forbidding the use of the machines when working over-time. Fortunately, the opposition to improved methods and machinery on the part of the men that are to use them is not as frequently met with in this country as in England; but there are enough instances on record to justify a word on the subject.

The idea that the introduction of machines for performing work which has previously been carried out by manual labor is detrimental to the best interests of the worker at a trade, is deeply rooted in the minds of a great many people. They apparently believe that there is just so much work to be done in the world at any given time, and no more. This attitude of men who work mainly with their hands was in evidence at the time when the earliest types of machines were introduced. The weavers in England fought the introduction of the mechanical loom; the sewing machine was opposed by the tailors; the molding machine, by the foundry workers. Of course, examples can be cited where the introduction of machinery has temporarily thrown a number of men out of work, but in the long run the community in general and these men as well have benefited. Taking a familiar example, it is beyond question that thousands of men who could have been employed on the farms in the United States are now displaced by our modern agricultural machinery; but is it reasonable to expect that the average standard of living would be as high as it is if all the farm labor were performed in the manner of a century ago? Improved machinery makes it possible to produce more quickly and cheaper, and, hence, should be a benefit to all. If it can be shown that in spite of the improved machinery the products are not sold any cheaper to the ultimate consumer, then the system of distribution and some other economic problems yet unsolved are responsible. Improved machinery is not at fault.

* * *

FAILURES THAT BECOME SUCCESSES

The fact that a method or machine is unsuccessful is not necessarily a proof that the principles involved are wrong. A new material or a new process of manufacture may so change conditions that an unsuccessful device becomes commercially practicable. The aeroplane, for example, became a possibility only after the internal combustion engine had been highly developed. The wish to navigate the air has been a dominant impulse of man in all ages, but although numerous models had been made, all were doomed to failure because of the lack of a practicable motive power. With a modern gasoline engine, Darius Green's "experiment" might not have ended so disastrously.

A common fault of tubular magazine rifles was the danger of explosion of the cartridges in the magazine from the impact of the bullet point of one cartridge on the primer of the cartridge ahead of it. Numerous schemes had been devised to obviate the defect, but none were considered successful. Magazine tubes having an internal spiral or thread to throw the cartridges out of line, had been tried but found faulty when used with the old form of military cartridge having a rimmed head. But with the rimless cartridge, the scheme works successfully. Shaving dies operate badly on some materials—drill rod, for example; when pressure is applied steadily, the metal is torn and left rough, but when the impelling force is applied as a series of blows, smooth cutting action results. Hence, the use of the pneumatic hammer to perform a shaving operation on drill rod that was found to be impossible when the power was applied by a press.

Many of us are cursed with the knowledge of things that are not so. We believe that experience has demonstrated that certain processes are impossible, whereas they are simply impossible when all the conditions are as they were in the original experiment. Modify one or more of those conditions and the impossible may become not only possible, but practicable. The progressive man has to learn to profit by the experiences of others, but he must also be a doubter of the accuracy of some recorded work to the extent of being willing to repeat it under new conditions with faith that different results may be obtained.

CHATTER IN MACHINE TOOLS

Given ample driving power, the efficiency of a machine tool in cutting metal may be said to be inversely proportional to its lack of rigidity. Logically, this should be stated as directly proportional to rigidity; but as no mechanism has a rigidity of one hundred per cent—that is absolute rigidity—we cannot draw a comparison between present realization and the ideal. The ideal in rigidity does not exist, and no one knows what the conditions would be if absolute rigidity of tool and work support could be realized. We simply know that weakness of the tool support and driving train causes excessive chatter. The stiffer these are, the smoother the cut, but in the best designs the tendency to chatter is likely to develop with heavy cuts and high speeds.

The purpose of machine tools is to force cutting tools through metal. The machinery and tool supports are solely for holding the tool against the work and driving the tool or work so as to take a progressive cut. When that object is accomplished in accordance with the requirements of the case, the designer's work is done, except that convenience of attendance, appearance, etc., must also be considered. These, however, are minor in comparison to the prime essential—presenting the work and tool in opposition, with ample driving power and the maximum rigidity of support that can be attained.

But a great difference may exist between two machines of the same weight and driving power as regards rigidity and tendency to chatter. This difference is due to friction of bearings and proportions of parts, which brings us to a consideration of the laws of vibration. A lathe, for instance, may chatter excessively when turning a piece of a certain diameter and using a tool ground to a certain shape. A change of cutting angle, lowering or raising the tool, running with open belt instead of back-gears, or other changes of the several factors involved, may promote smooth cutting.

Here is an opportunity for profitable investigation to determine what are the conditions of weights, torsional strength, cutting angles, hardness, etc., that tend to cause excessive chatter, or better, what proportions and arrangement of driving parts tend to produce the least vibration. Taking the typical engine lathe as an example, mechanics know that the smoothest and most accurate turning work is produced when running with an open belt. Chatter marks are more likely to show when the back-gears are in action. The difference is commonly attributed to irregularity of gear tooth action, but is it not largely due to lack of torsional rigidity of the back-gear quill? Tests have demonstrated that placing the two back-gears close together causes a great difference in the stiffness of drive. This probably is only one of the weaknesses not commonly known that could be eliminated in the engine lathe or milling machine.

* * *

After the recent floods in Ohio had subsided, a well-known machine tool builder received a request to overhaul some boring mills of his make, installed in a rubber plant. The workman sent found that the bearings were excessively worn and that new bushings were required for all the principal bearings. The wear was so abnormal that he made inquiries regarding the lubrication and discovered that the men were not allowed to use mineral or animal oils for lubricating their machines but could use linseed or cottonseed oils only. The lubricating properties of linseed and cottonseed oils are practically nil and the wonder is that the bearings were not worn worse than they were. Situations which demand the use of vegetable oils exclusively, would seem to require, for efficient up-keep, the use of ball bearings.

COST ESTIMATING IN MACHINE CONSTRUCTION

BY A. C. JEWETT*

Cost estimating varies in difficulty according to the nature of the work for which the cost is to be determined. In the larger engineering contracting and construction work, considerable data are available in the form of published records of work done and of bids submitted. Such data are not available for estimating manufacturing costs and it is doubtful if data collected in one plant could be utilized with safety in another, inasmuch as operations are far from being standardized and the elements of cost vary so greatly in different plants. In the course of time scientific management may bring about a standardization of machine operations and the establishment for such operations of unit times which may be of direct value in making estimates, but as yet nothing of this sort is available for factories in general. In most manufacturing concerns it is customary to keep careful records of all costs for various purposes. These data are analyzed and tabulated for use in estimating the probable cost of a new machine. For certain classes of work unit prices can be established, such as a pound price for castings, but in a larger part of the work it is hardly possible to fix a unit price. In such cases the probable cost, of machining for example, is estimated by finding what it has cost in the past to make some similar detail.

The factors affecting the cost of a machine are labor, material, and overhead expense. In producing a machine of new design the costs may divide themselves into the following classes: (1) Patterns; (2) Castings; (3) Machining; (4) Assembling. The cost of patterns depends upon the amount of lumber used and the time consumed, which will vary with the size and intricacy of the part. The cost of castings depends upon the difficulty of molding, the kind of metal and the number of castings to be made. The cost of machining depends upon the kind of material, the superficial area to be machined, the quantity of stock to be removed, the nature and accuracy of finish required, the intricacy of the work and number of pieces to be finished. The cost of assembling depends upon the size and intricacy of the machine and the accuracy of the workmanship upon its parts, which determines the amount of time which must be consumed.

The methods of estimating cost of manufacture may be based upon: (1) A straight pound price, or curve of comparisons; (2) The shop foremen's estimate of time and material, with burden added; (3) The bill of material, time records and machine rates determined from other work performed, plus burden. The following examples of these methods are taken from statements supplied by some of the larger manufacturers and may be considered typical of the practice in many concerns:

(1) The cost of machines of various sizes and known weight, which have already been built, is taken from the regular shop cost records. The costs per pound are computed and plotted as one coordinate and the total weights of the machines as the other. When enough data are available to establish the curve from various sizes of machines previously built, it may be used with considerable accuracy in predicting the cost of a similar machine of any estimated weight. If the machine has a certain degree of resemblance to established types, the established cost is taken and modified to suit the new features by an amount which these may seem to warrant.

(2) When a machine of new design is contemplated, drawings and specifications of which have been completed, a conference is held at which the works superintendent, the machine shop superintendent, the foundry superintendent, the superintendent of the pattern shop, and the chief engineer are present. The drawings and specifications are examined, and the superintendent of the foundry expresses his views regarding the molding of the cast pieces in the design, indicates where the design may prove impracticable from his standpoint, and makes suggestions whereby the cost of molding can be reduced. It is considered that the foundrymen must necessarily be consulted on a large part of the work, as to

* Address: University of Maine, Orono, Me.

the best method of constructing the pattern with reference to molding.

The superintendent of the pattern shop estimates the amount of lumber that will be cut up in constructing the pattern and the time required to build it. The cost of the pattern is then determined from the price of the lumber and the rate of the patternmaker. The cost of the castings is based upon a price per pound, which price has been determined from costs covering a considerable period. The engineering department furnishes estimated weights of the parts, so that the cost of the castings is obtained. The time of machining the work is estimated by the superintendent of the machine shop and, from previous cost records, the cost of machining is determined from the time. The assembling is also estimated by the superintendent of the shop or by one of his foremen, and the actual stock and labor cost of the product is obtained. Such parts as machine screws, that are purchased from other concerns, are easily figured from the purchasing department's records. The stock and labor costs are kept separate. It has been found in many plants that the labor cost should be increased by 100 per cent and the stock cost by 10 per cent to cover overhead charges. To the total is added 15 per cent for profit, to give the selling price. From the estimated weight and the estimated selling price, the price per pound is secured and compared with the price per pound of other machines on the market of a similar nature or design. By this method a check is made upon the estimated figures. If it is found that the price is going to be entirely out of reason with those of competitors, a revision in the design is made to reduce the cost.

A similar method, with certain variations, is followed in many other plants. In some the overhead charges are isolated for the separate shops. For instance, one plant adds twelve cents per hour-man to the material and labor cost to obtain the cost of patterns. In some cases the cost of patterns is considered a part of the overhead charge or expense. To the cost of molding, plus the pound price of iron, plus labor is added 80 per cent of the cost of labor and iron to obtain the cost of the castings, which is reduced to a pound price. This cost also includes the cost of special flasks or rigging. The machining time is figured at the actual price paid the men plus an overhead shop charge of twenty-two cents per hour. The cost of special tools, jigs or fixtures is figured in the same way and added in. The profit is commonly added by an executive officer. The amount of the profit to be added is determined by considering the various circumstances surrounding the particular job in hand, being varied by the probable competition, the risk of spoiling or losing any of the pieces handled, the payments and numerous other items.

(3) A consulting engineer who is an executive of a plant which has been very successful with the Taylor plan of management has said, in substance, the cost of manufacture of machines of new design may be determined by making a complete detailed analysis of the work to be done, basing the time upon elementary time units; in short, making up the time for each operation just as it is done in setting tasks on work that is to be done in the shop. Arrive at the cost of material by making careful estimates of the weight of the castings and other materials entering into the machine. Add a proper proportion for indirect expenses. The principal objection to so detailed an estimate is that it is rather expensive. Unit prices can only be developed where the line of machinery is of the same design and type of construction, the differences being chiefly in size. For work of this nature a unit price per pound of the machine's weight may be used where it is not necessary that an estimate should be very accurate. Such a unit is useless when applied to machines totally different in design and construction. The cost per square inch is also useless if accurate results are to be achieved, as the proportion of cost in relation to the number of square inches to be machined differs widely, depending upon the nature of the surface, the form of the part, difficulties encountered in setting, the number of pieces of each kind to be machined, etc. While many of these makeshift methods serve the purpose, it is only because a rather wild guess is good enough by reason of there being a comparatively wide margin, or because their application is restricted to estimating machinery of a very similar nature.

TURNING CAMS ON A LATHE

An ingenious method of turning cams on a lathe is used by the Carpenter-Tew Gear Co., Brooklyn, N. Y., and could be adopted by many shops which occasionally have to cut cams of the type shown in Fig. 1, but do not have enough work of this kind to warrant buying a cam machine or a cam cutting attachment for a milling machine.

The type of cam turned by this method is illustrated in Fig. 1, where it will be seen that the hub *A* is concentric with the surface *B* of the cam. The bore of the hub is also concentric with the surface *B* but the center of the surface *D* of the cam is 7/8 inch from the center about which the surface *B* is turned. These cams are made of 5-inch machine steel stock. Blanks for this purpose are sawed from the bar and set up in the

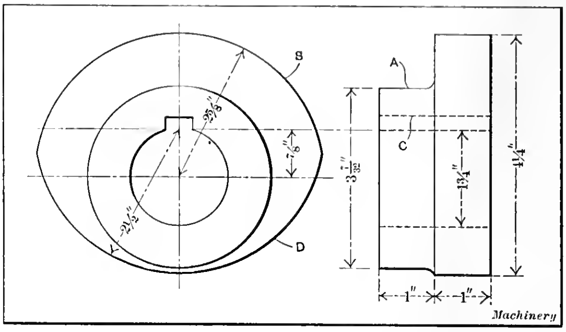

Fig. 1. Type of Cam to be turned

lathe, where the first operation consists of turning down the blank to form the hub *A*. The hub is then bored, after which the cam surface *B* is turned. After these operations have been completed on all of the blanks, the work is transferred to a slotter where the 1/2-inch taper keyway *C* is cut in each piece.

After the work has progressed to this stage, the final step consists of turning the cam surface *D*. For this purpose, the fixture shown in Fig. 2 is used. This consists of a plate which is bolted to the faceplate of the lathe by bolts fitting in the two slots. It was previously mentioned that the center of the surface *D* is 7/8 inch from the center about which the surface *B* was turned. Consequently the fixture is set 7/8 inch off center. The work is held on the stud *B*, the key *C* being provided to fit into the keyway which was machined in a

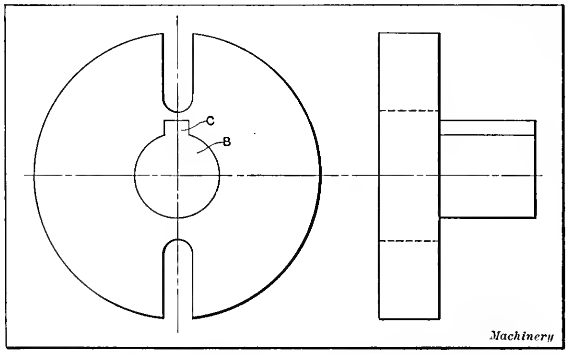

Fig. 2. Fixture used for turning Cams on a Lathe

previous operation and prevent the work from turning on the stud. The successive blanks are then mounted on this fixture, when it is an easy matter to turn the surface *D*. Referring to Fig. 1, it will be seen that there is an edge at the two points where the surfaces *B* and *D* meet. After the surface *D* has been machined, a file is applied to the work to reduce these two edges so that the roller will run smoothly when passing around the cam. These cams are used on a well-known printing press. E. K. H.

* * *

Curious incongruities are sometimes noted in plant management. Pattern lumber stored in the open air while chips and other metal refuse are kept under cover, is an example.

AN EARLY AUTOMATIC GEAR CUTTING MACHINE

A RECORD OF IMPROVEMENTS MADE IN GEAR CUTTING MACHINERY IN THE SHOPS OF R. HOE & CO., NEW YORK

BY DOUGLAS T. HAMILTON*

Little is known of the early development of automatic gear cutting machinery for the simple reason that no authentic records were kept, and no patents had been taken out before the early eighties. What is supposed to have been the first full automatic gear cutting machine was developed in the plant of R. Hoe & Co., New York City, makers of web printing presses. This first machine was evolved from a hand-operated gear cutting machine built by the Freeland Tool Works, New York City. The factory in which these early gear cutters were built was closed years ago; it was located on 34th St. between Tenth and Eleventh Aves. This first machine in its remodeled condition—converted into an automatic gear cutting machine—is shown in Fig. 1. When originally built it only had a down feed for the cutter slide, which had to be raised by hand, and the machine was indexed in a similar manner. The method of operating was to draw up the cutter slide with the left hand by means of the handwheel and ratchet at the top of the feed-screw, and index the work with the right hand.

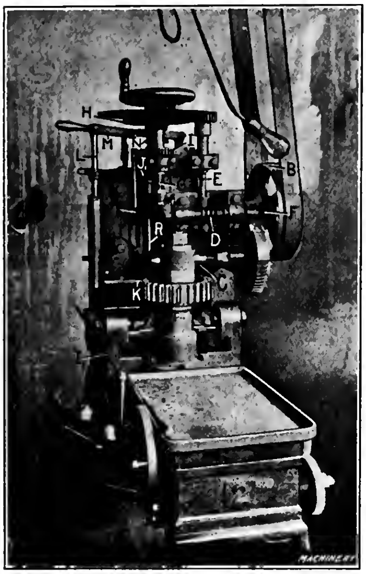

Fig. 1. Old Freeland Hand-operated Gear-cutting Machine, converted into an Automatic Gear-cutter

The Freeland gear cutting machine, as originally built, was supposed to be accurate as regards indexing, but after many tests were made of gears cut on this machine, it was found that the spacing of the teeth varied. As the work turned out was not of the required standard for the Hoe printing presses, Colonel Robert Hoe set about to develop this machine and make it much more accurate. The first step in this direction was to make an accurate dividing wheel, which is shown in Fig. 6. This dividing wheel was made from an iron casting of the shape shown, and was machined on its circumference providing a ledge as indicated in Fig. 7. Against this ledge 180 cast-iron blocks *B* are held by screws *C* and toe-clamps *D*. These blocks, which are slightly over one inch in length, were scraped to fit a gage, the sides of which were beveled to about 0.010 inch in the height of the block. When the 180 blocks had been finished to the desired size the cast-iron wheel was turned to approximately the required diameter and then the cast-iron blocks fitted to it. This procedure was followed until the circumference of the turned portion on the wheel was such that it exactly contained the 180 blocks. The diameter of the dividing wheel over the clamps is about 63 inches, and the separate sections or blocks are about 3/16 inch thick.

Obviously the making of this dividing wheel required the most painstaking work and consumed considerable time, as is evident from the statement that it took two years to complete this wheel, which was finished in 1879. After producing the master dividing wheel, the next step was to make the indexing or dividing wheels to be used on the Freeland gear cutter shown in Fig. 1, and also on others that were built later. These dividing wheels were cut on the old Whitworth machine shown in Fig. 5. The dividing wheel was placed on the rear end of the work arbor *A* and the wheel to be cut took the place of the work. The teeth were produced with a special shaped cutter, which was kept as sharp as possible.

The manner in which this dividing wheel was cut is as follows: The operator removed one of the blocks *B*, Fig. 7, from the master dividing wheel and located the indexing plunger in the space from which the block was removed. Then he cut one tooth space, using a very fine feed so as not to heat the work. When this was completed, the block was put in place and another block removed from a point on the circumference of the wheel diametrically opposite to the position from which the first block was removed. The wheel was then turned around and the locking plunger put in the place previously occupied by the block, whereupon the second tooth space was cut. Following this the wheel was divided into quarters, eighths, etc., until all the teeth were cut. In all cases the indexing was made from positions diametrically opposite in order to reduce to a minimum inaccuracies due to temperature conditions. After the teeth were roughly cut, the gear was put away to season and was then set up again and a light finishing cut taken. Some idea of the care taken in cutting these wheels may be gained from the fact that it required nine months to complete seven wheels. The room in which these wheels were cut was kept at a uniform temperature of 70 degrees F. by a fan. At the time that the master dividing wheel was made seven index wheels were completed, six of which were later used on machines built by R. Hoe & Co.

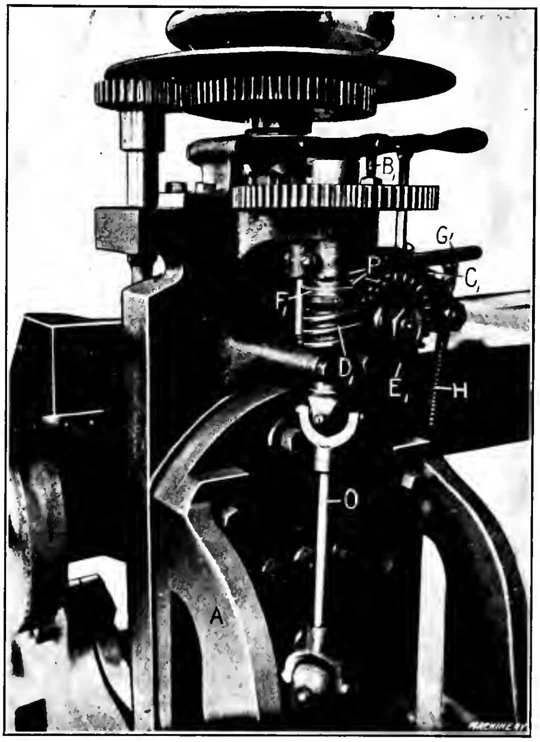

Fig. 2. Rear View of Machine shown in Fig. 1, showing Portion of Indexing Mechanism—an Improvement made by R. Hoe & Co.

The changing over of the Freeland hand-operated gear cutting machine into a fully automatic machine is credited to William Hall, who at that time had charge of the gear cutting department. The first improvement was made in 1880 by Mr. Hall and consisted of a device to provide an automatic stop and return for the gear cutter slide. Later he devised an attachment for indexing the work. The automatic stop and return for the cutter slide worked satisfactorily, but the indexing attachment did not. Trouble was caused by its fre-

*Associate Editor of MACHINERY.

quently failing to slip and preventing the work from indexing the full amount, thus of course, spoiling the gear. About the year 1882 Joseph Buckley, who was also employed in the gear cutting department, put on a safety device which stopped the down feed of the cutter slide when the indexing mechanism had not operated properly. This stopped the feeding down of the cutter slide, and prevented the gear from being spoiled.

The Whitworth Gear Cutting Machine

The gear cutting machine shown in Fig. 5, which was built by Joseph W. Whitworth & Co., Manchester, England, was the first machine to be employed in the shop of R. Hoe & Co. for cutting gears. This machine was used for several years before the Freeland machine was purchased, and as the Freeland machine was considered somewhat better as a manufacturing proposition, the same developments were not made on the Whitworth that were made on the former machine. This Whitworth machine stands today practically the same as it was when originally built. It is indexed by hand, by means of the handle *B* and shaft *C*, then through change gears *D* to a shaft at the rear, which carries a worm that meshes with the dividing wheel *E*. The handle *B* is rotated the required number of times and is then located in the disk *F* which has four notches. The dividing wheel *E* is keyed to the arbor *A* holding the work and in this way the work can be indexed for the cutting of each successive tooth. Considerable trouble was encountered in indexing this machine, owing to the fact that the operator had to depend only on the four notches in disk *F*, and when it was necessary to make an odd number of divisions the handle could not be locked and hence was not accurately located. To provide against improper indexing, Joseph Buckley put on a safety device which worked satisfactorily. A worm-wheel was fastened to shaft *C* and a bracket *T* was attached to the bed of the machine. This bracket carried a shaft on which a worm was held, meshing with the worm-wheel, and also three indexing cams having three, four and five grooves, respectively.

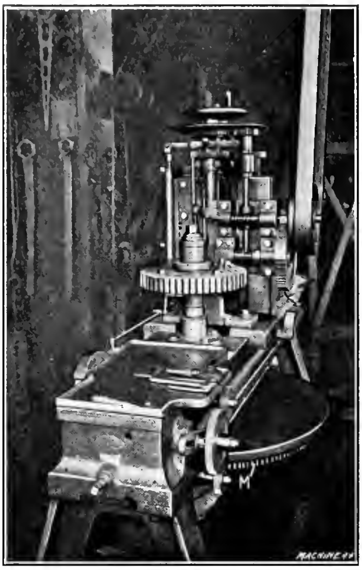

Fig. 3. One of the Six Automatic Gear-cutting Machines built by R. Hoe & Co., patterned after the Freeland Machine

Now when the operator rotates handle *B* it is necessary for these cams (only one of which is brought into use to give the desired number of divisions) to rotate into such a position that the rod *U* will drop into one of the notches. This allows the knob lever *N* to be pushed in, engaging the feed. If the lever *U* should not locate properly in the notch in the cam—owing to improper indexing—it would be impossible for the feed to be started, as the knob lever *N* is securely locked by rod *U*. The shaft on which the indexing cams are held is provided with notches in which a latch *S* fits, thus providing a means for bringing the proper cam into position to give the required number of indexings.

The gear cutter *G* is driven by a belt *H* which runs on a pulley *I* held on the top bracket *J*. This pulley, through a pinion and large bevel gear *K*, drives a vertical spindle which carries a spur gear, meshing with the gear *L* attached to the cutter arbor. The feeding of the cutter past the work is accomplished by a worm on the shaft carrying the large bevel gear which meshes with a spur gear located on the shaft *M*. This shaft, in turn, carries another spur gear that meshes with a larger gear on the screw operating the head carrying the cutter. When knob *N* is pushed in, it engages a clutch on the end of the feed-screw *M* thus throwing in the feed. An adjustable washer or dog held on the rod provided with the knob lifts up a finger and thus forces the clutch out of engagement at the end of each cut. This is accomplished by means of a compression spring.

The base *O* carrying the entire cutter slide mechanism can be swung around and set to any angle within a range of 90 degrees and is locked as indicated. This base is carried on a slide *P* which can be adjusted back and forth in relation to the work and thus greatly increases the capacity of the machine. The work arbor is held in a slide *Q*, which is adjustable along the bed by a screw and is locked in the desired position by the wrench shown. The rear shaft is splined so that the worm meshing with dividing wheel *E* can accommodate itself to the position of the wheel. The bracket carrying the cutter slide can be swung around to different angles, making the latitude of this machine practically unlimited. Bevel gears, spur gears, worm-wheels, etc., can be produced with equal facility, but, of course, not very rapidly. This old Whitworth machine is still in use for cutting worm-wheels having angular teeth—not helical.

The Freeland Gear Cutter

The Freeland gear cutter shown in Fig. 1, when originally built, was designed with the idea of cutting bevel gears, as well as spur gears. This is clearly indicated by referring to Fig. 1, where it can be seen that the cutter slide is held by trunnions to a bracket on the base of the machine. The work arbor remains in a vertical position and for the cutting of various bevel gears the entire head carrying the cutter slide is set over to the desired angle. When converted into an automatic machine, this feature was eliminated and a bracket *A* as shown in Fig. 2 was provided, being fastened to the cutter slide bracket and also to the bed of the machine. The mechanism which was added to this Freeland machine to convert it into an automatic gear cutter is extremely complicated and also very ingenious. In order to make the following description clear, it probably will be advisable to take up the additions in the sequence in which they were made.

Automatic Return for the Cutter Slide

By referring to Fig. 1 it will be seen that power is transmitted to this machine through a pulley *B* which, through the spur gears, drives the cutter arbor *C*. On the shaft directly in line with the pulley is a worm *D* that meshes with a helical gear on the vertical shaft *E*. This shaft is connected by spur gears to the feed-screw operating the cutter slide. On the extreme end of shaft *F* is held a bevel gear, meshing with another bevel gear mounted on the shaft *G*. This shaft, through spur gears, also connects with the feed-screw operating the cutter slide. The feed-screw carries a double sliding clutch *N* which is brought into engagement with the upper and lower clutches, and thus provides a means for moving the cutter slide up and down. The downward movement of the cutter slide is accomplished with the top clutch directly under spur gear *H*, while the lifting of the cutter slide is accomplished with the clutch located directly behind the spur gear *I*.

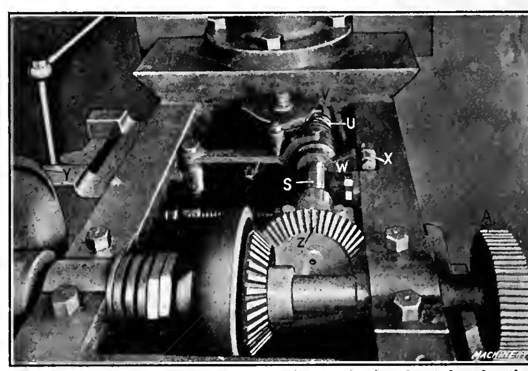

Fig. 4. Close View showing the Indexing Mechanism located under the Table which has been removed

The Automatic Stop

A further development in the Freeland gear cutting machine in connection with the automatic return was the automatic stop or trip. This stopped the downward feeding of the cutter slide and allowed it to be returned. The automatic stop consists of an adjustable dog *J* which is held in a slot in the cutter slide. This dog is so adjusted that it comes in contact with the lever *K* when the cutter slide has reached its lowest predetermined position. As the fulcrum lever *K* on which the rod *L* is resting is forced out by the adjustable dog, the support is withdrawn from the rod *L* allowing it to be forced down by a compression spring. Now rod *L* is pivoted to the yoke lever *M*, which is fastened to the double sliding clutch *N* carried on the feed-screw, and as the support is withdrawn from this rod, the sliding clutch is brought into engagement with the lower clutch, which is rotated as previously described to return the cutter slide to its "up" position. As the cutter slide ascends adjustable block *T* lifts lever *M*, disengages the clutch, and holds lever *M* in an intermediate position. At this point in the operation the indexing is accomplished by hand, after which the sliding clutch *N* is engaged with the upper clutch and the cycle of operations repeated.

The Automatic Indexing Mechanism

The automatic indexing mechanism added to the Freeland gear cutter by William Hall, while having been changed slightly from its original design, still works on practically the same principle as when first completed. As can be seen by referring to Fig. 2, the indexing mechanism is operated by a universal jointed shaft *O* at the rear of the machine. This is driven from the gear on the feed-screw through a spur gear and clutches *P*, the lower one being fastened to the top part of the knuckle jointed shaft. On the lower member of the knuckle jointed shaft is held a spur gear meshing with another spur gear on shaft *S*, see Fig. 4. This view shows the mechanism of the machine, the top guard or table being removed. Shaft *S* carries a worm *U* that meshes with a worm-wheel held to the shaft on which the four-lobe cam *V* is mounted. Shaft *S* rotates continually—when clutch *P* is engaged—in the correct relation to the operation of the cutter slide, allowing the required travel of the slide to one-quarter turn of the shaft carrying the cam.

As one of the lobes on this cam comes into contact with the roll on lever *Q*, it forces the cam *W* over, bringing it in contact with roller *X*. This roller, in turn, is connected to the indexing plunger that fits in a notch in the index wheel *Y*. Now as cam *W* comes in contact with the roller, it withdraws the indexing plunger and allows the index disk to be rotated through bevel gears *Z*, and also the dividing wheel *M* under the machine, see Fig. 3, to be rotated by the change gears A_1, the proportioning of the teeth in which, are such as to give the required space indexing. This indexing mechanism just outlined was that devised by Mr. Hall, and while the idea as arranged was practical, it did not always work successfully and considerable work was spoiled owing to the failure of the locking plunger to engage with the notch in the indexing disk and thus secure the correct indexing.

When the indexing mechanism just described was added, the automatic trip for returning the sliding clutch into engagement with the top clutch to feed the slide down, was also provided. This automatic trip works as follows: When the cutter slide rises and sliding clutch *N* is brought into an intermediate position by lever *M*, the link B_1 (see Fig. 2) transmits a movement to lever C_1, bringing the clutch *P* into engagement, and starts the indexing mechanism operating. The vertical shaft on which clutch *P* is held carries a worm D_1 which meshes with the spur gear E_1. The shaft carrying this spur gear also holds a cam similar in shape to that shown at *V* in Fig. 4. This cam guards against improper indexing in the same manner as the device put on the Whitworth machine shown in Fig. 5.

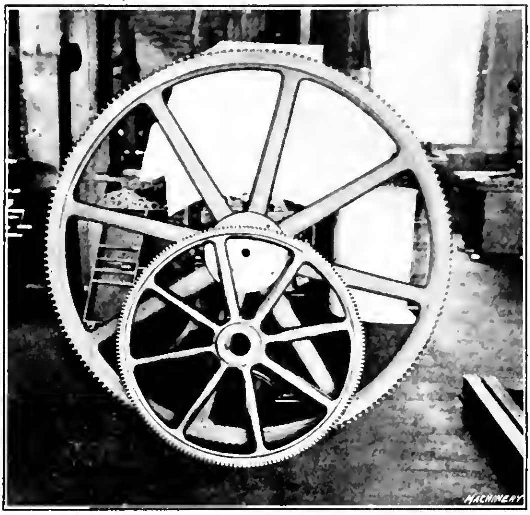

Fig. 6. Master Dividing Wheel and One of the Dividing Wheels reproduced from it on the Whitworth Machine shown in Fig. 5

As the indexing operation nears completion, cam F_1 held on the vertical shaft comes in contact with a bell-crank lever, not shown. This lever lifts a latch supporting lever G_1, allowing the latter to be pulled down by the spring *H*, and thus disengages clutch *P*. At this instant the cam at the rear of spur gear E_1 comes into position and raises the lever *M*, engaging the sliding clutch *N* with the top clutch to feed the cutter slide down again.

Automatic Safety Device

In order to provide against improper indexing of the work, Joseph Buckley put on a safety device that automatically stops the downward feed of the cutter slide, should the indexing mechanism fail to operate properly. This safety device is indicated in Fig. 1, and consists of a rod *I*, which is held to the slide carrying the indexing locking plunger. This rod through a bell-crank lever operates rod *R*, which carries a tooth clutch on its upper end. Now when the locking plunger fails to locate properly in the indexing disk, rod *I*, is forced back, transmitting an upward movement to the rod *R* and engaging the tooth clutch with the gear J_1. Gear J_1 is rotated by a gear held on the feed-screw, when the latter is being operated, and as the clutch is engaged the rod *R* is revolved. On the lower end of rod *R* is a one-lobe cam which comes in contact with lever *K*, forcing it out and withdrawing the support from rod

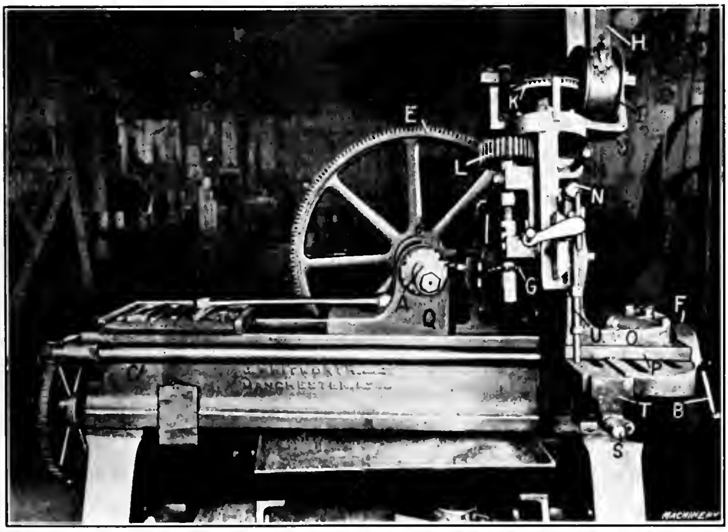

Fig. 5. Gear-cutting Machine built by J. W. Whitworth & Co., Manchester, England
This was the First Gear-cutting Machine purchased by R. Hoe & Co.

L, thus disengaging the clutch *N* and stopping the downward movement of the cutter slide. As lever *M* drops, the clutch *N* is held in an intermediate position by the adjustable rod *T*, which comes in contact with the projection on the lever.

The Remodeled Freeland Gear Cutter

In 1883 and 1884 R. Hoe & Co. built six machines patterned after the Freeland machine, improved upon by William Hall and Joseph Buckley. One of these improved machines is shown in Fig. 3, and as can be seen upon reference to it and that shown in Fig. 1, very little change has been made except in a slight remodeling of the automatic safety device, to provide against improper indexing. Six of the seven index wheels cut as previously described were used on these machines, one wheel being kept as a reference wheel. The driving belt is kept in contact with the pulley by means of an adjustable countershaft operated by a weight fastened to wire ropes that run over pulleys attached to a post. These remodeled machines are still doing good work in R. Hoe & Co.'s shops, and while they are not such rapid producers as machines of present-day design, they show to a remarkable extent the ingenuity of those instrumental in their development. As an

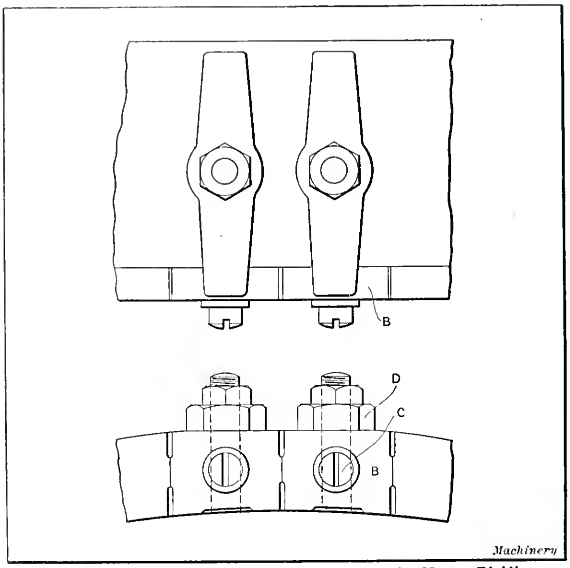

Fig. 7. Illustration showing how the Blocks on the Master Dividing Wheel shown in Fig. 6 were made and held in Place

indication of the desire of this company to keep in step with the progress made in gear cutting, it might be mentioned that the present equipment for this work includes Lees-Bradner hobbing machines, Gleason two-tool bevel gear generators, and Brown & Sharpe automatic gear cutters.

In closing the writer wishes to think Mr. Edwin J. Peirce, production manager, for permission to take the photographs presented, and also Mr. James D. Lamond, tool-room foreman, for the details concerning the interesting development of these automatic gear cutting machines.

KNURLS FOR KNURLING IN THE LATHE

The knurls commonly used for lathe work have spiral teeth and ordinarily there are three classes known as coarse, medium and fine. The medium pitch is generally used. The teeth of coarse knurls have a spiral angle of 36 degrees and the pitch of the knurled cut (measured parallel to the axis of the work) should be about 8 per inch. For medium knurls, the spiral angle is 29 degrees, 30 minutes and the pitch measured as before, is 12 per inch. For fine knurls, the spiral angle is 25 degrees, 45 minutes, and the pitch, 20 per inch. The knurls should be about 3/4 inch in diameter and 3/8 inch wide; when made to these dimensions, coarse knurls have 34 teeth, medium, 50 teeth, and fine knurls, 80 teeth. To prevent forming a double set of projections when knurling, feed the knurl in with considerable pressure at the start, and then partially relieve the pressure before engaging the power feed. Use oil when knurling.

CUTTING INTERNAL GEAR TEETH ON A VERTICAL SHAPER

An internal gear cutting proposition that would puzzle many machinists is the one illustrated in Fig. 1, which shows a brass casting, approximately five inches internal diameter, within which ninety gear teeth of twenty pitch were required to be cut. This work could easily be handled on a Fellows gear shaper if it were not for the fact that a projecting boss extended into the ring, thus preventing the

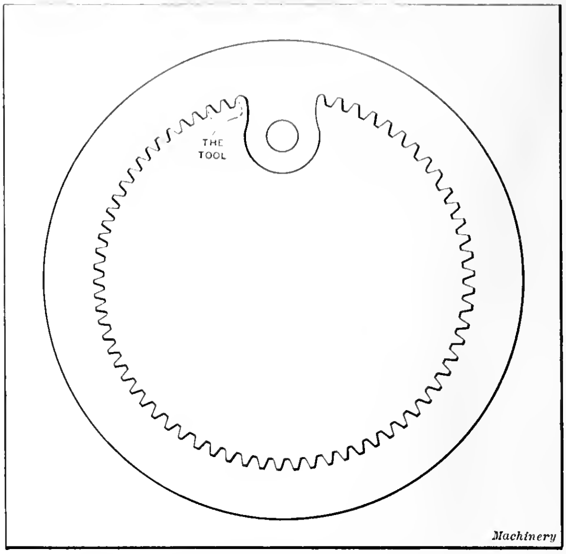

Fig. 1. The Ring in which the Internal Teeth were cut

use of a circular gear cutter. At the Rhodes Mfg. Co.'s shop in Hartford, Conn., where this job was handled, the work was done upon a Rhodes vertical shaper. The shaper with the work on it is illustrated in Fig. 2, from which it will be seen that the casting was mounted upon the circular table with the work centrally located. The tool used was of the shape indicated by the dotted lines extending around

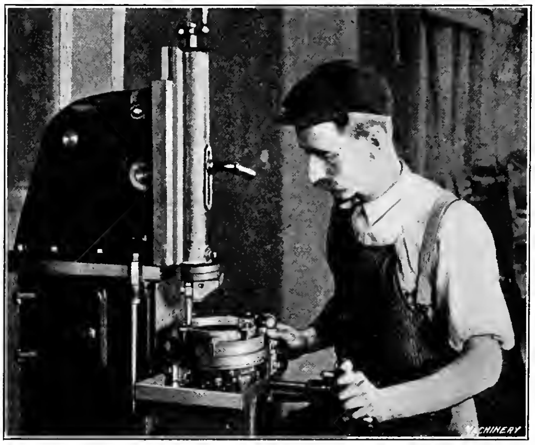

Fig. 2. Cutting the Teeth on a Rhodes Vertical Shaper

the first two teeth at the left of the boss shown in Fig. 1. The tool was first set so as to cut the first two teeth from the boss. The complete depth of cut was not taken with one stroke, but the work was fed out gradually to the tool by means of the hand cross-feed. After the first two teeth were cut the work was withdrawn from the tool, the circular table indexed to the correct pitch and the work fed in again to cut the third tooth. This operation was repeated, finishing one tooth at a time until the entire ninety teeth were finished. The second tooth on the cutting tool acted as a spacer and prevented the tool from springing away. The handling of a job of this kind is quite novel. C. L. L.

STRESS COEFFICIENTS FOR ROOF TRUSSES*

DATA ON THE DESIGN OF ROOF TRUSSES ARRANGED IN CONVENIENT FORM FOR THE DESIGNER

BY CARL E. SCHIRMER†

The current Data Sheet Supplement gives stress coefficients for various types of roof trusses and for different numbers of panels for each type of truss. The term "panel" means one of the spaces into which the upper chord of the truss is divided. In all cases the loading is assumed to be uniform and the stress in any member of a roof truss is obtained by multiplying the panel load by the coefficient for the member in question. These coefficients were obtained by graphical analysis. This method has the double advantage of being rapid and at the same time showing any error which may have been made, as the stress diagram must close if it has been properly drawn.

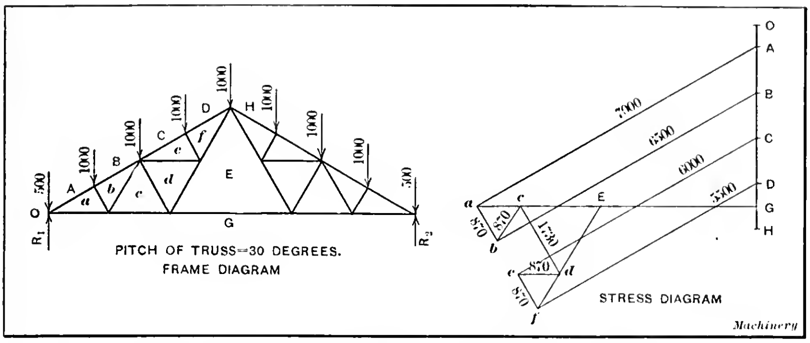

Fig. 1. Frame and Stress Diagrams for Eight-panel Fink Roof Truss

It is not the intention of this article to explain the principles of graphical statics but merely to present data on the design of roof trusses in a convenient form for use by a designer who is not frequently called upon to handle work of this kind. In order to give a brief description of the method by which these Data Sheets were computed, a frame diagram and a stress diagram are presented for three characteristic cases, *i. e.*, for a roof truss uniformly loaded but where the wind load is not considered; for a roof truss uniformly loaded and also carrying a uniform wind load; for the saw-tooth type of roof truss uniformly loaded.

Fig. 1 shows the frame diagram for an eight-panel Fink roof truss in which the distribution of the load is indicated, and also the stress diagram for this truss which is drawn to a scale equal to 1 inch = 1000 pounds. The stress diagram is drawn for one-half the truss, the other half being similar owing to the uniform loading of the truss. The stress diagrams which were drawn to derive the results presented in the Data Sheets, were laid out for the whole truss. The system of notation or lettering is such that any member lies between two letters. Thus *Aa* signifies the top chord member in the first panel on the left-hand end of the truss as shown in Fig. 1.

After drawing the stress diagrams, the results were scaled off and these results were pointed off to three decimal places (divided by 1000), thus obtaining the stress in any member for a panel load of one pound. For example, in the stress diagram shown in Fig. 1, *Aa* represents 7000 pounds for a panel load of 1000 pounds. The stress for a panel load of one pound is therefore 7000 divided by 1000 = 7.000. This value will be found in the table for the eight-panel Fink roof truss in the column for 30 degree pitch. It follows that for any panel load the stress in a given member can be found by multiplying the panel load by the coefficient for that member. The character of the stress (whether tension or compression) will be found in the second column of the Data Sheets. It should be thoroughly understood that in deriving these results, all of the panel loads were regarded as being equal and acting simultaneously.

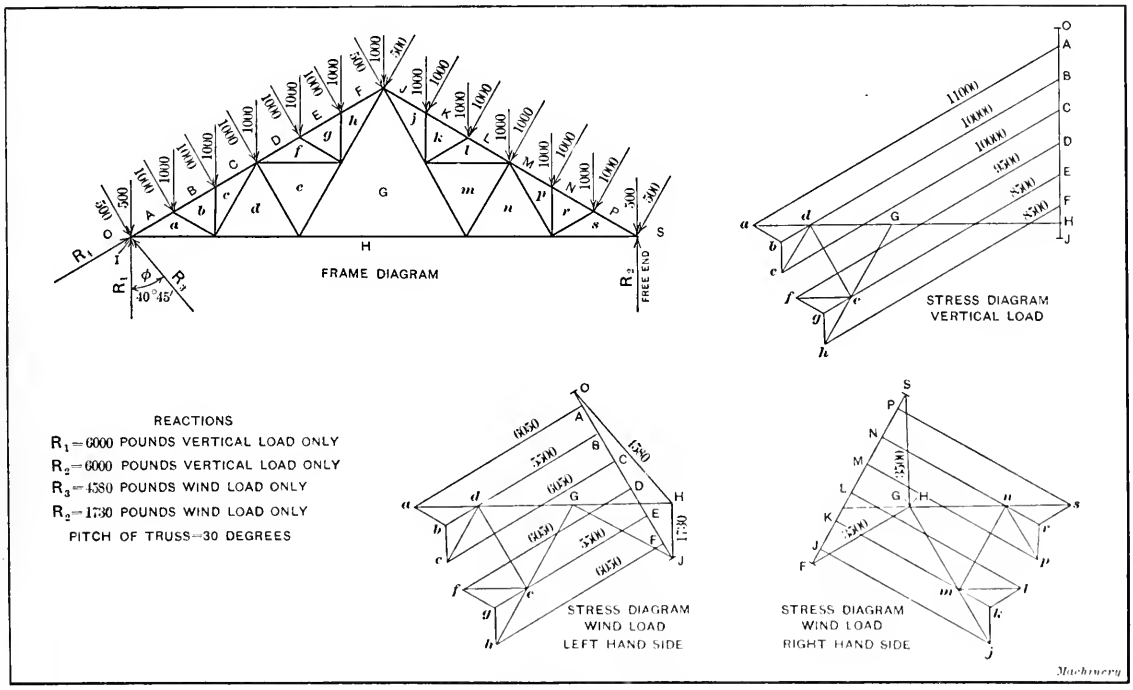

Fig. 2. Frame and Stress Diagrams for Twelve-panel Fan Roof Truss

Fig. 2 shows the frame diagram for a twelve-panel fan type

† Address: 1552 Indiana Ave., Toledo, Ohio.

roof truss carrying a uniformly distributed vertical load and a uniform wind load. It should be remembered that all of these loads do not act at the same time, but they are shown in this way in the diagram to save space. The same statement applies to the reactions. R_1 is only for vertical loads; R_2 is of a different amount for the vertical and the wind loads, but is always in the same direction; R_3 is the reaction for the left hand wind load only; and R_4 is the amount of the fixed-end reaction for the wind load on the free end side of the truss. A typical stress diagram for the vertical load is shown in this illustration, and it will be remembered that the method of constructing such a diagram was discussed in connection with the eight-panel Fink type of roof truss.

Referring to Table 1 it will be seen that two tables are given one for the wind load and the other for the vertical load. The results set forth in these tables are for the wind on the left-hand side of the truss which is considered fixed or stationary while the opposite end is considered free. Stress diagrams for the wind load on the fixed end side and on the free end side are also given in Fig. 2. The reaction R_2 for the free end is always vertical, whereas reaction R_3, which is for the wind load on the left-hand side of the truss, is at an angle. The direction of this reaction is determined from the stress diagram for the wind load on the left-hand side of the truss and corresponds to the direction of the line OH. The reaction R_2 due to the left-hand wind load is shown by the vertical line HJ both in direction and magnitude. The fixed end reaction R_4, due to the right-hand wind load, is given by the line FH in the stress diagram for wind load on the right-hand side.

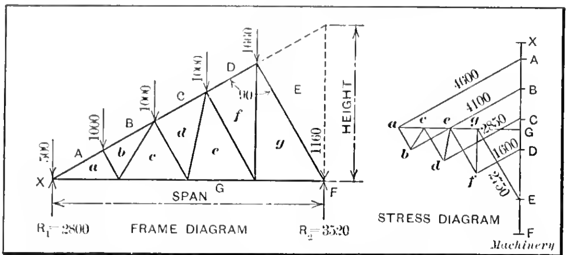

Fig. 3. Frame and Stress Diagrams for Four-panel Sawtooth Roof Truss

By comparing the respective diagrams for the wind loads on the two sides of the truss, it will be seen that the stress in the lower chord members is greater with the wind blowing on the fixed end or left-hand side. With the wind load on the fixed end, the members Gj, Gm, jk, kl, lm, mn, np, pr, and rs are not subjected to stress and consequently take no part in carrying the load—that is theoretically. The same members on the opposite side of the truss and in the same relative position, are inactive when the wind acts upon the right-hand or free end. The members Gh, dH and aH are likewise found to be without stress as far as right-hand wind load is concerned. As the truss must be proportioned for the maximum stresses and as the stresses due to wind load are greater with the wind acting upon the fixed end (in this case the left-hand end) the coefficients given in the Data Sheets are for the maximum stress. Many engineers assume an equivalent vertical load to take care of the wind load and add such a load to the loads due to the weight of the roof, to snow on the roof and to the weight of the truss itself.

In explaining the design of trusses for the sawtooth type of roof, the four-panel, 30-degree truss is taken as an example. Fig. 3 shows the frame diagram for this truss, in which it will be seen that uniform loading is assumed. The panels A, B, C and D are equal; hence the loads at AB, BC and CD represent the load carried by one panel, *i. e.*, 1000 pounds. The load XA at the left-hand end is equal to one-half of the panel load. It will be seen that the panel E is longer than the other panels and hence it carries a larger load; the load DE was assumed to be made up of one-half the panels D and E which amounts to 1660 pounds. The load EF at the right-hand end of the truss is equal to one-half the panel load E or 1160 pounds. It should be noted that the coefficients given for these loads are 1.66 and 1.16 respectively, from which it will be seen that with a given load at AB, BC or CD, which are equal, the load at DE or EF can be easily obtained by multiplying their respective coefficients by that load.

The height of the truss is taken as the vertical distance from the bottom chord to a projection of the top chord and the member gE makes an angle of 90 degrees with the top chord. The reactions are calculated by the method of moments. The left-hand reaction R_1 is 2800 pounds, and the right-hand reaction R_2 is 3520 pounds. It will be well to note that the coefficients given in the Data Sheet are 2.8 for R_1 and 3.52 for R_2. Multiplying these factors by the load at either AB, BC or CD, gives the respective reactions.

A stress diagram for this type of roof truss is illustrated in Fig. 3. Referring to the Data Sheet it will be seen that the stress coefficient for the member Aa in the 30-degree pitch column is 4.60. Multiplying the load at AB, which is 1000 pounds in this case, by this factor gives a stress of 4600 pounds, the member being under compression. The angle θ is the inclination of the top chord to the bottom chord.

In all types of roof trusses, except the sawtooth, the pitch is obtained from the following formula:

$$\text{Pitch} = \frac{\text{height}}{\text{span}}$$

In the case of the sawtooth type of roof truss the pitch is as follows:

$$\text{Pitch} = \frac{\text{height}}{2 \times \text{span}}$$

Therefore, the height of the truss is obtained by multiplying the pitch by the span or by twice the span, according to the type of truss under consideration. The height can be readily found by means of the preceding formulas for pitches of 1/3, 1/4, and 1/5 but for the 30-degree pitch this is not the case. To find the height of a 30-degree pitch truss, the following formula is used:

$$\text{Height} = \frac{\text{span}}{2} \times \tan 30 \text{ degrees.}$$

The use of this Data Sheet Supplement should prove of particular value in starting upon the design of a new building when it is desirable to compare the relative economy of several different types of roof trusses.

DRILLING HOLES IN GLASS

There are several methods of drilling holes in glass. For holes of medium and large size, use brass or copper tubing, having an outside diameter equal to the size of hole required. Revolve the tube at a peripheral speed of about 100 feet per minute, and use carborundum (80 to 100 grit) and light machine oil between the end of the pipe and the glass. Insert the abrasive under the drill with a thin piece of soft wood to avoid scratching the glass. The glass should be supported by a felt or rubber cushion, not much larger than the hole to be drilled. If practicable, it is well to drill about half way through and then turn the glass over and drill down to meet the first cut. Any fin that may be left in the hole can be removed readily with a round second-cut file wet with turpentine. For comparatively small holes, a solid drill is often used. Use steel rod or an old three-cornered file, grinding the end to a long tapering triangular shaped point. Grip the drill in a chuck and rotate rapidly. Use a mixture of turpentine and camphor as a lubricant. Holes up to about ½ inch diameter can readily be drilled in glass with a flat drill which has been hardened in sulphurous acid, a mixture of turpentine and camphor being used as a lubricant.

* * *

The year 1912 was a record one as respects German export and import trade. During that year, the value of the exports amounted to about $2,250,000,000 and the imports to about $2,675,000,000, so that the sum total of imports and exports came close to five billions. In many other respects, 1912 was a record year in German industries. The tonnage of merchant vessels constructed in German shipbuilding yards was over 375,000 tons, an increase of nearly 50 per cent over that in 1911. In the export trade, the United Kingdom was the greatest customer of Germany.

THE HOLLERITH TABULATING MACHINE IN THE BUSINESS OFFICE

A RAPID MEANS OF COMPILING AND TABULATING STATISTICS

BY S. G. KOON*

Statistics essential to the intelligent consideration of every manufacturing or selling proposition must be compiled quickly and tabulated promptly if they are to be of value. Information of value today is often valueless next week.

The president of a large steel company called suddenly for an analysis of the sales for the preceding five years. The next morning he had the complete analysis for the three most recent years. But as it would have taken a whole month, with a considerable increase in the accounting force, to give him the other two years, he accepted the three years then instead of five years a month later. The reason for this is simple. Hollerith tabulating machines and cards had been used for three years; prior to that reports were all in loose-leaf form, and the work of compiling the special report would have involved going to original sources and working over every piece of information from start to finish. By the Hollerith system, punched cards are used which sort, classify, and aggregate the amounts recorded, in any manner desired and practically automatically. This method of transferring records to cards, and

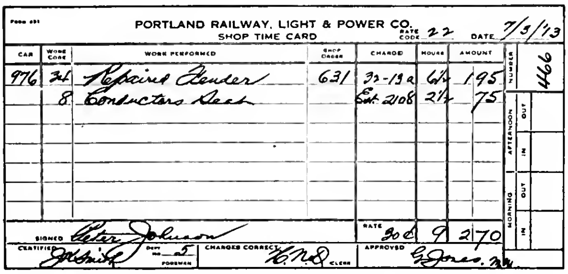

Fig. 1. Time Card for Two Operations from which Statistical Cards are punched

then analyzing the records, is capable of positive proof for correctness. It gives results which are available for reports immediately after closing business daily, weekly or monthly, as required. Figures may be obtained by this means within a few hours, where formerly weeks were needed. They may be obtained in much greater detail and at an expense far less than that of getting such complete results in any other way.

The system is used in factories of all sorts, in steel mills, by insurance companies, by electric light and traction and telephone companies, by wholesale merchandise establishments and department stores, by textile mills, automobile companies, numerous railroads, municipalities and state governments. It is used for compiling labor costs, efficiency records, distribution of sales, internal requisitions for supplies and materials,

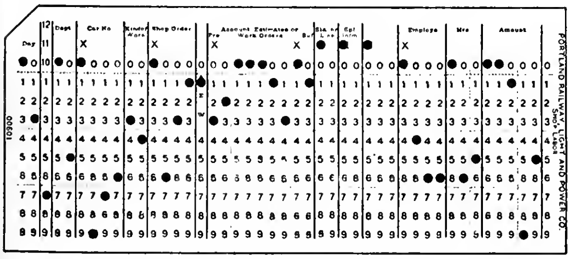

Fig. 2. Statistical Card punched for First Operation on Time Card

production statistics, day and piece work. It is used for analyzing risks in life, fire and casualty insurance, for plant expenditures and sales of service, by public service corporations, for distributing sales and cost figures as to salesman, department, customer, location, commodity, method of sale, and in numerous other ways. The cards, besides furnishing the basis for regular current reports, provide also for all special reports and make it possible to obtain them in a mere fraction of the time otherwise required.

The analyses and reports are obtained by means of cards, punched according to a code representing certain fundamental facts, and then run through two automatic machines. These first assort the cards according to a predetermined arrangement; then having obtained the grouping desired, they record details and totals on counters from which they are taken off to blanks suitably prepared. Electric contacts, made when a

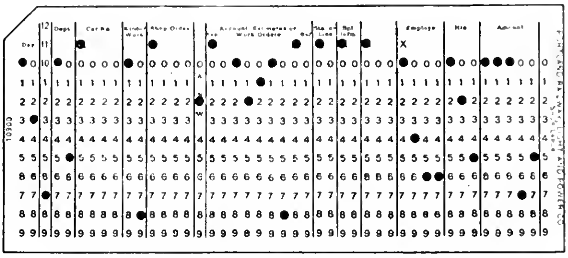

Fig. 3. Statistical Card punched for Second Operation on Time Card

punched hole in the card passes over a brush terminal in the apparatus, produce the action of either machine in so certain and positive a manner that far fewer errors are made than by any method of hand analysis. The cards can be grouped to give any possible result, and can be resorted and tabulated any number of times. The ability of these machines to handle this sort of analysis satisfactorily lies in their power to count combined facts. Each counter adds a different set of figures.

One machine tool builder uses this system for compiling costs, analyzing payroll, sales and shipments, keeping track of materials, and hence, compiling a perpetual inventory. The possibilities of its use are said to be almost untold. An electric service company, by adjusting the sorting machines to sort cards by car numbers, obtains the aggregate shop cost in

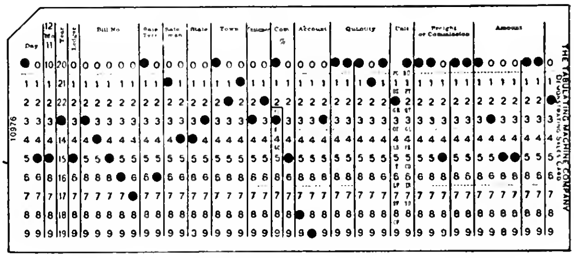

Fig. 4. Another Statistical Card punched from a Different Set of Specifications

labor and material during any given time and for each car automatically and quickly. Fig. 1 shows a shop time card made out for two operations, and Figs. 2 and 3 show the statistical cards punched from this record at the end of the week or month for distributing costs, etc. Following through the punching of the card in Fig. 2 from the information given on the time card for the first operation, Fig. 1, it will be seen that the day has been punched as 3, the month as 7, the department as 5, the car number as 976, kind of work as 34 (work code), shop order as 631, work order as 32-13, the employe as 466, hours as 6.5 and amount as 195 ($1.95). In the same way information for the second operation is punched on the card shown in Fig. 3. Fig. 4 shows a card punched from a different set of specifications. If the cost of any special kind of work, such as winding field coils, is desired, this can be obtained in the same way by running the cards through the machine again after setting it to catch and record that item. Set in still another way, the time spent by any employe upon any particular class of work or upon all kinds of work can be obtained.

The auditor of the Board of Education of New York City recently prepared his budget, covering an expenditure for 1913 of forty million dollars, from Hollerith cards which had been punched as a record of previous disbursements. One of the

*Address: 170 Summer St., Boston, Mass.

transcontinental railroads finds it necessary to refer repeatedly to traffic statistics in connection with rate litigation and kindred subjects. The volume of traffic is such that complete reports could not be obtained without enormous cost in both time and money, except for the fact that all traffic statistics are analyzed regularly by means of the tabulating system. This road estimates that present results in routine work without the aid of the machines would cost from 50 to 75 per cent more than at present.

In any shop, by punching cards direct from employes' time tickets, payrolls can be made up quickly and shop costs compiled easily, which must agree absolutely with the payrolls. From these cards, job costs to the finest detail can be figured promptly, and comparisons of men and work made. For every classification, whether part of the current analysis or of a subsequent special report, one and the same batch of cards is used over and over again, without any recopying of original

Fig. 5. Southern Pacific R. R. Co., San Francisco. Twelve tabulating machines are required to perform the traffic and other analyses on this railway system

entries. There is thus no possibility of repeated errors or transposition of figures; nor can any figure be used twice.

The cards are made in two sizes, each with two widths of column spacing. As the location of the column on the card determines the location of the column in the counter upon which the result is finally recorded, the machines are necessarily arranged to fit the card adopted. The long or full sized card will accommodate 37 wide-spaced or 45 narrow-spaced columns; the smaller card will take 27 or 34 columns. In the actual application to the card it is not simply a question of the

Fig. 6. Southern Pacific R. R. Co.'s Card Punching Department. The extent of the use of this system by a railroad is indicated by the number of girls employed in punching cards

notation of numbers and figures on the card, but of the indication of those symbols by means of perforations at measured distances from the top, bottom and ends of the card. The key punch used to perforate the cards accords with the card dimensions and the column spacing. It may be considered the writing instrument. The rate of punching varies materially with the amount of information carried. It is more rapid than ordinary card writing or the usual speed of journalizers or entry clerks. Depending upon the number of holes punched, cards are prepared by seasoned operators at the rate of 1500 to 4000 per day, the average output being not far from 2500. Many items are repeated from one card to the next. This is particularly true of dates, departments, classes of transaction, origin of business, etc. To avoid punching these individually,

Fig. 7. Carnegie Steel Co., Pittsburg. Two sorting machines at work sorting cards at the rate of 250 per minute each

a gang punch is used for multiple punching. This will punch a dozen or fifteen cards at once and covers nine or ten items on each card.

In nearly all cases, mechanical sorting is necessary before the cards can be used in the tabulator to obtain the required analysis. The sorting machine is used for the arrangement

Fig. 8. Cleveland Electric Illuminating Co. A complete statistical unit —two key punches at left, sorting machine in corner, tabulator in center, and gang punch at right in front of card cabinet

and rearrangement of the cards into orderly groups, such as by states, by agencies, by style of job or color of the product under analysis. The cards are sorted at a speed of about 250 per minute into pockets or boxes in the machine, each corresponding to one row on the cards. This is done for a single column at a time. Owing to the necessity of handling the cards, this rate of speed is cut down markedly in a day's run.

When the sorting has once been done, the cards are run through for tabulation, obtaining such totals as are necessary. If any further sorting is required the same set of cards which has been run through the tabulator is again put into the sorting machine, resorted in accordance with some other classification, and again run through the tabulator. The tabulator carries from two to five counters, each having from one to seven magnets. Each counter may therefore add numbers with from one to seven digits.

The tabulating machine, electrically controlled and mechanically operated, adds the numerical amounts up to a maximum of thirty-five columns at a time. The operating speed is 150 cards per minute. In the five-counter machine, 750 individual items may be added in one minute.

COLORING NON-FERROUS METALS AND ALLOYS*

CLEANING WORK—RECEIPTS FOR PRODUCING DIFFERENT COLORS—OXIDIZING—MOTTLING

BY E. F. LAKE†

Man is so much a product of nature that mere light and shade, or white and black, are only pleasing for a time. To fully satisfy his natural desires, man's vision must be stimulated by views of different colors and various combinations thereof. To look upon one color continuously is one of the most tiresome things he can do, as it affects his entire nervous system. This has led to the coloring of metals, and to producing many beautiful effects in place of the natural color of the metal which may become repulsive from being seen too frequently.

In thickly inhabited sections a great deal of coal gas is burned. More or less of the products of combustion together with the gases arising from the manufacture of other materials stay in the atmosphere and give to brass and bronze objects a dark, dirty color by attacking their surfaces. The oxygen and moisture in the atmosphere also give these metals or alloys a disagreeable color. Hence coloring or coating is also resorted to for the purpose of enhancing and preserving the original beauty of the metal. Sometimes rich and beautiful browns and greens are produced on copper alloys that have been subjected to atmospheric conditions for years. Therefore these conditions have been studied and chemical means have been found for producing the colors quickly and on a commercial scale.

Copper is more susceptible to coloring processes and materials than any of the other metals, and hence the alloys containing large percentages of copper are readily given various shades of the yellow, brown, red, blue and purple colors and also black. Alloys with smaller percentages of copper, or none at all, can be given various colors, but not as easily as if copper were the principal ingredient, and the higher the copper content, the more readily can the alloy be colored. The shades, and even the colors, can be altered by varying the density of the solution, its temperature and the length of time the object is immersed. They can also be altered by finishing the work in different ways. If a cotton buff is used one shade will be produced; a scratch brush will produce another, etc. Thus to color work the same shade as that of a former lot all the data in connection with these operations must be preserved so they can be repeated with exactness.

Many different kinds of salts are made into solutions for the coloring processes. When capable of producing the desired results it is always best to use the simple salts. It is often necessary to combine two or more salts in the solution to get the required color, but these deteriorate in strength much more rapidly than the simple salt solutions and hence the last piece immersed will have a lighter color than the first one. When adding salts to bring back the original strength of the bath, they should first be dissolved in a small amount of water to prevent their settling to the bottom where they might become covered with an insoluble mud that would prevent them from being dissolved. In making the solutions it should be remembered that a strong solution will produce the color quickly and a weak solution more slowly. When a uniform coating can be produced the strong solution is always the best owing to the time factor. The most effective and lasting results, however, are obtained with the weaker solutions, and hence they are used for high-grade work. While these solutions are often used cold, there are many cases where better results can be obtained when they are heated. Raising the bath to the boiling point will insure a complete solubility of the salt.

Cleaning Work to be Colored

Cleaning the work is of the utmost importance before attempting to give it any kind of color. A greenish or brownish film forms on copper, brass, bronze, etc., when they stand, as they are attacked by the moisture in the air and the simultaneous presence of carbonic acid which gradually changes into carbonates. This film is a mixture of carbonate of copper and oxide. Often sulphur compounds are formed when the atmosphere is impregnated with the products of combustion arising from the coal gas burned in cities and towns. This is nearly always stronger in rooms than in the open. If these films are not removed before coloring they show up as stains and the work will be streaked or spotted. Touching the work with the bare hands after it is cleaned will also leave a slight film that will make the work spotted, and hence it should be strung on wires or handled in other ways that will prevent it from being touched with the hands.

Several acid dips can be made that will remove these films and leave the bright clean metal with its original smooth surface. Work that will stand heating can be heated to a dull red and then plunged into dilute sulphuric acid, after which it should be soaked in old aquafortis and then thoroughly rinsed. It should be soaked long enough to have a uniform metallic appearance, and the bath should be large enough in volume to prevent its heating up from the hot work. The best results are obtained with straw-colored aquafortis, as the white is too weak and the red too strong. In diluting the sulphuric acid it should always be poured into the water slowly, as heat is generated, and too rapid mixing generates so much heat that the containing vessel is liable to crack and the escaping liquid to cause burns. To pour water into sulphuric acid will cause an explosion that is almost sure to result in serious, if not fatal, burns from the flying liquid.

A good method of removing these films, without heat, is to soak the work in a pickle composed of spent aquafortis until a black scale is formed and then dip it for a few minutes into a solution composed of 64 parts water, 64 parts commercial sulphuric acid, 32 parts aquafortis and 1 part hydrochloric acid. After that the work should be thoroughly rinsed several times with distilled water. If the strong aquafortis is used for the pickle in which the work is soaked it will cause a too rapid corrosion of the copper during the time of the solution of the protoxide. Hence the spent aquafortis is better on account of its slower action and it also saves the cost of new. A dip that is useful for removing the sand, etc., that sticks to castings is composed of 1 part spent aquafortis, 2 parts water and 6 parts hydrochloric acid. A few minutes will suffice for small pieces, but large castings can remain in the bath for thirty minutes. They become coated with a black mud and when this is thoroughly washed off they should be bright.

If a further whitening of the work is desired a solution may be made by mixing 3 pounds nitric acid, 4 pounds sulphuric acid and 40 grains sodium chloride (table salt), combining this with 40 times its bulk of water and allowing it to cool before using. If a dead surface is desired the following mixture can be added to the bath: 2 pounds nitric acid, 1 pound sulphuric acid, 10 grains sodium chloride and 40 grains zinc sulphate. The degree of deadness is determined by the length of time the work is left in the bath. As with all other solutions, the work should be well rinsed after leaving the bath and then thoroughly dried. Another dead dipping bath can be made from one part of a concentrated solution of potassium bichromate and two parts of concentrated hydrochloric acid. Many other combinations of chemicals may also be made for cleaning or whitening the work or giving a dead finish after it has been colored, but those given above will suffice for the present.

Bright Castings

The bright clean color sometimes seen on bronze castings has been thought by many to be the result of an acid dip. This has been produced, however, by plunging the castings into water while they are still red-hot. It is seldom that brass castings can be given this color as they usually contain too much lead. Likewise the bronze castings must be free

* For previous articles published in MACHINERY on coloring metals see "Coloring Iron and Steel Products," June, 1913, and other articles there referred to.

† Address: 1453 Waterloo St., Detroit, Mich.

from lead as well as iron, antimony or other impurities, and the water into which they are plunged must be clean, or a dirty, unpleasant color will be the result. The castings must also be as hot as possible when quenched. If too hot the metal will be brittle and hence the highness of the temperature is governed by the toughness that is desired in the casting, but if quenched after they have cooled too much the color will be dull. Copper ingots can be given a beautiful rose-red color by this method.

To Produce Yellow to Orange Colors

From a golden yellow to orange color can be given polished brass pieces by immersing them for the correct length of time in a solution composed of 5 parts caustic soda to 50 parts water, by weight, and 10 parts copper carbonate. When the desired shade is reached the work must be well washed with water and dried in sawdust. Golden yellow may be produced with the following: Dissolve 100 grains lead acetate in 1 pint water and add a solution of sodium hydrate until the precipitate which first forms is redissolved, and then add 300 grains red potassium ferricyanide. With the solution at ordinary temperatures the work will assume a golden yellow, but heating the solution darkens the color until at 125 degrees F. it has changed to a brown. A pale copper color can be given brass by heating it over a charcoal fire, with no smoke, until it turns a blackish brown, then immersing in a solution of zinc chloride that is gently boiling, and finally washing thoroughly in water. Dark yellow can be obtained by immersing for five minutes in a saturated solution of common salt containing some free hydrochloric acid and which has as much ammonium sulphide added as the solution will dissolve.

To Produce a Rich Gold Color

A rich gold color can be given brass by boiling it in a solution composed of 2 parts saltpeter, 1 part common salt, 1 part alum, 24 parts water, by weight, and 1 part hydrochloric acid. Another method is to apply to the work a mixture of 3 parts alum, 6 parts saltpeter, 3 parts sulphate of zinc and 3 parts common salt. The work is then heated over a hot plate until it becomes black and then washed with water, rubbed with vinegar and again washed and dried. Still another solution is made by dissolving 150 grains sodium thiosulphate in 300 grains water and adding 100 grains of an antimony chloride solution. After boiling for some time the red-colored precipitate must be filtered off, well washed with water and added to 4 pints of hot water. Then add a saturated solution of sodium hydrate and heat until the precipitate is dissolved. Immerse the brass articles in the latter solution until they have attained the correct shade. If left in too long they will be given a gray color.

To Produce White Colors or Coatings

The white color or coating that is given to such brass articles as pins, hooks and eyes, buttons, etc., can be produced by dipping them in a solution that is made up as follows: Dissolve 2 ounces fine grain silver in nitric acid, then add 1 gallon distilled water and put into a strong solution of sodium chloride. The silver will precipitate in the form of chloride and this must be washed until all traces of acid are removed. Testing the last rinse water with litmus paper will show when the acid has disappeared. Then mix this chloride of silver with an equal amount of potassium bitartrate (cream of tartar) and add enough water to give it the consistency of cream. The work is then immersed in this and stirred around until properly coated, after which it is rinsed in hot water and dried in sawdust.

Silvering

Another method of silvering that is applicable to such work as gage or clock dials, etc., consists of grinding together in a mortar 1 ounce very dry chloride of silver, 2 ounces cream of tartar and 3 ounces common salt. Then add enough water to make it of the desired consistency and rub it on the work with a soft cloth. This will give brass or bronze surfaces a dead white thin silver coating, but it will tarnish and wear if not given a coat of lacquer. The ordinary silver lacquers that can be applied cold are the best. Before adding the water, the mixture as it leaves the mortar can be kept a long time if put in very dark colored bottles, but if left where it will be attacked by light it will decompose.

Assorted Colors

Some very interesting results in coloring brass can be obtained by dissolving 200 grains sodium thiosulphate and 200 grains lead acetate in 1 pint water and heating it to from 190 to 195 degrees F. Immersing the work in this for five seconds will make it pale gold; fifteen seconds, brown gold; twenty-five seconds, crimson; thirty seconds, purple; forty-five seconds, an iridescent bluish crimson green; sixty seconds, pale blue; sixty-five seconds, mottled purple; eighty seconds, nickel color; eighty-five seconds, mottled blue and pink; one hundred and ten seconds, mottled purple and yellow; two and one-half minutes, pale purple; four minutes, mottled pink and yellow; five minutes, mottled pink and gray; ten minutes, mottled pink and light blue. Other combinations of colors can also be obtained, but some of these fade and change color unless protected by a coat of lacquer. By using one-quarter ounce of sulphuric acid in place of the lead acetate a variety of colors can also be produced, but they will not be as good a quality as those made with the above solution. Nitrate of iron can be used with equally good results.

To Produce Gray Colors

A solution of 1 ounce of arsenic chloride in 1 pint of water will produce a gray color on brass, but if the work is left in too long it will become black. The brass objects are left in the bath until they have assumed the correct shade and then are washed in clean warm water, dried in sawdust and finally in warm air. A dark gray color that can be made lighter by scratch brushing can be obtained by immersing the work in the following solution: 2 ounces white arsenic oxide, 4 ounces commercially pure (c. p) hydrochloric acid, 1 ounce sulphuric acid and 24 ounces water. A steel gray can be produced with the following: 20 ounces arsenious oxide, 10 ounces powdered copper sulphate, 2 ounces ammonium chloride and 1 gallon common hydrochloric acid. After mixing, this should stand for one day. A 5 per cent solution of platinum chloride in 95 per cent water will also produce a dark gray color if it is painted on and the brass is warmed. Weaker solutions will make the color lighter. Copper can also be colored, but the platinum does not adhere as firmly to the surface as it does on brass. A coating of lacquer is required to make it permanent. By smearing the work with a mixture of 1 part copper sulphate and 1 part zinc chloride in 2 parts water and drying this mixture on the brass, with heat, a dark brownish color is obtained. If desirous of immersing the work a weaker solution could be used. The color is changed very little by exposure to light.

To Produce Lilac Blue and Violet Colors

The lilac shades can be produced on yellow brass by immersing the work in the following solution when heated to between 160 and 180 degrees F. Thoroughly mix 1 ounce chloride, or butter, of antimony in 2 quarts muriatic acid, and then add 1 gallon water.

To give brass a blue color dissolve 1 ounce antimony chloride in 20 ounces water, and add 3 ounces hydrochloric acid. Then warm the work and immerse it in this solution until the desired blue is obtained. After that, wash it in clean water and dry in sawdust. A permanent and beautiful blue-black can be obtained by using just enough water to dissolve 2 ounces copper sulphate and then adding enough ammonia to neutralize and make it slightly alkaline. The work must be heated before immersion. Copper nitrate, water and ammonia will also yield this rich blue-black, but if the brass is very highly heated after immersion it changes to a dull steely black. On copper or work that is copper-plated this latter produces a crimson color.

A beautiful violet color can be produced on polished brass with a mixture of two solutions. First, 4 ounces sodium hyposulphite is dissolved in 1 quart water, then 1 ounce sugar of lead is dissolved in another quart of water and the two are well stirred together. By heating this to 175 degrees F. and immersing the work the correct length of time, it takes on the violet color. The work first turns a golden yellow and this

gradually turns to violet. If left a longer time the violet will turn to blue and then to green. Thus this same preparation can be used for all of these colors by correctly limiting the time that the work is immersed.

To Produce Green Colors

When left to the natural action of the atmosphere, or ageing, most of the brasses and bronzes first turn green, and very decidedly so if near the ocean where the moisture from the salt water attacks the metal. This green color gradually darkens and then turns brown and finally black. Some of the shades it assumes are very beautiful and hence they have been produced by chemical means, as nature is too slow in its action. So many different chemical combinations are used for this purpose that it would require a book to enumerate them all and hence only a few can be mentioned. Some of the green colors can be produced by the solutions given above, but the antique, or rust, greens require different mixtures.

One solution that will produce the verde antique, or rust green, is composed of 3 ounces crystallized chloride of iron, 1 pound ammonium chloride, 8 ounces verdigris, 10 ounces common salt, 4 ounces potassium bitartrate and 1 gallon water. If the objects to be colored are large, this can be put on with a brush and several applications may be required to give the desired depth of color. Small work should be immersed and the length of time it is immersed will govern the lightness or darkness of the color. After immersion, stippling the surface with a soft round brush, dampened with the solution, will give it the variegated appearance of the naturally aged brass or bronze. Another solution that will give practically the same results is composed of 2 ounces ammonium chloride, 2 ounces common salt, 4 ounces aqua-ammonia and 1 gallon water. The work may have to be immersed or painted several times to give it the desired coating, and after washing and drying it should be lacquered or waxed. The Flemish finish can be given brass with a solution composed of 1/4 ounce sulphuret of potassium, 1 to 2 ounces white arsenic, 1 quart muriatic acid and 10 gallons of water. The arsenic should be dissolved in a part of the acid by heating and then mixed with the balance of the acid and water. Two ounces sulphuret of potassium in a gallon of water may also be used if it is heated to 160 degrees F. One ounce sulphuric or muriatic acid in a gallon of water darkens the color produced by this last mixture.

To Produce Brown Colors

Many different shades of brown can be produced and many different chemicals are used to form solutions or pastes for this purpose. In these liver of sulphur, either potassium sulphide or sodium sulphide, is one of the most commonly used chemicals. One-fourth ounce liver of sulphur in 1 gallon water will give bronze a brown color when used cold but if heated it is more effective. The depth of the color is governed by the length of time that the work is immersed. If left in too long, however, it becomes black and if too much liver of sulphur is used the color will be black. Copper is turned black even with the weak solutions. To set the color it should afterwards be immersed in water containing a small amount of sulphuric or nitric acid. Brass is not attacked by this solution but if caustic potash is added it causes the liver of sulphur to color the brass. Then 2 ounces liver of sulphur should be added to 1 gallon water and from 2 to 8 ounces caustic potash, according to the shade of brown that is desired; the more potash the darker will be the color. A solution composed of 1/2 ounce potassium sulphide in 1 gallon of water will produce a gray or greenish color on brass when cold but when heated to 100 degrees F. it produces a light brown; at 120 degrees, a reddish brown; at 140 degrees, a dark brown; and at 180 degrees, a black color.

The barbedienne bronze, or brown, color can be produced on cast brass or bronze by immersing in a solution made by dissolving 2 ounces golden sulphuret of antimony and 8 ounces caustic soda in 1 gallon water. The work must be properly cleaned beforehand and afterwards scratch-brushed wet, with a little pumice stone applied when brushing. It must then be well washed and dried in sawdust. A second immersion in a solution of one-half the above strength will have a toning effect, and the work must again be washed and dried. The high light can be made to show relief by rubbing the object with pumice stone paste on a soft rag. A dead effect can be produced by immersing in a hot sulphuret of antimony solution for ten or fifteen seconds, then rewashing and immersing in hot water for a few seconds and drying in sawdust. The work should be lacquered to preserve the tones and waxed when the lacquer has become dry and hard. This brown color can be darkened by a five-seconds immersion in a cold solution of 8 ounces sulphate of copper in 1 gallon water. Some other processes use two solutions, the first of which is heated and the second used cold, after which the work is rinsed in boiling water.

To Produce Black

There are as many different processes and solutions for blackening brass as there are for browning, and consequently only a few can be given. Trioxide of arsenic, white arsenic or arsenious acid are different names for the chemical that is most commonly used. Its use can be traced back to the fifth century and it is the cheapest chemical for producing black on brass, copper, nickel, German silver, etc. It has a tendency to fade and a much greater tendency if not properly applied, but a coat of lacquer will preserve it a long time. A good black can be produced by immersing work in a solution composed of 2 ounces white arsenic and 5 ounces cyanide of potassium in 1 gallon water. This should be boiled on a gas stove, in an enamel or agate vessel and used hot. Another cheap solution is composed of 8 ounces sugar of lead, 8 ounces hyposulphite of soda and 1 gallon water. This must also be used hot and the work afterwards lacquered to prevent fading. When immersed the brass first turns yellow, then blue and then black, the latter being a deposit of sulphide of lead.

The ammonia-copper carbonate solution much used for medals, ornaments, etc., is made by taking the desired quantity of the strongest ammonia water and mixing it with an equal amount of distilled water, and dissolving carbonate of copper in it until it is thoroughly saturated and a little remains undissolved. This is placed in a stone crock and surrounded with water and then heated to from 150 to 170 degrees F. before the work is immersed. After immersing for a few seconds the brass will turn black and it is then removed and first rinsed in cold water and dried and then given a coat of dead, black lacquer.

A black that will withstand the wear of such articles as desk telephones can be given to brass with a solution that is made as follows: Mix 1 ounce nitrate of copper with 1 ounce water. Then mix 1 ounce nitrate of silver with 1 ounce water. Then combine 1 part of the nitrate of silver solution with 2 parts of the nitrate of copper solution and 3 parts water. Heat the brass, bronze or copper article to 250 degrees F., and give it two coats of this solution with set-in-rubber brushes. When the fluffy smut is brushed off with a stiff bristle brush, the work will be found to have a pleasing brownish black color that is tenacious. If it is desired to change this to a dead black the article can be immersed for 5 minutes in a cold solution made from 2 ounces liver of sulphur in 1 gallon water. It is then removed and heated until uniformly dead black and again brushed. It can then be given a coat of flat lacquer or waxed.

Oxidizing

Solutions that produce the green, brown or black colors are usually used when it is desired to oxidize copper, brass or bronze. A dark slate green can be produced with a solution composed of 8 ounces double nickel salts, 8 ounces sodium hyposulphite and 1 gallon water. The color is almost instantly produced when the temperature of the solution is above 150 degrees F., but below the boiling point, and the articles immersed. After removing and rinsing in water the relief is easily produced with pumice stone or other abrasives. This green color harmonizes well with the metal color.

The browns and blacks are coated on the metal in the same manner as described above under these headings; the solutions that are used hot give the best results, as the coating is more tenacious and better withstands the

buffing that is necessary when oxidizing the work. Many beautiful effects are produced by these combinations of colors, and while it is not difficult to relieve the rough surfaces of cast, stamped or pressed articles it requires considerable skill to properly relieve turned or polished surfaces.

Mottling

After properly buffing and cleaning the work, a handsome mottled effect can be produced by first immersing it in a boiling solution composed of 8 ounces sulphate of copper, 2 ounces salammoniac and 1 gallon water. This produces a light taffy color that soon changes to an olive green. The work should be removed when the taffy color appears and dipped in a second solution composed of 4 ounces sal-soda in 1 gallon water and that has the surface covered with a small amount of lard oil or gasoline. After that the work is again immersed in the first solution until the olive-green color is produced. The oil spreads over the surface and prevents the uniform action of the first solution, and hence the taffy and olive-green colors are mottled together with a pleasing effect. The same process might be used with different chemical solutions to mottle work with other combinations of colors.

Coloring Aluminum

Aluminum is the most difficult of metals to color. Heretofore aluminum parts have only been colored by coating them with lacquers of different colors, but a process has recently been patented by Salamon Axelrod in Germany that produces different metallic colors. Either a neutral or alkaline cobaltous nitrate is made into a water solution into which the articles are dipped, or it may be painted on pieces too large to dip. After that the work is heated and the degree of heat determines the color. A low temperature produces a steel gray color that changes to brown with a higher heat and to a durable and permanent dead black when the temperature is still higher. Zinc, tin and other white metals may also be colored with similar cobalt salt solutions.

The gun-metal finish can be given aluminum by immersing it for from six to ten seconds in a cold solution of 12 parts hydrochloric acid, 1 part chloride of antimony and 87 parts distilled water. After that, thoroughly wash it in running water for several minutes, dry with heat and lightly buff with a high-speed wheel. The color penetrates the metal and its depth is governed by the length of time it is immersed. If immersed longer than ten seconds the solution should be weakened, as hydrochloric acid eats the metal.

Nearly any color can be plated on any of the metals or alloys by electro deposition, but this is an art or trade that requires experienced platers. Electrochroma is the name given a new plating process that promises to revolutionize the older methods of plating on colors. It produces any desired shade of green, blue, red, violet or yellow and black and white by immersion in the electrolyte for from one-half minute to two minutes. The work is made the cathode. One of its special features is the coloring of leaded glass. The lead can be given any desired color, while the glass is not affected but is left clean and with a clear luster. Heretofore the lead has been painted by hand, which was a long, tedious job, often consuming a day or more for one piece. It is also easy to match colors with this plating process and they are permanent enough not to require lacquering or waxing. The plating processes, however, are separate and distinct from those given above, as these do not require an electric current nor the high degree of knowledge and skill that goes with the plater's profession.

NEW YORK CENTRAL LINES SAFETY EXHIBIT CAR

The safety exhibit car is a new feature that has just been introduced by the New York Central Lines. This car has been put into service in connection with the work of the safety department of the company. It is intended primarily as an instruction car for the purpose of teaching the 125,000 or more employes of the railroad, the principle of "safety first," although it is also an interesting exhibit for the general public. An interior view of the car is shown in the accompanying illustration. Along each side is a shelf about 3 feet from the floor, which carries models of various metal- and wood-working machines used in the locomotive repair and car shops. These models are equipped with guards and various safety appliances such as are used on the machines which they represent. Along the side walls of the car above the models there are rows of pictures which form an instructive feature of the exhibit. On one side of the car, the pictures are devoted entirely to unsafe practices, there being about 100 photographs showing the common practices of railroad employes which cause accidents resulting in injuries to themselves and others. Beside a picture showing the improper or unsafe method, there is another showing the safe and proper way. Another section of the picture gallery deals with the trespassing question, there being a number of pictures showing to what extent persons risk their lives, needlessly, by trespassing on railroad property. Above these pictures there is a statement calling attention to the fact that nearly 5300 people were killed and 5700 injured, while trespassing on the railroads of the United States during the year ending June 30, 1912. Attached to the exhibit car, there will be a coach equipped with a stereopticon so that illustrated lectures on safety can be given to employes at various points along the New York Central Lines.

AN INSTANCE OF RAPID GEAR-CUTTING

As an instance of the celerity with which up-to-date gear cutting concerns are required to work at times may be cited the making of a large special semi-steel gear by the Philadelphia Gear Works. This was a 56-inch, 3-inch circular pitch spur gear, with a 10-inch face, weighing 3340 pounds. The order came in on a Saturday morning and the pattern was made, sent to the foundry and the gear casting was returned on Wednesday morning. The gear blank was turned up Wednesday afternoon and Thursday morning, and the teeth were cut and finished by Friday morning. At the time this work was going through, a 15-inch mating pinion was carried through and shipped with the large gear on Friday afternoon.

STEAM POWER PLANT PIPING DETAILS—6

PROVIDING FOR EXPANSION AND CONTRACTION STRAINS IN PIPING SYSTEMS—(Continued)

BY WILLIAM F. FISCHER*

Exhaust mains as used in connection with condensing systems are known as vacuum exhaust mains, while those discharging the steam directly into the atmosphere are known as atmospheric exhaust mains. Atmospheric and vacuum exhaust mains expand and contract the same as do high-pressure steam mains, but not to the same extent, as the steam temperatures are lower. Exhaust mains are considerably larger than live-steam mains, however, and contain a much greater cross-sectional area of metal in the walls of the pipe; therefore they exert a greater thrust or pressure when expanding, which tends to strain the valves and fittings in the line, and even the machinery to which the exhaust piping is connected.

The thrust or pressure exerted by an exhaust main as it expands may be figured in exactly the same manner as described in the August number of MACHINERY. (See heading: "The Force of Expansion," page 959.) As exhaust mains are of greater diameter than live-steam mains, they will not bend, or buckle as easily when strained by expansion of the piping system, and this should be taken into account when making provision for expansion and contraction, even though the actual expansion be slight.

The materials commonly used in the construction of exhaust steam mains are steel, wrought iron and cast iron. Large vacuum exhaust mains are nearly always made of cast-iron pipe. Tables V, VI and VII are for use in figuring the expansion of atmospheric and vacuum exhaust mains. Table V is to be used for wrought iron pipe, Table VI for steel pipe and Table VII for cast-iron pipe. As the coefficients of expansion for the various metals vary slightly at different temperatures, this has been taken into account in preparing these tables. The values of the coefficients for different steam temperatures are given at the foot of each table.

Explanation of the Tables

The tables are to be used only for exhaust mains carrying steam at atmospheric pressure or lower. The temperature of exhaust steam at atmospheric pressure (14.7 pounds per square inch absolute pressure) is 212 degrees F. Steam at atmospheric pressure or lower will not be recorded on a steam gage, as the gage is so arranged that the pointer or hand registers zero at atmospheric pressure or lower. Steam pressures below atmospheric pressure are règistered either on a vacuum gage or mercury column. A column of mercury approximately 30 inches high exerts a pressure of 15 pounds per square inch at its base; therefore, two inches of mercury is equivalent to approximately one pound pressure per square inch. If a vacuum gage attached to a condenser registers 26 inches it means that the condenser is working under a 26-inch vacuum, or a pressure approximately equal to $26 \div 2 = 13$ pounds lower than atmospheric pressure, or $15 - 13 = 2$ pounds absolute pressure, approximately. Absolute pressure is the pressure reckoned from a complete vacuum; therefore atmospheric pressure (zero pressure as shown by a steam gage) is, in reality, approximately 14.7 pounds per square inch above vacuum.

The upper line of each table gives the vacuum in inches of mercury, as recorded on a vacuum gage connected either to the condenser or to the exhaust main. In the second line of each table is given the temperature of the exhaust steam, corresponding to the vacuum, in inches of mercury. The figures in the body of the table represent the expansion, in decimals of an inch, per lineal foot of pipe. In the first column of the table the initial temperature of the pipe is given (temperature before steam is turned into the piping system). The values given in the last column are for exhaust mains carrying steam at atmospheric pressure. To find the expansion, in inches, of an exhaust main of a given length in feet, multiply the constants as given in the table, by the length of pipe, in feet.

Example:—A cast-iron vacuum exhaust main 35 feet long discharges its steam to a surface condenser which operates under a vacuum of approximately 26 inches of mercury, as recorded on a vacuum gage attached to the condenser, or the exhaust main. The initial temperature of the pipe before steam is turned into it is 30 degrees F. How much will the pipe expand? The expansion in inches, per foot of length, is found in Table VII under 26-inch vacuum, and opposite 30 degrees initial temperature of pipe, to be 0.00685, which, multiplied by 35 (the length of the pipe in feet), gives $0.00685 \times 35 = 0.24$ inch, or approximately $\frac{1}{4}$ inch.

Allowing for Expansion and Contraction in Steam and Exhaust Mains

It is considered good practice when figuring for expansion, to allow one-half the calculated amount when cutting the pipe to length.

Example:—If, in a run of pipe 75 feet between connections, or points where the branch pipes are taken off from the header,

Coefficients of expansion used in computing the above table: Steam temperatures 100 degrees to 125 degrees inclusive, 0.00000660; steam temperatures 140 degrees to 176 degrees inclusive, 0.00000673; steam temperatures 182 degrees to 212 degrees inclusive, 0.00000688.

* Address: 3959 Fulton Ave., Woodhaven, N. Y.

the expansion is calculated to be 2 inches, it would be good practice to allow one-half of this amount when cutting the pipe to length. In other words, the total length of pipe between connections should be 75 feet minus 1 inch. The steam-fitter takes up the other inch, putting a cold strain on the pipe and springing the bends sufficiently to make up the joints. to strain the piping sufficiently to make up the joints. If one-half, or any part, of the expansion is allowed for when cutting the pipe to length, the steam-fitter should be notified to that effect, as otherwise he is apt to find the pipe short and install a "Dutchman" in the line, not knowing that expansion had been allowed for in the shop.

Coefficients of expansion used in computing the above table: Steam temperatures 100 degrees to 125 degrees inclusive, 0.00000565; steam temperatures 140 degrees to 176 degrees inclusive, 0.00000576; steam temperatures 182 degrees to 212 degrees, 0.00000590.

When steam is turned into the piping system, the elongation of the main, due to expansion, removes the cold strain, and in this way the fittings, valves and pipe joints are, at any time, strained only one-half as much as if none, or all, of the expansion were allowed for when cutting the pipe to length.

Most of the large concerns making a specialty of furnishing and erecting piping material have adopted this rule in their shops and it has proved to be satisfactory for conditions in general. When estimating the pipe length, some designers allow for all of the expansion in the line, with the result that when the steam-fitter comes to erect the piping system he finds it necessary, especially in long lines of piping, to install what is known as a "Dutchman" or filler piece (see Fig. 41) in order to make up the required length, as he finds it impossible

Anchoring Steam Mains

The method of anchoring steam main and branch pipes and the location of the anchors are very important details which should be given the proper attention when designing and erecting a piping system. If the anchors are not properly located the expansion of the piping may throw severe strains on the joints, resulting in loose gaskets and bolts and causing leakage. A steam main should never be anchored at two or more points in its length, unless an expansion bend or joint is provided at some point between the anchors; otherwise the anchors would be very apt to fail, or the pipe would bow or spring out of shape and strain the joints of the main header and branch pipes.

No special rules can be given for designing and anchoring

Coefficients of expansion used in computing the above table: Steam temperatures 100 degrees to 125 degrees inclusive, 0.00000600; steam temperatures 140 degrees to 176 degrees inclusive, 0.00000612; steam temperatures 182 degrees to 212 degrees inclusive, 0.00000626.

against expansion and contraction. The designer must depend more or less upon his own judgment in placing the expansion bends and anchors where they will do the most good. Pipe anchors should always be supported on rigid foundations, or steelwork, in order to resist the severe strains which they are subjected to. Any movement of a pipe anchor, or its foundation, defeats the purpose for which it was intended and is liable to cause the expansion strains to come on some member of the piping system where least desired, with subsequent damage to the steam main or machinery to which it is connected.

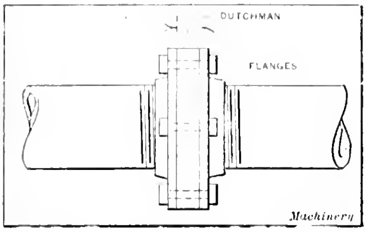

Fig. 41. "Dutchman" required when Pipes are cut Short enough to allow for All Expansion

As a guide in placing anchors and bends, see Fig. 39 (August number of MACHINERY) and also the following examples and illustrations showing several methods of caring for expansion and contraction.

Caring for Expansion and Contraction

Having determined the amount a steam pipe will expand in service, the next question that arises is how the expansion shall be taken care of so that the piping system can expand and contract freely without injury to the joints, valves and fittings in the line.

For steam mains of moderate length—say 50 to 100 feet—where flexible pipe connections are provided between the main header and the engines and boilers, the main header may be

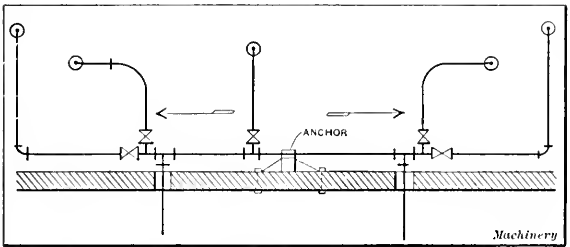

Fig. 42. Diagram showing Method of anchoring a Steam Line of Moderate Length

anchored rigidly at, or near the center of the line, thus allowing expansion in both directions, as indicated by the arrows in Fig. 42. In this case, the joints nearest the anchor are subjected to the least strain, the greatest strain falling on the joints near the end of the header. If the lines are very long it is usually better to install an expansion bend or loop in the header somewhere between the different branches, as shown in

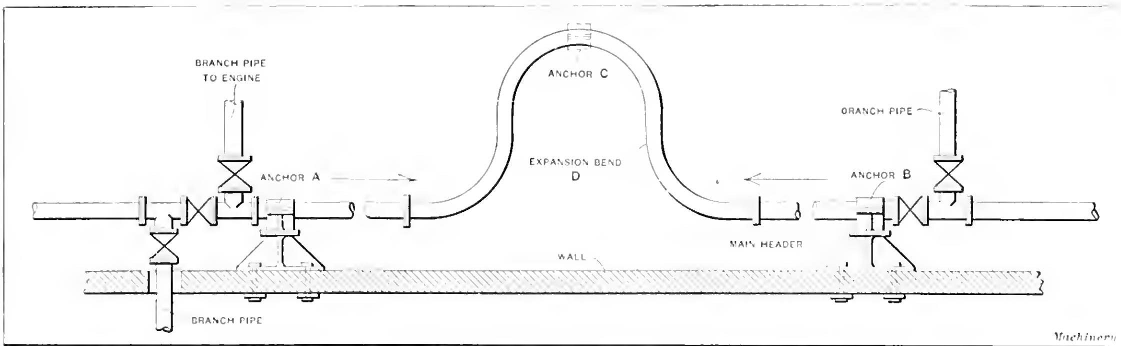

Fig. 43. Illustrating Method of compensating for Expansion and Contraction by the Use of an Expansion Bend

Fig. 43, provided the expansion in the line is sufficient to warrant the use of a loop. In Fig. 43, the main header is shown anchored close to the branch pipes at *A* and *B*, and an expansion bend is placed at any convenient point between the branch pipes, as shown at *D*. In very long pipe lines, it may be necessary to anchor the expansion bend at *C*, in order to prevent the main header from buckling sideways. When heated, the main header expands in the direction of the arrows, tending to close the bend; thus, in order to insure sufficient elasticity, the expansion bend should be designed to suit the elongation of the main header. If one-half of the expansion between points *A* and *B* is allowed for when cutting the pipe to length, expansion bend *D* would be sprung or stretched this amount during erection in order to make up the pipe joints, and would thus take care of approximately twice as much expansion as the same bend would if none of the expansion were allowed for when cutting the pipe. Rules for designing expansion bends will be given in a later installment.

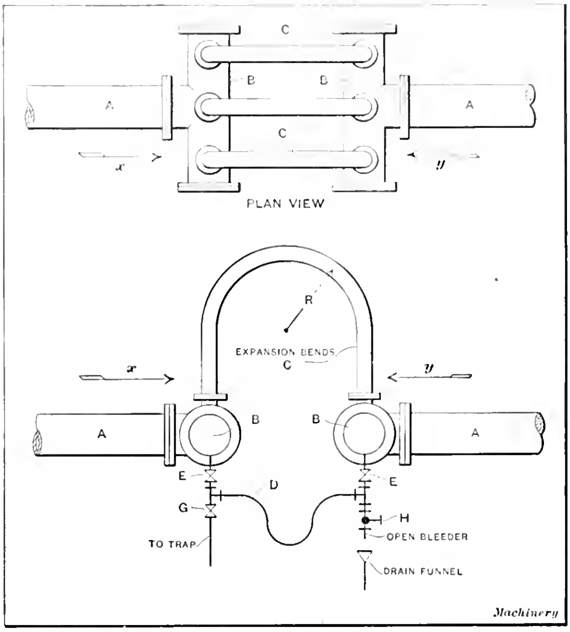

Fig. 44. An Expansion Bend formed of Three Pipes to secure Flexibility

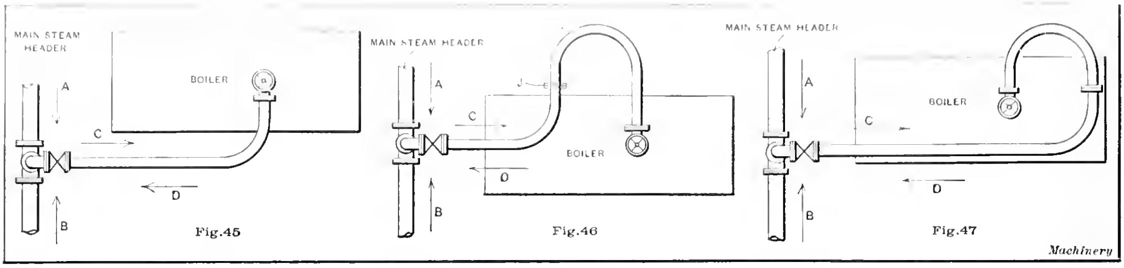
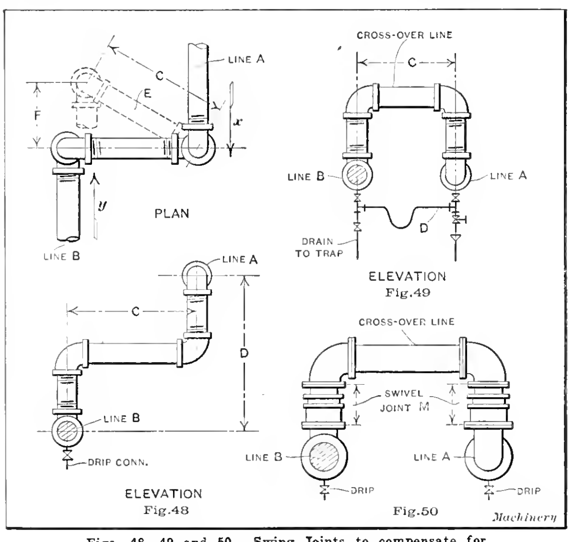
The old type of slip-expansion joints are seldom if ever used on high-pressure steam mains, as there is always more or less danger of the joint pulling apart from the pressure in the main. These joints, when used in the past, have proved a constant source of trouble and expense, requiring frequent repacking and adjustment, and almost invariably have been discarded for the more modern type of expansion bend, or balanced expansion joint now on the market. The balanced type of expansion joint is constructed so that the pressure is equalized in such a way as to prevent the joint from pulling apart. For high-pressure pipe work, expansion bends should always be given the preference over all types of expansion joints, provided there is sufficient space available to accommodate the bend. Expansion bends act as a spring, the deflection of the bend being distributed uniformly throughout the bend, thus serving to take up any movement of the pipe due to expansion or contraction.

Expansion bends made of large pipe are considerably stiffer and more rigid than bends of smaller pipe and do not deflect as readily unless bent to a very large radius. Where lack of space prohibits the use of an extremely large single-expansion bend, the expansion in a steam main of large diameter may be taken care of as shown in Fig. 44. In this case, the main header *A* is broken as shown, making connection with manifolds *B*, to which are connected U-bends *C*. The combined areas of bends *C* should be equivalent to, or greater than, the area of the main header *A*, in order that the flow of steam may not be retarded at this point. Of course, the use of a number of small bends *C* makes a more flexible connection than would a single bend of the same size as the main header, if bent to the same radius as the smaller bends. Referring to the elevation, shown in Fig. 44, we see that as the water of condensation tends to lodge in the manifolds *B* until it is picked up by the rapidly flowing steam and carried over at high velocity through bends *C*, it might cause a dangerous "water hammer" in the line. This should be guarded against by connecting a drain pipe *D* to the bottom of each manifold *B* as shown. Drain pipe *D* should be bent into the form of an expansion loop, in order to prevent expansion strains on the small valves and fittings in the drain line as the main header expands, as indicated by arrows *x-y*. Drain pipe *D* should be connected to a steam trap or other drip return system, through valve *G*. It is also advisable to provide an open bleeder, or emergency "test drain" connection, as shown at *H*, leading to an open funnel-shaped fitting, for testing or clearing the line of water when shutting down. Valves *E* are for emergency use only, being used in case it becomes necessary to disconnect or repair the drain pipe; they should always remain wide open during operation, so that if the trap or drip return system failed to operate, the water of condensation entering one manifold would flow down through drain pipe *D* into the bottom of the other manifold, where it would be carried on by the steam flow. In this manner, a dangerous water pocket could be avoided. (For further information regarding drip connections of this kind, see Fig. 28, page 705, MACHINERY, May, 1913.)



Figs. 45, 46 and 47. Different Methods of providing for Expansion and Contraction in Branch Pipes

Figs. 45, 46 and 47 show three different methods of providing for expansion and contraction in the branch pipes connecting the boilers with the main header. The connections take care of any movement of the pipes in either direction, as shown by the arrows *A*, *B*, *C* and *D*. The connection illustrated in Fig. 45 is not quite as flexible as that shown in Figs. 46 and 47. The connection, Fig. 47, requires more pipe than either of the other two. The connections, Figs. 46 and 47, are preferable where considerable movement has to be taken care of in the direction indicated by arrows *A* and *B*. The connection, Fig. 46, may be made up of two bends, if so desired, by using a flanged joint at *J*.



Figs. 48, 49 and 50. Swing Joints to compensate for Expansion and Contraction

Swing Joints

Figs. 48, 49 and 50 show different methods of taking care of expansion strains in steam piping by what are known as "swing joints." Figs. 48 and 49 show methods usually employed in making up swing joints on small and medium size pipe lines, where screwed fittings are used. In Fig. 48, pipe lines *A* and *B* are at different levels, as indicated at *D*, and are offset as at *C*. When the pipe expands in the direction of the arrows *x* and *y*, the pipe swings, or rotates on the threaded joints sufficiently to take up the expansion *F*, assuming the position shown by the dotted lines *E*. If, in this case, the steam flow were in the direction of arrow *x*, flowing from line *A* to line *B*, any water of condensation forming in the line, or carried over from the boilers with the steam, would be carried on by the steam flow without danger of water hammer at this point; but, if the steam flow were in the direction of arrow *y*, line *A* being at a higher elevation than line *B*, would form a water pocket in the riser. To prevent this, the line should be dripped at the low point as shown in the elevation.

Fig. 49 shows an arrangement of swing joints where pipe lines *A* and *B* are on the same level, but offset as at *C*. With this arrangement, the vertical legs of the cross-over connection will form a dangerous water pocket in the lines unless properly drained at the inlet side. In a case of this kind it might be advisable to connect a drain pipe to both vertical legs of the cross-over line and connect them as at *D*.

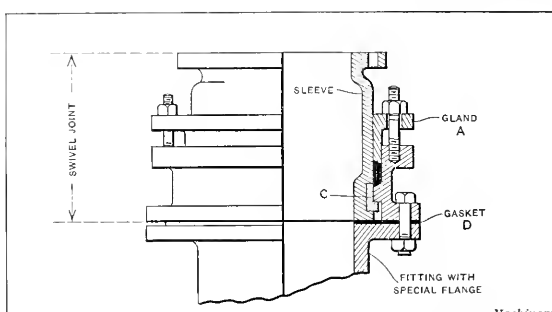


Fig. 51. Detail of Crane Co.'s Swivel Expansion Joint

Fig. 50 shows a method of connecting swing joints where either bolted flanged pipe and fittings are used or screwed pipe with screwed fittings. In this case, the swivel expansion joints *M* are connected to each vertical leg of the cross-over line, and rotate in a packed gland as the pipe expands.

Fig. 51 shows an enlarged detail and part section of one of these joints, as manufactured by the Crane Co. The upper half of these joints has flanges which match the fittings. The lower body flanges are of a special diameter and have special drilling; for this reason it is necessary to provide a special flange on the fittings to which the lower flanges connect. These swivel joints are constructed in such a manner that it is impossible for the sleeves to blow out or pull apart without shearing the circumferential bushing ring *C*. The joint, when made up, is packed steam-tight by screwing down the packing gland *A*. The upper sleeves of these joints will make a complete revolution while under pressure, with no danger of the joint blowing out or pulling apart.

Swivel expansion joints may be obtained with either screwed or flanged ends, as desired, for steam pressures as high as 250 pounds per square inch. For high pressures, however, it is advisable to use long radius steel pipe bends wherever possible in preference to expansion joints, or swing joints of any type. Pipe bends decrease the number of joints in the line, and if they are properly proportioned for the service will give far more satisfaction than the methods described in the foregoing. Swing joints are used mostly for low-pressure steam heating work, to take up the expansion in the different branches of the piping system, pipe risers, etc.

FORMULA FOR DETERMINING THE BALL CIRCLE DIAMETER FOR BALL BEARINGS*

BY WILBUR C. PRIOR†

The formula which is developed in this article is one which the writer has found very useful in solving ball-bearing problems, and it can also be used to advantage in other kinds of work. Its use will be illustrated at the end of this article. This is the only formula known to the writer for figuring the ball circle diameter where there is a space between consecutive balls. Smith and Marx, in their book on machine design, give the formula $R = \dfrac{r}{\sin \dfrac{180 \text{ deg.}}{n}}$ but this applies only to full type bearings and, even when it can be used, it is more cumbersome than the one given below:

In the diagram let:

D = ball circle diameter;

d = ball diameter;

S = space between balls;

n = number of balls.

It should be noticed that the distance S is measured on a straight line joining the centers of adjacent balls.

Construction

Draw the perpendicular bisector XZ of the chord WY. This line will pass through the center of the circle (A perpendicular bisector of a chord passes through the center of the circle).

Derivation of the Formula

In triangle XYZ:

$$\text{Side } XY = \frac{d+S}{2}$$

$$\text{Side } YZ = \frac{D}{2}$$

$$\text{Angle } XZY = \frac{180}{n}$$

$$\text{Cosecant } XZY = \frac{\dfrac{D}{2}}{\dfrac{d+S}{2}} = \frac{D}{2} \times \frac{2}{d+S} = \frac{D}{d+S}$$

Denoting cosecant XZY by C we have:

$$C = \frac{D}{d+S}$$

$$D = C\ (d+S) = \text{diameter of ball circle.}$$

* For further information on ball bearing design see MACHINERY'S Data Sheet No. 25, entitled "Formulas for Ball and Roller Bearings."
† Address: Forestville, Conn.

Example

The following example illustrates the use of the formula in connection with the values of C corresponding to different values of n in the table. Given the number and size of the balls, and the space required between consecutive balls; to find the ball circle diameter:

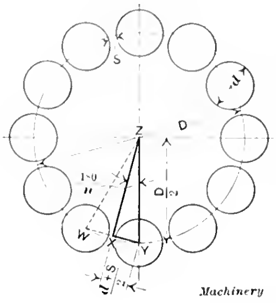
Let number of balls = 17;

diameter of balls = 5/16 inch;

space between balls = 1/8 inch.

Then looking in the table opposite 17 in the n column we find 5.4464 in the C column.

TABLE OF CONSTANTS FOR FINDING BALL CIRCLE DIAMETERS WITH SPACE BETWEEN BALLS



n	C	n	C	n	C

PROJECTILE FOR DESTROYING AEROPLANES

The means for destroying aeroplanes and airships are keeping pace with the new inventions made in the aeronautical field. Thus, for example, tests have been made in Germany with a special projectile intended for the destruction of dirigible airships. The projectile is fired from a regular army rifle, and is provided with small wings or projections which open during the flight of the projectile under the influence of a spring, which latter is compressed while the projectile is still in the rifle barrel but expands as soon as it has passed from the muzzle. An ordinary bullet leaves such a small hole in the envelope of the dirigible that the gas escapes very slowly. The wings or projections of the present bullet will tear a hole of considerable size in the fabric and in addition will cause a device contained in the bullet to ignite the gas.

WAGES OF GERMAN LABORERS

Robert Grimshaw, of Dresden, Germany, writes that the wages of ordinary day laborers in twenty-three German cities of over two thousand inhabitants are officially reported as follows: Munchen (Munich), 3.70 marks (88 cents); Berlin, Charlottenburg and Rixdorf, 3.60 marks (85.7 cents); Leipzig, Dusseldorf and Stuttgart, 3.50 marks (83.3 cents); Hamburg, Frankfurt-on-Main, Nurnberg and Essen, 3.40 marks (80.9 cents); Dresden, Dortmund, Koln (Cologne) and Duisberg, 3.25 marks (77.4 cents); Bremen and Kiel, 3.20 marks (76.2 cents); Breslau, Hannover and Magdeburg, 3.00 marks (71.4 cents); Königsberg, 2.75 marks (65.5 cents); Chemnitz and Stettin, 2.50 marks (59.5 cents).

AUTOMOBILE REAR AXLE DESIGN

A DISCUSSION OF CHAIN AND GEAR TRANSMISSIONS

BY K. W. NAJDER*

There are two important methods of transmitting the torque of the motor to the driving wheels of a motor-driven vehicle—either by means of a chain or a shaft—and each of them possesses advantages and disadvantages.

Chain Drive

In almost every instance the chain is exposed to dust and dirt which causes it to wear out, and that means a considerable loss of power, or in other words, less efficiency. As the chain is placed between the frame and the wheel the distance between the wheel and the spring seat is greater, and in consequence the bending moment of the axle is much higher, as the bending moment varies directly with the distance of the spring seat from the wheel. Another great objection to the chain drive is the noise.

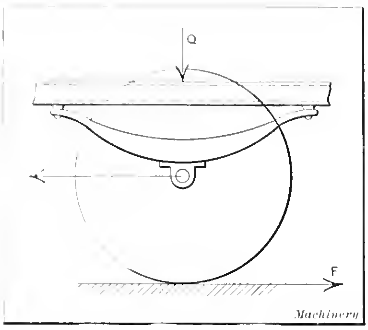

Fig. 1. Diagram illustrating Relation between Weight of Car and Retarding Force

On the other hand, when chain drive is applied, the rear axle is made from one piece, and is not parted in the center as is the case with a shaft driven axle. Further, in regard to the bending stresses, the axle can obtain the most favorable I-section. It does not carry any heavy parts, like differential gears and their housing, and being light and free from other weights, it can travel a rough road much more easily, is not subjected to very severe shocks, the bumps of the axle are reduced and in consequence the life of the tires and the rims is much longer. The shaft driven axles of heavy-duty trucks would have to carry the heavy weight of differential gears and their housings, and that is the main reason why the chain drive is applied to heavy commercial and racing cars.

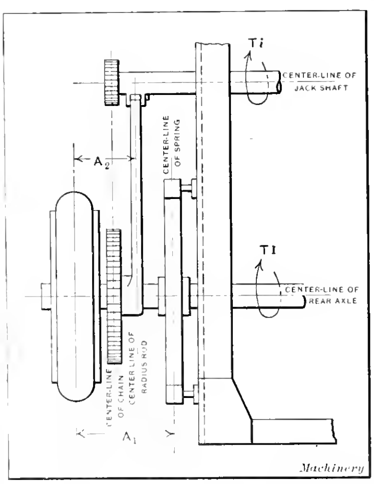

Fig. 2. Diagram showing Method of calculating Rear Axle Stresses with Chain Drive

Shaft Drive

The advantages and disadvantages of a shaft drive can be seen from what was said in regard to the chain drive. As long as the housings of shaft-driven axles were made of cast iron or steel, the shaft drive was not much in favor as the axles were heavy, the strains were great, the axles were subjected to severe shocks and bumps from the ruts of the road, and the life of the rims and tires could not be very long. With the introduction of pressed steel housings, however, the shaft drive began to receive preference over the chain drive.

An endeavor is being made to make all parts of the shaft driven axle out of pressed steel, and by that means the weight can be considerably reduced, but it will not lower the strains in the axle to any appreciable extent, as there will still be heavy parts which cannot be made lighter, such as bevel gears, ball bearings, and ball bearing housings. Generally the differential housings are supported from below by means of truss rods in order to reduce the bending moment due to the weight of the differential housings.

The rear axle pushes the car; consequently, means have to be provided to transmit this shoving force from the axle to the frame. The simplest way is to use the front end of the side springs for this purpose, and in such cases the front ends of the springs are fixed to the frame. The springs have to be strong enough to transmit this power and to withstand the skidding of the wheels; consequently they should also be figured for buckling. In heavy cars, radius rods are provided for this purpose. Another way to transmit this thrust is by means of a propeller shaft housing, the front end of which is fastened by means of a fork, or a globe joint to a cross member of the frame, or to the rear end of the transmission case. In order to make the construction sufficiently rigid, rods are run diagonally from the ends of the axle toward the front end of the propeller shaft housing.

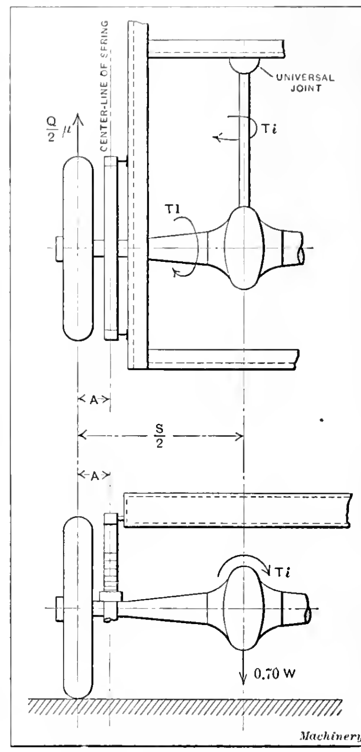

Fig. 3. Diagram for determining Rear Axle and Housing Stresses with Shaft Drive

Besides the shoving force, there is another force to be taken care of with the shaft drive construction. This is the torque exerted by the motor. On account of this torque, in starting the car forward the driving pinion tends to climb up on the gear and to carry the propeller shaft with it. The whole housing also tends to rotate in a direction opposite to that of the road wheels, and this must be prevented by proper means. The simplest way is to let the front end of the springs perform this duty. In this case the spring seats have to be fastened rigidly to the housing, and two universal joints between the axle and transmission have to be provided. In heavier cars, a special torque rod is attached near the center of the axle housing, the front end of which is pivoted, with coil springs interposed, to a cross member of the frame. In this case, two universal joints are usually provided also. If the propeller shaft housing is utilized to transmit the shoving force to the frame, as mentioned above, this same member can also be used for transmitting the torque. In this case, only one universal joint is required, but its fulcrum has to coincide with the center of the globe joint, or the fork on the front end of the construction. There should be sliding movements in the universal joints, and whenever the torque rod is applied the spring seats have to be arranged so that they can swivel around the axle housing.

The object of the shaft driven axle is to transmit power from the motor to the driving wheels. It is subjected to severe shocks and stresses due to the bumps and ruts of the road,

* Address: 63 Franklin Blvd., Pontiac, Mich.

and has to withstand all strains and stresses of stopping the car. In addition, it must carry more than half the weight of the car, and its load. The slightest deviation of a shaft from the correct line or the slightest inaccuracy in the meshing of the gears puts additional strains on the motor. To secure and maintain perfect meshing of the gears, good bearings are absolutely essential and they ought to be adjustable to take up inevitable wear. The weight of the car should be carried by the housing, and all shocks transmitted by it to the frame. The live axle should be absolutely free from all weights and shocks; it should transmit only the torque of the motor to the rear wheels, and should be subjected only to torsional stresses. In the chain construction, the jackshaft applies the power, and the dead rear axle only carries the load.

Adhesion

Let Q pounds indicate that portion of the weight of the car which is carried on the rear wheels. In Fig. 1, the weight Q is communicated to the ground through a wheel. No matter how much the friction between the wheel and the ground may be, the retarding force F cannot exceed the weight Q. If a greater force than this is applied to move the vehicle forward, the wheel will not only turn but it will also slip on the ground. Then, because the retarding force F cannot even be equal to Q, if the coefficient of friction of the wheel on the ground is μ, $F = \mu Q$ and that is the maximum condition. This factor μ is called the factor of adhesion. The coefficient of friction on an average road is 0.60. We see that we can make the calculations for the rear axle, starting with the torque of the motor, or we can start with the portion of the weight of the car which is carried on the rear wheels.

Rear Axle Calculations—Chain Drive

In Fig. 2, let

Q = Load on rear wheels;
r = Radius of the rear wheel;
i = Ratio of transmission;
I = Combined ratio of transmission and ratio of rear axle;
μ = Coefficient of friction = 0.6;
T = Torque of motor;

$$TI = Qr\mu \text{ and for one wheel } TI = \frac{Qr\mu}{2}$$

The radius rods have to withstand the skidding of the wheels and the tension of the driving chains. The maximum skidding of the wheels $= Q\mu$.

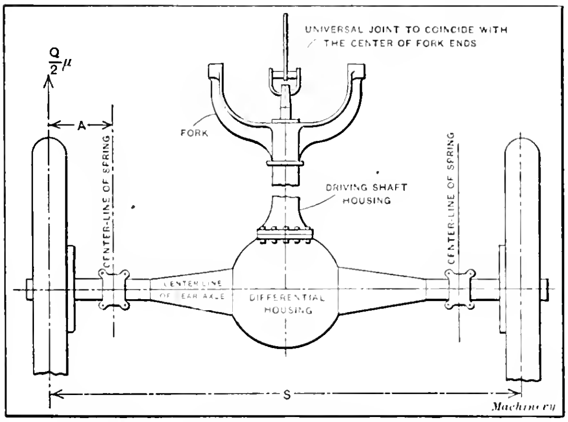

Fig. 4. Diagram for determining Stresses with Shaft Housing and Fork Construction

$$\text{Tension of driving chain} = \frac{\frac{1}{2}\,I\,T}{\text{Radius of large sprocket}} = \frac{\frac{1}{2}\,i\,T}{\text{Radius of small sprocket}}$$

The factor of safety for chains should be taken at from 8 to 10, the same as for radius rods. The rear axle should be made out of good nickel steel having a tensile strength of 90,000 pounds per square inch, elastic limit 57,000 pounds per square inch, elongation 19 per cent, reduction of area 53 per cent. The following gives the analysis of a suitable steel for axle construction:

Carbon	0.44
Manganese	0.36
Phosphorus	0.007
Silicon	0.03
Sulphur	0.019
Nickel	3.33

The rear axle is under the strain of bending on account of the load on the rear wheels and the strains of the radius rods. These factors are:

(1) Moment for one wheel $M_1 = \frac{Q}{2} A_1$

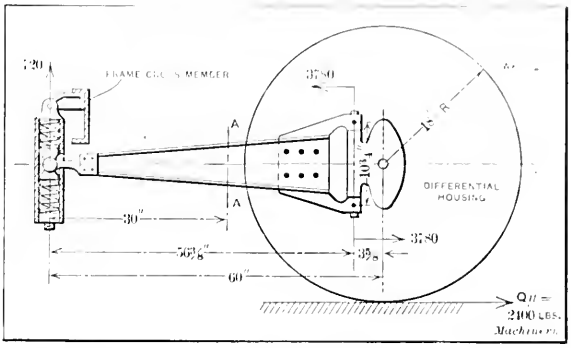

Fig. 5. Diagram illustrating Method of making Torque Rod Calculations

(2) Moment of the radius rod $M_2 = \frac{1}{2}$ ($Qr\mu$ + tension of the driving chain) A_2.

Resultant bending moment of the axle $M = \sqrt{M_1^2 + M_2^2}$.

Shaft Drive

The live axle is exposed only to a torsional strain TI, but as the axle is parted into halves, each half takes the torque $\frac{TI}{2}$. The factor of safety should be taken at from 7 to 8.

Rear Axle Housing

The housing is exposed to a strain of two bending moments between the two spring seats. These moments are as follows:

(1) Moment of the load of the car $M_1 = \frac{Q}{2} A$.

(2) Moment of skidding $M_2 = \frac{Q}{2} \mu A$.

Resultant bending moment $M = \sqrt{M_1^2 + M_2^2}$.

To be exact, there is also a third bending moment on account of the weight of the differential gears and housing. Let W be the weight of the whole rear axle and suppose that only 0.70 of this weight acts at the center of the axle. Then the bending moment on account of this weight is:

$$M_3 = 0.70\, W \frac{S}{4}$$

Resultant bending moment $M = \sqrt{(M_1 + M_3)^2 + M_2^2}$

We see that the most dangerous section of the axle housing is at the center of the axle. Very often an axle housing is of such construction that the strains of stopping the car when the brakes are applied are transmitted to the housing and from there to the torque rod. In this case, the housing should be strong enough to withstand the braking stresses, that is the torque $Qr\mu$ or TI. The factor of safety of rear axle housing should be from 10 to 12.

Rear Axle with Driving Shaft Housing and Fork

With the driving shaft housing and fork construction, the strains in the rear axle housing are somewhat greater. With this construction, one universal joint is sufficient. The driving shaft housing is utilized to transmit the shoving force of the axle to the frame and this same member is used for transmitting the torque. The fulcrum of the universal joint has to coincide with the center of the fork on the front end of the construction. The driving shaft housing is subjected to buckling and compression on account of the shoving force and is also subjected to bending on account of the torque of

the motor. There are the following stresses on the axle housing:

$$M_1 = \frac{Q}{2} A.$$

$$M_2 = 0.70\,W \frac{S}{4}$$

Besides these two moments, we have a third moment on account of the shoving force, that is the skidding of the wheels. As with this construction of the axle the springs do not take up the shoving force, this force is taken by the axle housing and we get:

$$M_3 = \frac{Q}{2} \mu \frac{S}{4}.$$

Resultant bending moment $M = \sqrt{(M_1 + M_2)^2 + M_3^2}$.

Torque Rod

The object of the torque rod is to transmit the torsional moment Tl from the rear axle housing to the frame. The torque rod is attached near the center of the axle housing, the front end of which is pivoted, with coil springs interposed, to a cross member of the frame. Two universal joints are usually provided with the torque rod construction.

Let the load on rear wheels = 4000 pounds.

Coefficient of friction $\mu = 0.6$.

The torque of the axle is $4000 \times 0.6 \times 18 = 43{,}200$ inch-pounds.

Torque of the ball is $\frac{43{,}200}{60} = 720$ pounds.

Torque of the housing pin is:

$$-10\tfrac{3}{4} \times F + 720 \times 56\tfrac{3}{8} = 0.$$

$$F = \frac{720 \times 56\tfrac{3}{8}}{10\tfrac{3}{4}} = 3780 \text{ pounds.}$$

where F = force acting on housing pin.

The bending moment of the rod can be easily obtained at any section, and so for instance, the bending moment at section A-A is $720 \times 30 = 21{,}600$ inch-pounds. The problem then consists in designing a coil spring which will not be overstrained when compressed under the load of 720 pounds.

Let P = Load acting upon the spring in pounds;
D = Diameter of spring wire in inches;
R = Mean radius of coil in inches;
K = Allowed stress = 70,000 pounds per square inch;
G = Torsional modulus 10,500,000;

$$P = \frac{\pi D^3}{16} \times \frac{K}{R} = 0.1963 \frac{D^3}{R} K;$$

$$D^3 = \frac{P R}{0.1963\,K};$$

$$D^3 = \frac{720 \times \tfrac{5}{8}}{0.1963 \times 70{,}000} = 0.032;$$

$D = \sqrt[3]{0.032} = 0.33$ inch = about 5/16 inch = thickness of wire.

$$\text{Deflection of one coil} = \frac{64\,R^3}{D^4} \times \frac{P}{G} = \frac{4\pi R^2}{D} \times \frac{K}{G}.$$

$$\text{Deflection of one coil} = \frac{4 \times 3.14 \times (\tfrac{5}{8})^2 \times 70{,}000}{0.33 \times 10{,}500{,}000} = 0.099$$

inch.

If there are, for example, ten coils, the deflection of the spring will be $0.104 \times 10 = 1.04$ inch.

The torsional forces become very great when a car is moving on a steep grade, but the maximum stresses occur when the wheels suddenly strike a large obstacle. The resistance to rotation of the wheels then increases rapidly, and the fly-wheel momentum, adding to the normal torque of the motor, produces a momentary driving effect greater than in regular running. The torque rod must be of proper dimensions to withstand such extraordinary stresses. In respect to the construction of torque rods, designers are of many different minds. Some favor a single tube, others favor two tubes arranged like a V, and still others prefer a tube around the propeller shaft with one universal joint. Many are coming to the use of stamped rods, and this is now considered very good practice.

ECONOMY IN TOOL DESIGN

BY E. H. PRATT*

The production of duplicate parts has developed many interesting features in regard to tool design. One feature which is of considerable importance is the study of tool economy. It is a well-known fact that jigs, tools and special machinery form the basis of all duplicate part systems and that the success of the system is judged largely from an economical standpoint. Many jigs and tools are so designed that even though they produce interchangeable parts accurately their use is prohibited on account of the excessive first cost; or, on the other hand, of the cost of operation. It is necessary,

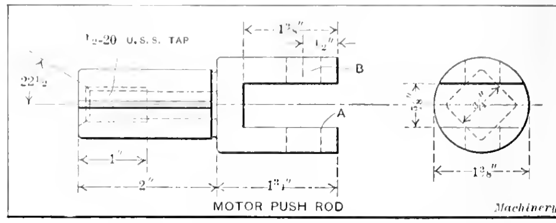

Fig. 1. Valve Push Rod for Automobile Motor

therefore, that the designer should study the problem in hand so that he will be able to design a tool as cheaply as possible which will at the same time be easily operated and produce accurate work. However, it is not always the cheapest tool that is the most economical in the long run, and it is the object of this article to show two extreme cases—one in which the cost was increased and the other decreased.

An Example of False Economy

Having many thousand automobile motor push rods of the type shown in Fig. 1 to machine, considerable time was taken

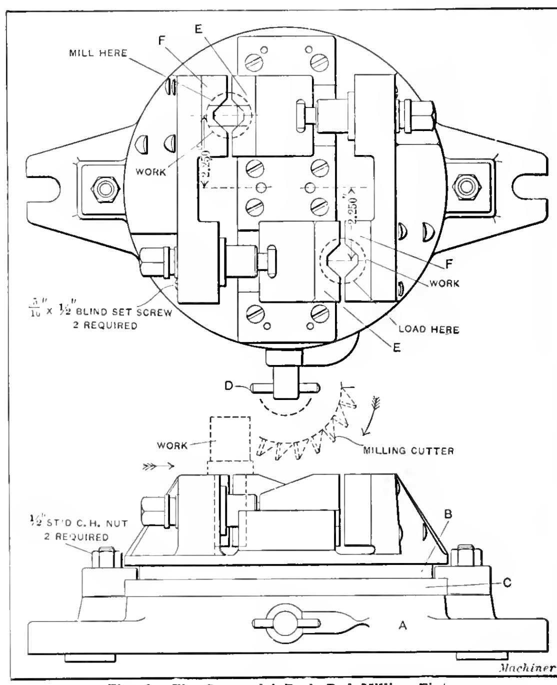

Fig. 2. The Successful Push Rod Milling Fixture

to design jigs and tools to perform the milling and drilling operations. The smallest diameter of these push rods was turned in an automatic screw machine and varied considerably in diameter, which made it necessary to hold them in an adjustable fixture. In turning these push rods in the automatic screw machine a very uneven surface was produced owing to the fact that considerable stock was removed.

The first fixture which was designed for milling the slot A in these push rods, which eventually proved unsuccessful,

* Address: 1501 E. 75th Place, Cleveland, Ohio.

is shown in Fig. 3. This fixture was designed to hold twelve push rods at a time and was made on the indexing principle, so that while one row of push rods was being milled the operator was loading the opposite side. When the milling operation was completed the locking plunger *A* was withdrawn by means of handle *B* and the fixture indexed by hand. This milling fixture was rigidly constructed, and though considerable time was taken in making it accurate it was found mill the slot central with the large diameter, and therefore the fixture was a failure.

In endeavoring to locate the difficulty, it was found that by clamping more than one of the push rods in the jigs at a time the variation in the size of the V-blocks tended to throw the work in different directions. The variation in the size of the V-blocks was only about 0.002 inch—where the blocks fitted in the fixture—but when the lower end of

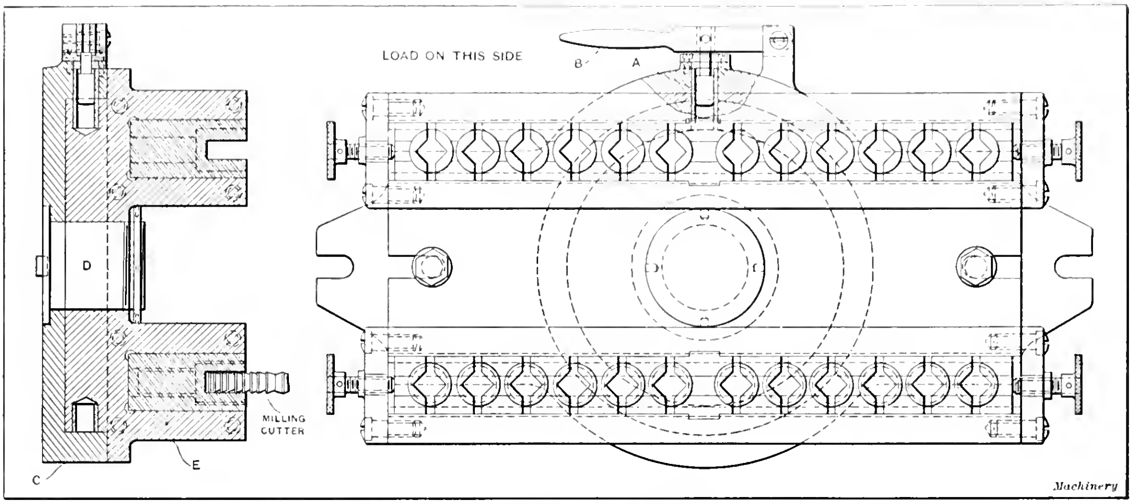

Fig. 3. Milling Fixture which proved Unsuccessful for milling the Slot in the Push Rod shown in Fig. 1

impossible to mill two sets of rods and have the slots central.

By referring to Fig. 1 it will be seen that the slot *A* is wide and deep, and the push rod could not be supported at the upper end to withstand the strain of the cut owing to the fact that the large diameter was not concentric with the small end. The construction of the milling fixture, as far as the base is the push rod was thrown out of line, the error was multiplied at the large end where the cutter was working. This not only caused the slot to be out of center, but prevented the succeeding push rods from being clamped tightly enough to hold them rigidly, therefore causing chatter. It was found, however, that by placing one push rod at a time in this fixture

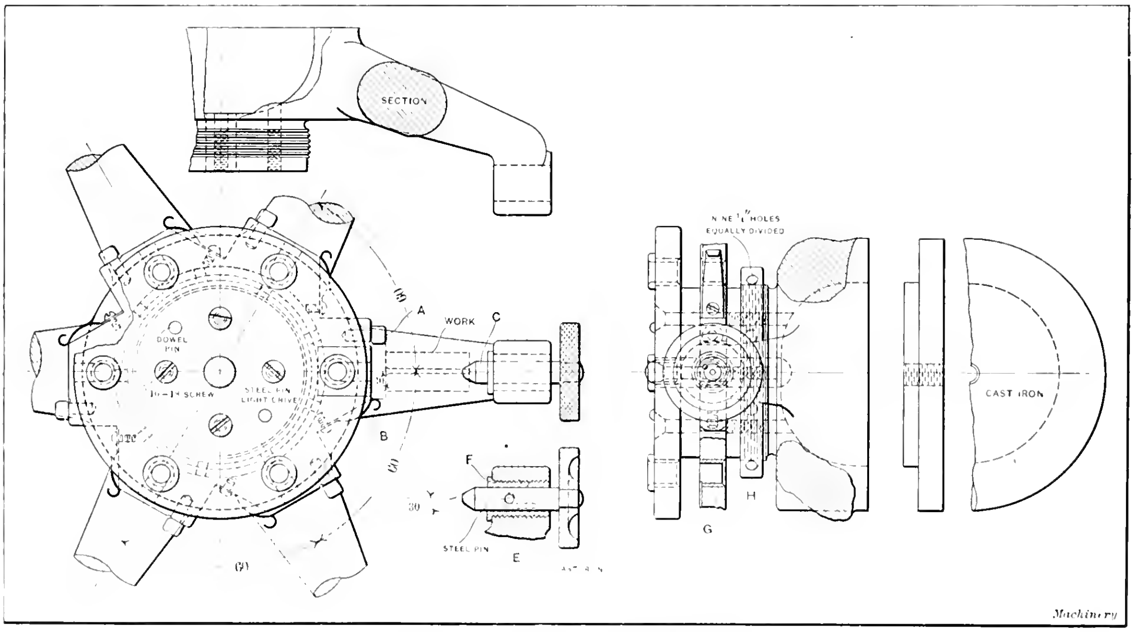

Fig. 4. The Drill Jig which proved a Failure

concerned, is of simple design and consists of a casting *C* provided with the usual pivot *D* and a top swinging member *E*. This top casting is formed to the shape shown and is provided with two channels for carrying the V-blocks in which the work is clamped. The milling operation is performed lengthwise of the jig. This fixture would be found suitable for many varieties of work, but for this push rod, which varies considerably in diameter, it was found impossible to the slot could be milled central. This furnished an idea that led to the design of the milling fixture shown in Fig. 2.

The Successful Milling Fixture

The fixture which proved successful for milling the slots in the push rods is shown in Fig. 2. This fixture consists of the usual base *A* to which is held the swiveling part of the fixture *B*, this being locked to an index plate *C* by the pin *D*. The index plate *C* is clamped to the base by two toe clamps as

illustrated. The principle on which this milling fixture was designed was to hold only two push rods at a time, so that while the cutter was operating on one the operator could be placing another piece in the opposite vise. The movable jaws *E* were operated independently of each other and were provided with adjustment for wear; and also made strong enough to insure long service. The jaws *E* and *F* were relieved in the center so that they only came in contact on the upper and lower portions of the smallest diameter of the work. This prevented the work from being thrown off center and also held it much more rigidly. The fixture was indexed one-half turn and was locked in position by pin *D* fitting in hardened and ground bushings. This fixture, although somewhat expensive to make, proved an accurate and rapid producer.

The Drilling Jig

By referring to the push rod shown in Fig. 1 it will be seen that a ½-inch hole *B* is drilled through the lugs. The first drilling jig made to handle this work is shown in Fig. 4 and was designed to hold six push rods at a time. This fixture was intended to be used on a multiple spindle drilling machine. The principle upon which this jig was designed was to hold the six push rods as indicated by the heavy dotted lines in Fig. 4. The push rod was held up against a hardened block *A* by a flat spring *B* and a cone-pointed plunger *C* fitting the hole produced in the push rod in a previous operation. This plunger was designed on the quick-acting principle, as shown in section at *E*. A pivot was driven into the rod *C* which worked in an elongated slot in the bushing *F*. The lower face of the slot on the push rod was held up tightly against the bushing plate *G* by a nut *H*. Although this drilling jig is apparently well designed, it was an absolute failure owing to the method of clamping. It also produced inaccurate work and was extremely expensive to make.

The Successful Drilling Jig

The drilling jig which was finally made for drilling these push rods is shown in Fig. 5. It was made from stock castings and consisted of a baseplate *A*, bushing block *B*, locating bar *C* and a hinge clamp *D*. Only three push rods were held in this jig at a time, but two jigs were made and used by the operator. One jig was filled while the other was under the drill press. Only three spindles of a six-spindle multiple

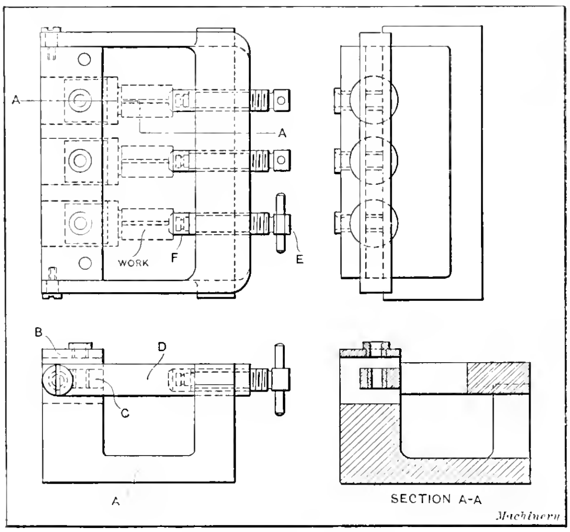

Fig. 5. The Successful Drilling Jig

spindle drilling machine were used for performing the operation, but this was handled so rapidly that there was no lost time between moves; hence the jig proved to be entirely satisfactory. In this case the largest body of the push rod fits in similarly shaped holes in the jig, being held in place by screws *E* which have compensating caps *F* fitted to them.

These examples of jig and tool design show what might be considered true and false economy. The expensive milling fixture and the inexpensive drilling jig for the push rods are tools that might be placed in the true economy class, as they are operated at a minimum of expense and produce accurate results. The first milling fixture that was thought to be technically designed and also the drill jig shown in Fig. 4 are tools that are not economical from a manufacturing standpoint. The conclusion can therefore be drawn that it is not always the simplest nor, on the other hand, is it the most expensive jig that is the most economical, but rather the one that is designed after a very careful study of shop conditions. Too much thought cannot be given to the manufacture of drilling jigs which are to be used by inexperienced workmen.

USING CURVED FILES ON AUTOMOBILE BODIES

An interesting development in filing has been made by the automobile makers in Detroit and vicinity, who have a great deal of filing to do on sheet metal automobile body sections. A large part of this work is the cleaning up of brazed joints, and for this purpose they find that files curved to a radius of approximately two feet give the best results in getting at the

Type of File used on Automobile Bodies

work and in clearing the chips. If an ordinary solid file is used it must be bent while hot, and only one side is available without rebending.

The Vixen File Co., of Philadelphia, Pa., has met the demand for curved files by furnishing a curved base upon which the ordinary straight "Vixen" file blade may be mounted. The steel used in "Vixen" files will stand this bending in a cold state, so that after one side has been worn out it is simply necessary to remove the blade and reverse the bend. The accompanying illustration shows a file and its application to the work. C. L. L.

* * *

The war in the Balkans, aside from attracting the attention of the world in general, has had a direct effect upon the machine trade in the curtailing of the emery supply. The best emery in the world comes from the island of Naxos, a Greek possession, and from this island and Asia Minor are mined the bulk of the world's emery. When the war broke out, the emery miners dropped their picks and shovels to take up their rifles and the emery supply was practically cut off. As a consequence, emery wheel manufacturers are devoting more attention to artificial abrasives, especially as a rise in the price of Greek emery is anticipated when the supply is resumed. The mining and exportation of the Naxos emery is under the direct control of the Greek government.

Some one has said that much valuable energy is wasted in preserving secrecy. Inefficiency and secrecy in a manufacturing plant are twins, and go hand-in-hand.

MAKING MOTOR POPPET VALVES

ELECTRIC WELDING, AUTOGENOUS WELDING AND MACHINING OPERATIONS

BY DOUGLAS T. HAMILTON*

The poppet type of valve generally used in gas engine construction is one of the parts which requires more attention and care in its manufacture than is usually recognized. It is absolutely necessary that the head or valve disk form a perfect bearing in the valve seat, not only to economize in fuel, but also to provide for a quiet and smooth running engine. The valve heads are necessarily subjected to the high temperatures of the burning gases and therefore should be made so that they will resist warping. They also should be made from a material which will resist the tendency to burn or oxidize, which results in a leaky valve. To overcome the rapid deterioration of engine poppet valves, many attempts have been made to secure a material that will give a long life. Among the materials which have been tried with more or

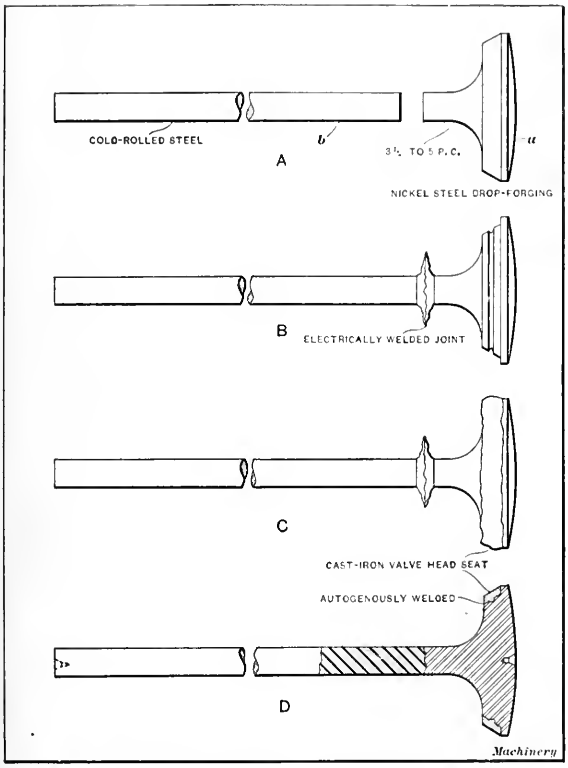

Fig. 1. Various Stages of Manufacture through which an Improved Poppet Valve passes

less satisfactory results are vanadium steel, nickel steel and cast iron. The disadvantage of making a valve head from cast iron is that it breaks off easily, and, although the bearing obtained is satisfactory, the life of the valve is short, owing to the corners breaking off. Several attempts have been made to secure a cast-iron head to the stem by riveting, but the results have not been entirely satisfactory. Another method which has been tried is to fasten a cast-iron ring to a nickel steel drop-forged head, but this has proved unsuccessful, owing to the ring's breaking, even though electrically welded. In the following article is described a method which consists in depositing a high silicon cast iron on the seat of the valve head by autogenous welding.

Preliminary Machining and Electric Welding Operations on Poppet Valves

As indicated in Fig. 1, a poppet valve consists of two parts, *viz.*, a head *a* and a stem *b*. As a rule, the head is made from a nickel steel drop-forging, containing from 3½ to 5 per cent nickel. The stem is made from a piece of cold-rolled steel, generally 25/64 inch in diameter, and long enough to meet the requirements of the engine in which it is to be used. After the drop-forging has been made and the cold-rolled stock has been cut off to the required length, these two members are welded together in an electric welder of the type shown in Fig. 2.

In operation, the head is clamped between copper jaws *A* and the stem held in a similar manner by the jaws *B*, the

Fig. 2. Electrically-welding Poppet Valve Heads to Stems in a Toledo Electric Welder

two ends of the work being butted together. The copper jaws are now brought down tightly on the work by means of a foot lever. The electric switch attached to the lever which the operator grips with his right hand, is then closed, turning on the current and immediately heating the ends of the work. When the proper temperature is reached—almost a white heat—the two pieces are brought together by means of the lever *C*, which the operator controls with his right hand, and as the metal is in a semi-fluid condition the pressure exerted on the lever joins the two ends, forming a homogeneous mass and a perfect weld. Forcing the work together in this manner when in a highly heated state, forms a flash at the joint, as indicated at *B* in Fig. 1, which is removed in a subsequent operation. For welding this particular valve stem, two legs of a three-phase 440-volt current are used,

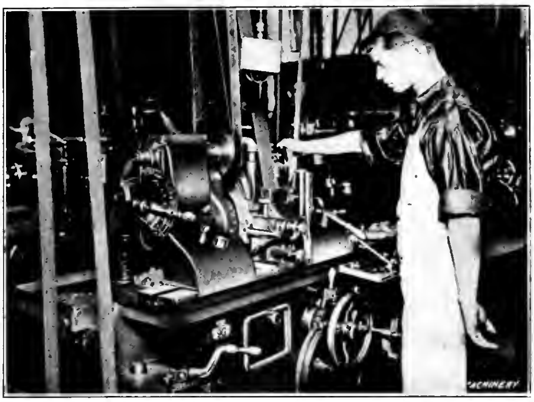

Fig. 3. Grinding Poppet Valve Stems in a Landis Plain Grinding Machine

which through a transformer in the machine is cut down to five volts. The welded stems are turned out at the rate of 2500 per day of nine hours.

After electric welding, the stem is cut off to the required length and both ends of the valve are centered; then the head is machined, a roughing and finishing cut being taken, and at the same time a small groove is cut in the seat, as indicated at *B* in Fig. 1. The next operation is to remove the burr or flash left by the welding operation in a hand screw machine.

* Associate Editor of MACHINERY.

Depositing Cast Iron on the Valve Seat by Autogenous Welding

What might really be considered the most interesting operation in the manufacture of this poppet valve is the building up of a seat on the head by means of what might properly be termed a "putting-on tool," the cast iron being deposited by means of an autogenous torch. To accomplish this operation, the valve is placed on the fixture *A*, Fig. 6, resting on its head.

Fig. 4. Group of Autogenous Welding Operators at Work on Motor Poppet Valves

This fixture is rotated by means of a foot treadle, thus enabling the operator to deposit the cast iron evenly around the surface of the seat of the valve head. The cast iron, before being deposited, is in the form of a rod ¼ inch in diameter, and is made from a grade of cast iron containing a high percentage of silicon—from 5 to 10 per cent. It has been found after many experiments that this grade of iron gives unusually satisfactory results for autogenous welding. The bar *B* is melted by the autogenous torch *C*, which develops a heat of about 6300 degrees F. It requires only a very short time for the operator to deposit the required amount of cast iron, when the valve is removed from the fixture and placed in the lime on the bench to cool, as indicated at *D* in Fig. 6.

Fig. 5. Poppet Valve before and after applying the Cast Iron by Autogenous Welding

Fig. 6. Close View of Welder at work applying Cast Iron to Poppet Valve Heads by Autogenous Welding

Fig. 4 shows a group of operators at work in the plant of the Metals Welding Co., Cleveland, where this information was obtained. The condition of the valve heads before and after depositing the cast iron is shown at *A* and *B* in Fig. 5, and also at *B* and *C* in Fig. 1. After the valve has cooled, it is taken to a hand screw machine and a light cut removed from that portion on which the cast iron was deposited. This operation is performed to determine whether or not there are any defects in the seat, due to the metal not running freely, and thus causing blowholes or cold shuts.

Final Machining Operations

The roughed valves are now taken to a hand screw machine and the cast-iron seat is machined. After machining, the valves are taken to the grinding machine shown in Fig. 3, where the valve seat is ground to the required angle and diameter, after which the stem is ground to ⅜ inch diameter, a limit of 0.0005 inch being allowed on a stem 7 inches in length. The lower end of the stem is casehardened and upon the completion of this operation the valve is ready for use.

It will be seen from the foregoing that although a poppet valve seems to be rather simple in construction, it requires the most painstaking care in its production, and its life depends largely on the proper execution of the various operations outlined. At *D* in Fig. 1 is shown a poppet valve completed and ready for use on a gas engine, with the exception of the cutting of the slot in the head which is used for driving the valve when grinding in the seat; this illustration also shows clearly the three materials used in its make-up.

* * *

The General Electric Co. has brought out a new incandescent lamp which is said to use only one-half as much current for the same candlepower as the present tungsten lamps. The new lamp contains a specially shaped tungsten filament surrounded by an inert gas like nitrogen at atmospheric pressure. The gain in efficiency of incandescent lighting thus made within the past six years, is about sixfold, the present tungsten lamps requiring only about one-third as much current as the common carbon filament lamp for the same lighting effect.

METHODS USED IN MANUFACTURING THE JONES SPEEDOMETER

MAKING THE PARTS, ASSEMBLING AND TESTING FINISHED INSTRUMENTS

BY EDWARD K. HAMMOND*

Few automobile accessories add more to the interest derived from driving an automobile than the speedometer, for this instrument affords a constant indication of the speed at which the machine is traveling, a record of the distance covered on each individual trip and the total number of miles traveled during the season. Various forms of mechanism have been employed for actuating the different types of speedometers on the market. In the Jones speedometer, with which this article is concerned, the mechanism is controlled by centrifugal force. When a body is rotating about a fixed center, a tendency is developed for the material to fly off at a tangent. The magnitude of centrifugal force is expressed by the following equation:

$$F = \frac{WV^2}{GR} = \frac{WRN^2}{2933.9},$$

where

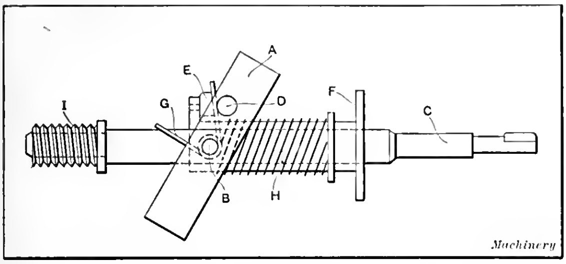

Fig. 1. Diagram illustrating Principle on which the Jones Speedometer operates

V = linear velocity of center of gravity of rotating body in feet per second $= \dfrac{2\pi RN}{60}$;

G = acceleration of gravity = 32.17;

N=R.P.M. of rotating body;

W = weight of rotating body in pounds;

R = radius in feet.

Fig. 1 shows the mechanism which actuates the Jones speedometer. A flexible shaft connects the instrument to a gear, secured to the inside of the hub of one of the front wheels. (One of these gears is shown in Fig. 2.) Hence, the speed at which the car is traveling controls the speed of rotation transmitted to the instrument. Referring to Fig. 1, A is the governor or rotating member, the centrifugal force of which actuates the speed indicator. This governor is pivoted at the point B. The spindle C is connected to the wheel of the car by means of the flexible shaft previously referred to. It will be evident that as the spindle C revolves, centrifugal force gives the governor A a tendency to rotate about the pivot B toward a position where its plane will be perpendicular to the spindle C. This tendency is resisted by the saddle spring G, which bears against the pin D in the governor. The tension of the saddle spring is so regulated that the position of the governor causes the needle of the speedometer to indicate the speed at which the car is traveling. The manner in which this result is obtained is as follows:

Fig. 2. Gear on Front Wheel of the Car, which drives the Speedometer

As the governor A moves toward the vertical position, the pin D, which engages with the finger E, draws the governor disk F forward. The governor disk is in contact with a small fiber roller at the end of a bell-crank. As the disk is drawn forward, the bell-crank revolves on its pivot and causes the indicating needle to move over the scale on the speedometer dial, thus showing the rate at which the car is traveling. The spiral spring H returns the disk toward the zero point when the speed of the car is retarded.

Making the Speedometer Parts

In the present article the purpose is to describe a number of interesting methods of instrument making employed in the factory of Jones Speedometer, New Rochelle, N. Y. Fig. 3 shows several of the parts, which will be referred to later in connection with the methods used in making or assembling them. The speedometer spindle is shown at C in Fig. 3. These spindles are roughed out from machine steel, the op-

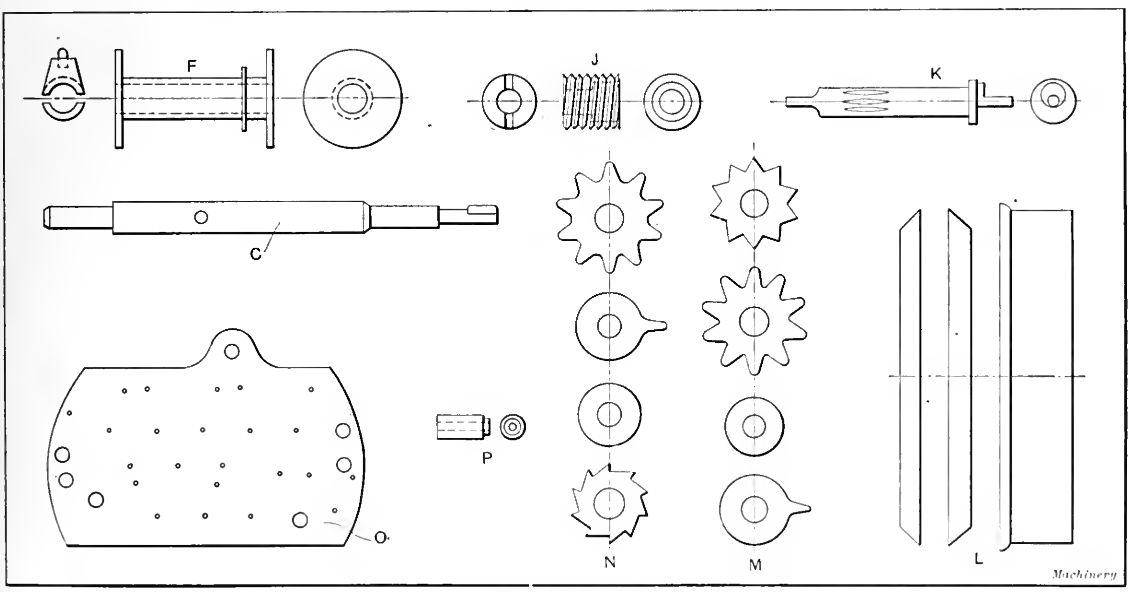

Fig. 3. Some Parts of the Jones Speedometer

*Associate Editor of MACHINERY.

eration being in accordance with standard practice. The next step is to form the key at the right-hand end of the spindle which engages with the coupling on the flexible shaft. This key is swaged on the shaft by the punch and die illustrated in Fig. 4. The end of the spindle which is to be swaged is inserted in the hole E in the die. When the press is tripped, the pins A are forced down by means of the hardened steel studs A_1, carried by the punch. The tapered ends of the pins A force the swaging punches B in against the work and form the key on the spindle. The top of the key is given the required shape by means of the pin C. This pin is forced down by means of the cam D, which is actuated by a hand lever. The position of the pin controls the height to which the metal can flow during the swaging operation. The punches B and pin C are returned by spiral springs when the ram of the press rises.

After the spindles have been roughed out and swaged, they are taken to the hardening department where they are hardened locally at the points where the cone bearings are to be ground in a subsequent operation. Upon the completion of the hardening process the hole is drilled in the spindle to receive the pivot B, upon which the governor is carried. The work is then taken to a Sloan & Chace bench lathe, equipped with a compound rest upon which the grinding attachment is mounted. The work is carried in an ordinary draw-in chuck and the bearing cones are ground at an angle of forty-five degrees. After this the work is taken to the Brown & Sharpe universal grinders where the body of the spindle is ground.

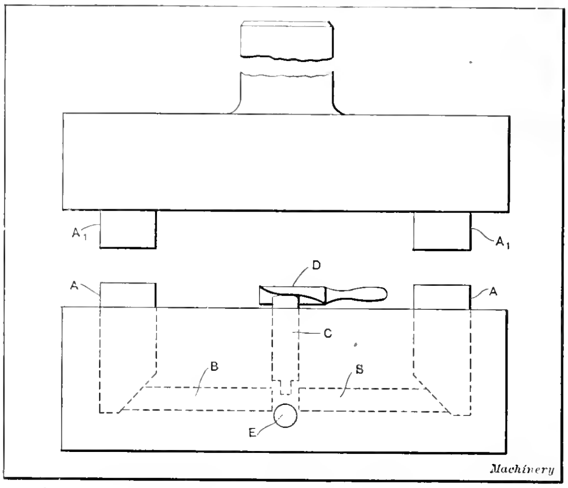

Fig. 4. Punch and Die used for swaging Key on End of Speedometer Spindle

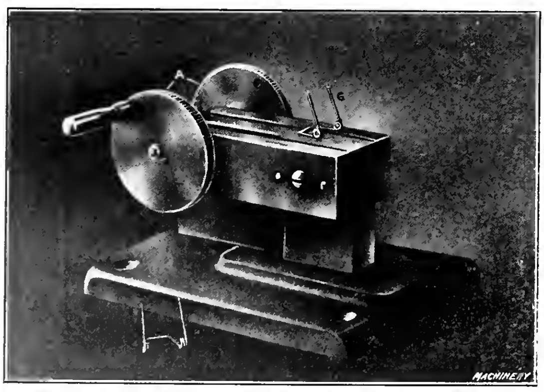

Fig. 5. Special Machine for winding Saddle Springs

The governor disk F is shown in detail in Fig. 3. These disks are made on Brown & Sharpe automatic screw machines, the only unusual point in this company's practice being the method of tooling the machines. It is necessary for these pieces to be finished to a high degree of accuracy, and experience has shown that better results are obtained by mounting the forming tool on the front slide and the cut-off tool on the rear slide, although this is at variance with the standard practice. The drill and reamer for machining the hole through the center of the governor disk are carried in the turret of the "automatic" in the usual way. After the governor disks have been cut off on the screw machine, they are taken to the punch press department where one end of the disk is finished in a die to the form shown in the end view to the left. The body of the spindle and the hole in the governor disk through which it slides have to be finished within a limit of 0.0001 inch, as the least shake between these two members would be detrimental to the operation of the instrument.

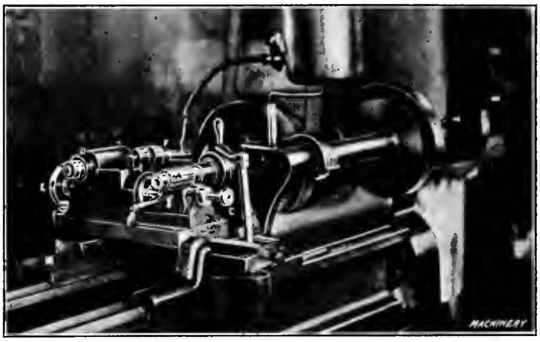

Fig. 6. Hobbing Attachment for Lathe, on which Eccentric Pinions are hobbed

Fig. 5 shows a special machine which was designed for producing the saddle springs shown at G in Fig. 1. These springs are made of piano wire, which is cut off to blanks of the required length and bent to form the U-shaped end of the saddle spring by means of a suitable punch and die. The work is then brought to the machine shown in Fig. 5. This machine grips the end of the saddle spring and two coils are wound around the mandrel by means of the handles on the index wheels. In operation, the two index wheels A are set at zero; the blank is then placed in the machine and both disks are turned through two revolutions, which brings them back to the index points. In this way the springs are turned out with the ends in exactly the same plane, the work being finished so perfectly that little if any adjustment is necessary before the springs are ready to be assembled in the instrument.

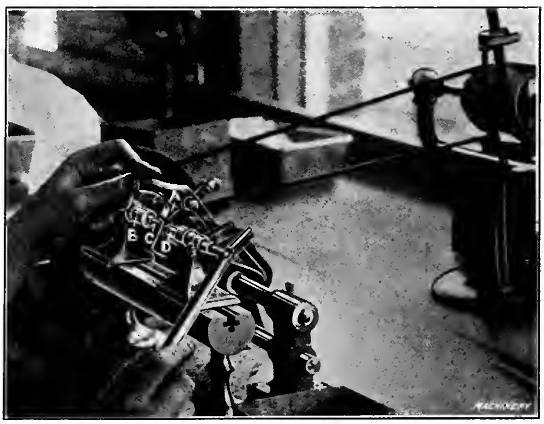

Fig. 7. Bench Lathe with Special Chasing Attachment for turning Bushings

The speedometer mechanism illustrated in Fig. 1 is carried in ball bearings of the cone and cup type. The bearing cups used for this purpose are illustrated in detail at J in Fig. 3. These cups are made on either Brown & Sharpe or Acme automatic screw machines. After being hardened, the bearing cups are ground on a Rivett grinder.

Making the Odometer Parts

It has already been mentioned that the Jones speedometer is equipped with an odometer which indicates both the dis-

tance traveled on individual trips and the total distance traveled by the car during an entire season. A number of different styles of instruments are made, some of which are arranged to indicate a season mileage of 100,000 miles, while others provide only for 10,000 miles. All types of instruments are arranged to indicate individual trips, up to 100 miles in length. A "reset" button is provided at the side of the instrument, and by pushing this button the dials which

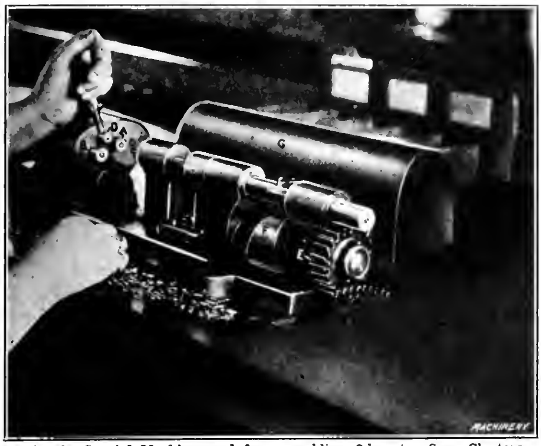

Fig. 8. Special Machine used for assembling Odometer Gear Clusters

indicate the distance traveled during individual trips are instantly returned to zero.

Motion is transmitted to the odometer by means of the worm I on the speedometer spindle, as shown in Fig. 1. This worm engages with teeth machined in a vertical "eccentric pinion," which is shown in detail at K in Fig. 3. As the speedometer spindle revolves the small eccentric at the end of the eccentric pinion operates a pawl which transmits motion to the trains of gears which turn the dials of the odometer.

The gears which actuate the odometer are arranged in clusters assembled on bushings P, Fig. 3. Each of the gears

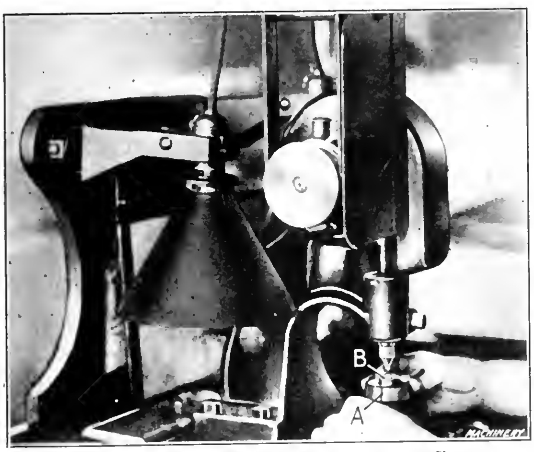

Fig. 9. Riveting the Odometer Dials onto the Gear Clusters

in these clusters has ten teeth and a dial graduated from zero to nine is mounted at the top of the cluster. The gearing is arranged in such a way that the dial at the right-hand end makes one complete revolution. At this point, a pawl of the type shown at the bottom of the series M in Fig. 3, engages with a gear of the next cluster to the left and moves it through one space, *i.e.*, one-tenth revolution. After this operation has been repeated ten times, a pawl on the second cluster of gears engages with a gear of the third cluster and moves it through one space. It will be obvious to the reader that the distances indicated by the successive dials to the left have ten times the value of the distance indicated by the dial to the right. Consequently the figures brought into view by the action of this train of gearing indicate the number of miles which the car has traveled.

The blanks from which the eccentric pinions K are made are formed in Brown & Sharpe automatic screw machines. After the forming operation has been completed, the work is transferred to a machine equipped with a magazine and feeding chute which delivers it to an eccentric chuck in which the work is held while the eccentric is turned. Fig. 6 shows a very simple form of hobbing attachment for an engine lathe, which is used to hob the teeth on the eccentric pinions. It will be seen that the hob A is carried on an arbor held in the lathe spindle. The work is held in the collet B and supported at its outer end by means of a tailstock C, in which the end of the eccentric pinion fits. The tailstock and collet are adjusted by means of the wheels D and E, respectively. The work is rotated by means of a universal-jointed rod F,

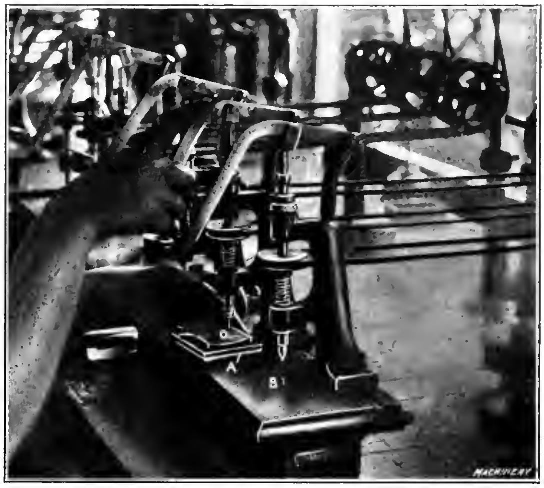

Fig. 10. Drilling the Odometer Plates with "Depthing" Gages

which is geared to the lathe and transmits motion to the collet through a worm and worm-wheel enclosed in the fixture.

The different forms of gears used to actuate the odometer are stamped out from brass ribbon stock. In order to have the work assembled properly, it is obviously necessary for the hole in each gear to be exactly at the center. Compound sub-press dies are used for this purpose, of the type generally used in watch, clock and instrument work. The small bushings on which the gear clusters are mounted are produced on an automatic screw machine. This work is fairly accurate, but there is always some doubt as to the parallelism of the hole with the outside of the bushing. In order to guard against errors from this source, the bushings made on the

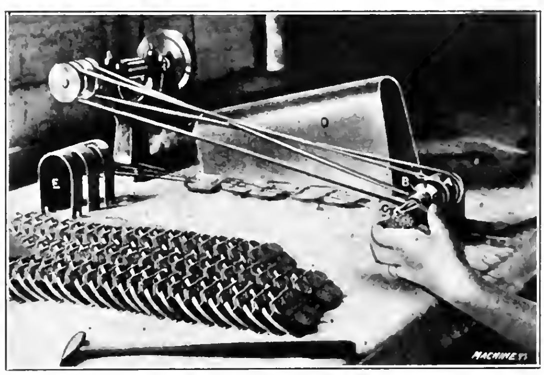

Fig. 11. Special Machine for winding Springs into the Odometer

automatic screw machine are transferred to the bench lathe shown in Fig. 7. This lathe has been equipped with a special chasing attachment. The bushings are carried on a small mandrel in the lathe spindle, which just fits the hole in the bushing, and the outside is turned by means of a tool carried in the chasing attachment. In this way, the hole is sure to

be parallel with the outside of the bushing. The design of the mechanism will be readily understood by referring to the illustration. A is the guide on the chasing attachment which fits over the guide bar B, carried in the lathe spindle. The parts A and B are hardened, ground and lapped, and any slight wear which may occur is compensated for automatically. The bushing to be turned is mounted on the small mandrel C, and the tail center D is pushed up against its outer end by means of the hand lever, thus providing the necessary drive. The mandrel on which the work is carried is ground after the fixture has been set up on the lathe, so that it is sure to be in proper alignment. At intervals, the operator measures the size of the pieces turned on this lathe with a micrometer, and three or four times a day she refers the work to the foreman of the department in order that he may have an opportunity of checking the accuracy of the parts.

Assembling the Gear Clusters

The finished bushings and gears are taken to the assembling department where the gear clusters are assembled on "nests" A, which are virtually small dies in which the teeth of the different gears in the cluster fit. In order to locate the dial in the proper relation to the gears in the cluster, a gage B is provided. This gage is merely a leaf hinged to the fixture and provided with three holes through which three numerals on the dial can be seen. After the cluster has been placed in the fixture, the dial is so set that the proper figures show through the holes in the gage. The riveting machine is then brought into action, riveting the end of the bushing down over the edge of the hole in the dial.

Drilling the Odometer Plates

The different parts of the odometer mechanism are assembled on a brass plate of the form shown at O in Fig. 3. It will be seen that there are thirty holes which have to be drilled in these plates. In order to do this work with the greatest possible dispatch, the method of drilling by means of a "depthing" plate has been adopted. This is another method which is in quite general use in instrument making and combines the benefits of rapid production with a high

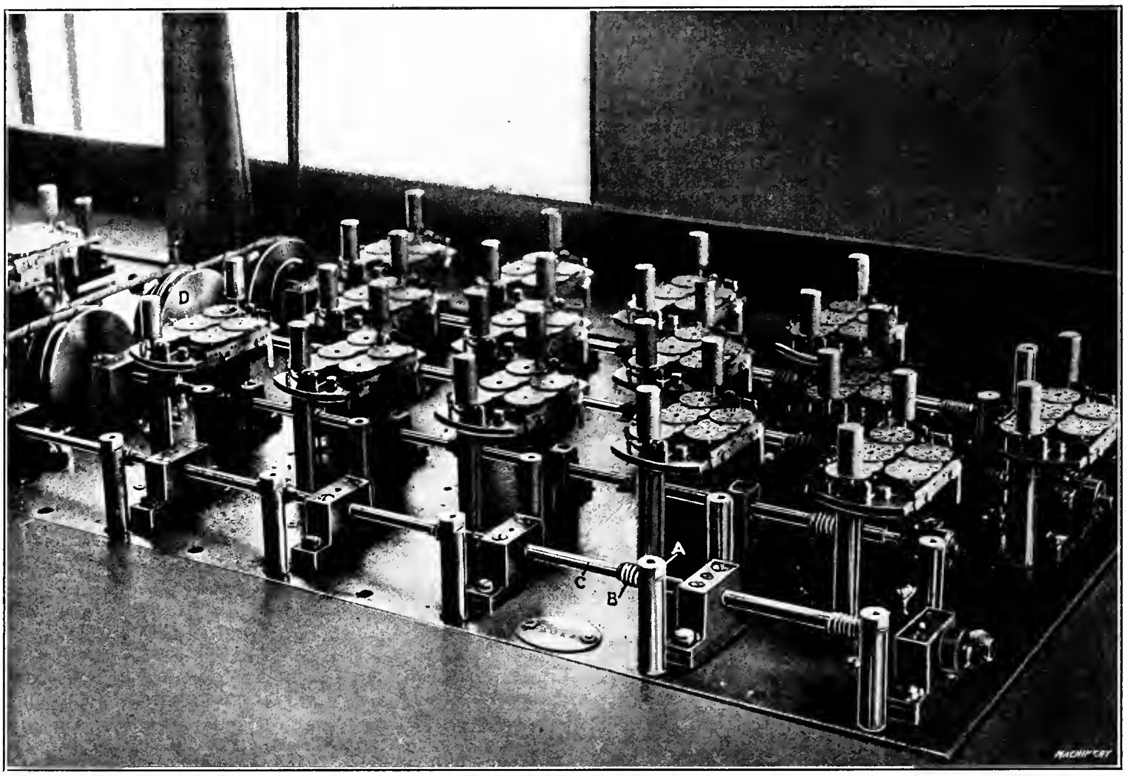

Fig. 12. Method used in testing the Accuracy of the Odometer

the special machine shown in Fig. 8. This machine consists of a horizontal press, equipped with dies to fit the different gears which constitute the cluster being assembled. Taking as an example the series shown at N in Fig. 3, the two upper gears are fitted in the dies A and B, and a bushing is then placed in the die at the end of the horizontal spindle C. The machine is operated by a foot-treadle which turns the cam F through the gears E. When the treadle is pushed forward, the spindle C moves over and forces the bushing into the hole in the gear carried in the die A. The index D is then set to bring the die B in alignment with the spindle, after which the foot-treadle is pressed a second time to push the bushing into the hole in the gear in die B. The relative positions of the dies are such that the different gears constituting the cluster are assembled in the proper position in relation to each other. The mechanism is enclosed by the guard G, which was removed to show the mechanism.

After the gear clusters have been assembled, they are transferred to an H. P. Townsend riveting machine, shown in Fig. 9, where the dials are riveted onto the top of the clusters. The riveting machines used for this purpose are fitted with degree of accuracy. The six large holes in the odometer plate have been drilled before the work comes to the battery of Stark bench drills, shown in Fig. 10, and two of these holes are utilized for locating the work on the depthing plate A. The pin B on the table of the bench drill is in exact alignment with the spindle. This pin fits into holes on the under side of the depthing plate and brings the work into the required position for drilling the different holes. The girls who operate these machines sit on stools which run on rails in front of the bench. After the holes have been spotted, the operator moves over to the next machine in which holes of one size are drilled; she then moves on as necessary, in order to get in position to drill and ream the different sizes of holes in the odometer plates.

It has already been mentioned that an instantaneous "reset" device is provided for use in connection with the part of the odometer which indicates the distance traveled on individual trips. This reset device is operated by pushing a small button on the side of the instrument. Each of the three dials in this part of the odometer works against the tension of springs, being held in the position to which they are moved

by means of suitable ratchets and pawls. When the reset button is pushed in, it releases the pawls and consequently allows the dials to be returned to the zero position. The springs which actuate the reset device are wound on the lower end of the bushings on which the gears and dials of the trip mileage odometer are assembled. There are three clusters of gears in the train and it will be evident that as two of these clusters rotate right-hand, the third (or intermediate) cluster rotates left-hand. Hence, it is necessary to wind two of the springs right-hand and the third spring left-hand. Fig. 11 shows a special machine which was developed for use in winding these springs. It consists of a spindle *C*, provided with a suitable clutch mechanism for engaging a small washer at the end of the sleeve on which the spring is to be wound. It will be noted that two belts run from the countershaft to the machine, one being open and the other crossed. There are two foot treadles under the bench, and by pushing one of these treadles the friction clutch *A* is engaged to drive the arbor through the crossed belt which winds the right-hand springs. By pushing the other treadle, the opposite side of the clutch is engaged with the cone *B* and the machine drives through the open belt, thus winding the left-hand springs. The belts and clutch are ordinarily enclosed by the guards *D* and *E*.

Fig. 13. Testing the Accuracy of the Speedometer

The springs consist of flat strips of bronze which are attached to the bushing at one end and are wound up by means of the frictional contact of the opposite end with the case in which the spring is contained. For a length of one inch at the free end, the spring is approximately double the thickness of the remaining section. These springs are rolled from bronze wire on a W. W. Oliver rolling mill equipped with a special form of rolls. These rolls are of such a size that a spring is produced at each revolution. The rolls are ground away slightly for a distance of one inch on their circumferences. This reduction leaves the necessary "thick spot" on the end of each spring. The wire from which the springs are rolled is fed into the mill from a reel, and the springs are rewound from the mill onto a second reel. They are then cut up, as required, for use in the assembling department.

The speedometer mechanism is enclosed in a brass case which consists of two parts. The lower part is a deep cup, while the upper part or cover is a sleeve in which a bevel glass is mounted. The method of setting the mechanism in the sleeve is quite interesting. It is obviously necessary for this joint to be both dust- and water-proof in order to protect the mechanism from injury. The method by which this is accomplished consists of first mounting the sleeve upon an expanding chuck. The nickel-plated "bezel" plate which goes under the glass is next placed in position, after which the plate of bevel glass is put in place and the brass cylinder is spun down over its edge. A very neat looking job is produced in this way, and the joint is tight enough to make it absolutely water-proof. The glass, bezel plate and sleeve are shown at *L* in Fig. 3.

Testing the Finished Instruments

The work produced in each department of the factory is subjected to strict inspection before being sent on to the assembling department. After the odometers have been completed, they are set up on testing stands of the type shown in Fig. 12. It will be seen that these stands consist of rows of vertical studs *A* on which the odometers are clamped by means of knurled-headed screws. The eccentric pinions which mesh with the worms on the speedometer spindle in the finished instrument engage with worms *B* on the horizontal shafts *C*. These shafts are driven by belts running over the pulleys *D*. The odometers are tested first at a speed of 125 miles an hour and then at a speed of 10 miles an hour. As the instruments are started from the zero point, their indications should all coincide at any period of the test. Any instrument which shows an error of as much as one-tenth mile an hour is sent back to the assembling department and adjusted until it will endure the test satisfactorily.

After the odometers have been tested as described, the entire instrument is assembled and then tested on machines of the type shown in Fig. 13. It will be seen that this machine consists of a fourteen-step cone *A*, and the speedometers to be tested are driven by means of a rubber pulley *B*, which is temporarily mounted on its spindle and engaged with the different steps on the cone. In this way, speeds of from 2 to 100 miles per hour are available. These tests are conducted for two purposes: First, to see that the instrument indicates accurately when running at the different speeds which are produced by successive steps on the testing cone; second, to make sure that the instrument runs steadily. When any error is discovered, it is usually due to imperfection in the saddle spring or else to improper adjustment of the ball bearings in which the spindle runs. The latter is the most frequent source of error, and the first step taken to remedy it is to adjust the bearings slightly. If this does not give the required result, the instrument is taken apart and the saddle spring adjusted or replaced as may seem advisable. It is the extreme care taken in producing each part of these instruments and testing them which has won a favorable reputation for the Jones speedometer in automobile circles.

ETCHING ON BRASS AND STEEL

BY WALTER H. STICKLER*

In the How and Why section of the August number of MACHINERY a request was made for information on the subject of etching. For etching on brass a satisfactory ground can be made from equal parts of beeswax, burgundy pitch and asphaltum. These constituents are melted together and thoroughly stirred in order to secure a uniform mixture. This ground is warmed before using and spread evenly over the surface that is to be etched. After the ground has had time to cool, it is removed from those sections of the metal that are to be etched, after which the etching fluid is applied. A satisfactory etching fluid consists of one part of nitric acid to four parts of water. After the "biting" has been completed, which takes only a few minutes, the work is dipped in hot water to wash off the acid. The surface of the work can then be cleaned by wiping it with a cloth dipped in benzine or gasoline.

For etching steel the ground is also made of equal parts of beeswax, burgundy pitch and asphaltum. This ground is applied to the work according to the instructions given for application on brass pieces. The etching solution used for steel consists of

Pyroligneous acid	4 ounces
Alcohol	1 ounce
Nitric acid	1 ounce

As soon as the biting operation is completed the work is dipped in hot water to wash off the biting solution, after which the work is cleaned with gasoline or benzine, as in the case of etching operations on brass. In order to obtain satisfactory results it is important to have the work perfectly clean before the ground is applied.

THE ADVANTAGES OF CAST-IRON GEARS

BY EDGAR H TRICK*

There is more to be known about gears than most people think. All engineers and designers of machinery, and many users of gears know a lot about the theory of gears—systems of tooth development, involute and epicycloidal teeth, etc.; but, getting down to brass tacks, as the saying is, how many know just exactly wherein lies the superiority of one gear over another? The two principal sources from which this excellence may come are the material from which the gear is made and the process by which it is made.

General purpose gears are made from cast iron, cast or forged steel, or bronze. When made of the two latter materials some peculiar or extraordinary service is required of the gear—with the discussion of which we are not concerned. By far the greatest number of gears are made from cast iron and cast steel. Concerning the relative advantages of these two materials there is much difference of opinion. Of late years users of gears have quite run away with the idea that cast steel gears are best under any and all conditions. Nothing could be more erroneous; nothing more outrageously violates scientific knowledge. Under all ordinary conditions cast steel gears have but a single sharply defined superiority over cast-iron gears, *i. e.*, that of greater strength. Nor has this fact been clearly apprehended by designers, for no appreciable reduction has been made in the size of the hubs, arms or rims of gears out of consideration of the fact that they are made of steel—cast-iron sizes prevailing in all cases.

True economy is here altogether lost sight of; for, obviously, if cast steel is the stronger material, less of it should be used. How much less is the question. Designers may calculate and engineers may judge, but experience alone can demonstrate. The practical determination of this point must necessarily take years to effect, just as it did in the case of the cast-iron gears. Unfortunately the element of time cannot be eliminated. Until this important matter is satisfactorily settled all efforts for economy must be ignored in the matter of cast steel gears; a higher price must be paid per pound and an extravagant amount of material used.

On the other hand, cast iron has a number of distinct advantages over cast steel, both for the designer and the user. Cast iron is a much easier metal to work with than cast steel, having less shrinkage and less warpage than cast steel; nor will it so readily transmit vibration. This latter peculiarity can readily be demonstrated by striking with a hammer on a wheel of cast steel and on one of cast iron. The tone of the resulting noise is much higher in pitch in the case of the cast steel, due to the shorter and more rapid vibrations. The noise from the cast iron is lower in tone and of shorter duration, due to the opposite conditions. Thus cast-iron gears immediately take the preference from the standpoint of closest approach to silence in operation. It may here be said that it is a scientifically proven fact that workmen subjected to loud, raucous noises at their work become dull and sluggish in their mental processes, and their efficiency falls in exact proportion.

Only in exceptional cases is it necessary to use cast steel gears for their superior strength. In the vast majority of cases a good cast-iron gear is amply strong enough for the service required of it. There are three conventional methods of making gears. When the teeth are to be cut the rim of the pattern is made a solid blank. The resulting casting is bored, turned on its periphery and faced on both sides of the rim. The finished blank is then put on the gear-cutting machine and the teeth cut as desired. The two remaining methods relate to gears designed to have cast teeth. In the one case a full pattern is made; that is, all the teeth are cut on the pattern. This is the old fashioned, expensive way which entails a vast deal of labor both in the laying out and the formation of the teeth. Although tooth-forming machines have done much to relieve this situation in the jobbing shops, the spacing of the formed teeth on the periphery of the wheel is extremely difficult to do accurately—simple as it looks to those who have never had it to do. The other method referred to is that of machine-molding the gear. This is by far the best method, being the simplest, most accurate and the cheapest. All that is required in the way of a pattern is a sweep, a part of the hub, an arm, and a tooth block. The latter is fixed on the arm of the machine and two or three teeth, as may be desired, are rammed at a time, the spacing being done with absolute precision by the machine. The chances for inaccuracy are reduced to a minimum; the whole trick is up to the patternmaker and, since his efforts are confined to but two or three teeth on the block, he concentrates his whole ability there, with the result that a perfect gear is produced. The clearances in a well made machine-molded gear may be just as close as in a cut gear of the same pitch. The comparative ease with which machine-molded iron gears can be made makes them by far the most economical to use, and if this fact were better known to engineers and designers of machinery, cast-iron gears produced by this method would invariably be specified.

Everyone familiar with foundry practice knows that the outside skin of a casting is its hardest part. This single peculiarity lends to machine-molded cast-iron gears the soundest argument in their favor. It takes long service to wear through this hard shell on the faces of the teeth, whereas in the case of cut gears, all of this valuable wearing surface is entirely cut away before the wheels go into service. Cast steel gears do not have these advantages. The high temperature at which steel is poured necessitates the use of silica sand in the molds. This has to be rammed so hard that machines cannot conveniently be used, making a full pattern necessary. Moreover, steel castings are hard to make; it takes a "real molder" to make a good one. Since nearly all the labor in the steel foundries is done by unskilled foreigners, who do not appreciate the niceties of gear molding, it is extremely difficult to get a good cast steel gear, accurate to pitch, round, and true to theoretical tooth contour. The silica sand burns to the faces of the teeth, which "scabs" and "pits" them, so that almost invariably every tooth face has to be chipped to secure even an indifferent bearing: hence the noise and clatter that is so noticeable in cast steel gears with cast teeth. If the teeth do not bear across their entire face, the very object that the designer had in mind is altogether lost.

The matter of shrinkage in cast steel is difficult to control, so much so, in fact, that few manufacturers will guarantee large wheels to come near the pattern allowances. No two wheels will shrink just alike, so that the question of whether the wheels will preserve the circularity of the pattern is in grave doubt. Therefore, aside from exceptional cases where great strength is required, designers should be extremely chary of specifying cast steel gears unless the teeth are to be cut. There is but one principal object in cutting the teeth of gear wheels: there are a number of minor reasons. The first is to insure perfect tooth contact; the others are to lessen the noise of operation, to improve the appearance of the wheels, to discover flaws in the material, etc. Since perfect contact can be secured by machine-molding the teeth, why cut them? The expense of cutting is an appreciable consideration. If cast iron will do, why use cast steel? Cast iron is by far the cheapest. The argument is advanced that steel wears longest. The hard skin on the teeth of machine-molded gears of cast iron so lengthens their time of service that even that argument is in grave doubt. We are brought face to face with the fact that, after all, nothing can quite take the place of a well made machine-molded cast-iron gear. The matter of the gears is often the largest item of expense in certain classes of machinery, as in the case of bending and straightening machinery. If the greater part of the cost of the gear patterns can be saved by having them of cast iron and machine molded, why not do it? The specification of the cheapest as well as the best gears for the purpose in mind is the true indication of the designer's ability.

ATTACHING RUBBER TO METALS

Rubber may be attached to alloys containing one of the antimony group of metals by vulcanizing it while in contact with the alloy, and to other metals, by coating them, for instance, by electroplating, with an alloy containing antimony, and vulcanizing the rubber while in contact with this coating.

AUTOMATIC TURRET MACHINE FOR MACHINING STEAM RADIATORS

BY CHESTER L. LUCAS*

While the automatic drilling and turning of small castings in a turret lathe is an everyday operation, it is somewhat out of the ordinary for similar automatic operations to be performed on castings weighing from fifty to seventy-five pounds.

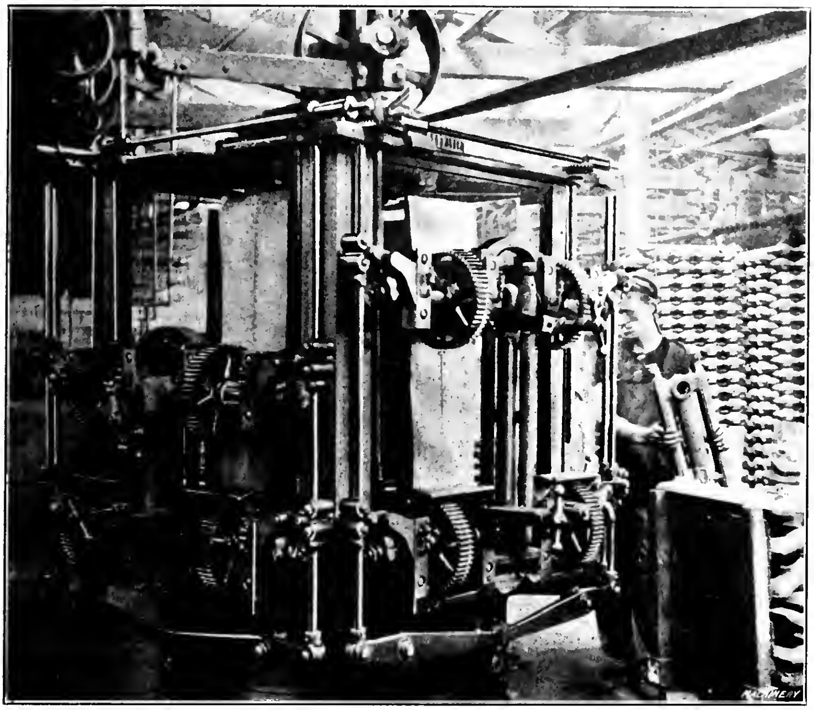

Fig. 1. A Turret Machine for Large Work

This is the class of work, however, that is being done on the automatic drilling and counterboring machine illustrated in Fig. 1. This machine was made by the O. Bryant Machine Co., Buffalo, N. Y., and is in successful operation at the radiator plant of the H. B. Smith Co., Westfield, Mass.

This machine has been nicknamed the "merry-go-round" by the operators, from the fact that the work and tool mechanism revolves continuously about a central supporting post, the entire mechanism of the machine being in the form of a square vertical turret. The turret has four working faces, each of which is provided with a separate set of tools and feeding mechanism, so that each face performs all the work on one casting complete. Referring to Fig. 1, the operator stands at the loading point and clamps a casting in place while the turret is passing. This being done, the feeding mechanism commences to advance the tools, drilling and counterboring at both ends of the casting on its way around the machine, and when the casting comes around again to the operator at the operating point, the work is finished and the casting ready to be taken out and replaced with another piece of work. The machine is continuous in its operation, there being no indexing mechanism of any kind. The main advantage of the turret construction is that the work is automatically returned to the loading point after being finished and the operator can do the removing and loading from one position. At the same time, by having four pieces of work under way at once, there is always one casting ready to be removed.

One of the radiator castings upon which the operations are performed may be seen near the bottom of Fig. 2. On each casting the work consists of drilling out a two-inch cored hole at each end of both sides, making four holes in all. There are four cutting tools working simultaneously on each casting, each of which combines a two-inch drill and a three-inch counterbore. Each of the holes is counterbored to prepare the radiator sections for assembling. These radiator castings come in various styles and lengths so that the machine must be, to a certain extent, adjustable for the various sizes. In order to accommodate the different lengths of castings the upper sets of working tools on each face of the turret may be raised or lowered to suit the particular piece which is being machined.

By referring again to Fig. 1 it will be seen that the cutters on the face of the turret, shown at the right, are working on long castings, while the mechanism on the left-hand face is operating on short castings. This means that the operator must have two piles of castings at the loading point so that when the "short face" comes around he can supply a short length casting, and when the "long face" of the turret appears he can put in a long casting.

A good idea of the feeding mechanism with which each of the turret faces is supplied, may be had by referring to Fig. 2. Here the casting is shown at *A*, being clamped in position by straps *B*, which are held in place by means of levers *C*. The cutting tools are shown at both sides of the top and bottom of the casting at *D*. These tools are operated from corresponding shafts *E*, which receive their motion through vertical shafts at the rear of each face, and these are, in turn,

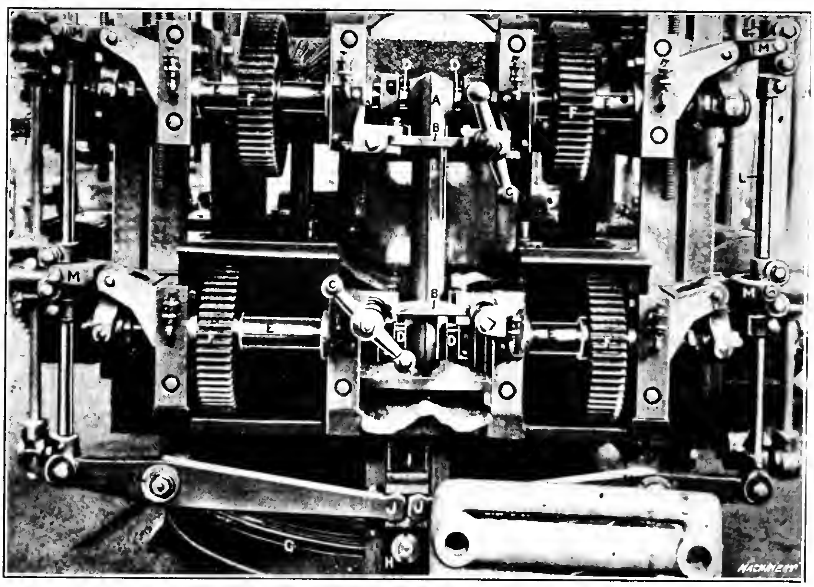

Fig. 2. One of the Turret Faces

*Associate Editor of MACHINERY.

operated by spur gearing from the central stud. The spur gears are at the top of the machine and may be seen in Fig. 1. Motion from the vertical shafts is transmitted to the tool spindles by means of bevel gearing. The tools on the opposite sides of the work revolve in opposite directions; therefore the cutting tools on one side of the work must be made left-handed. Upon auxiliary shafts, behind each face of the turret, are the broad faced driving gears which mesh with tool spindle gears *F*. These broad faced gears are wide enough so that the gears *F* which are fixed upon the tool spindles may have travel enough to allow for the machining of the work and still be properly in mesh.

The forward feeding of the tool spindles is accomplished in an interesting manner. There is a continuous circular cam track *G* around the base of the machine, and extending from each of the four faces of the turret is a cam roll mounted upon the opposite end of stud *H*, which continuously bears against this track. The cam track is straight at the loading point; that is, there is no rise, but as soon as the loading point is passed, there is a gradual ascent of the cam track, causing the cam roll to rise steadily and forcing slide *I* up with it. Pivoted in this slide are the ends of the two toggles *J*, which are fulcrumed upon studs *K* on the turret face. Therefore, as the inner ends of the toggles are raised, the outer ends are depressed, and carry downward with them vertical shafts *L*. Upon these shafts *L* are mounted bellcranks *M*, which, through connections at their lower ends with tool spindles *E*, tend to force these spindles inward when shafts *L* are lowered. Thus as long as the ascent in the cam track is maintained, the tool spindles feed in, causing the drilling and counterboring tools to act on the work from both sides of the casting. The cam track is made perfectly straight for the last one-eighth revolution, so that the counterboring tools simply revolve against the work and smooth the surfaces. This is just previous to the ejecting and loading point, at which time there is an abrupt drop in the cam track, allowing the spindles to retreat, and permitting the operator to unclamp the work and set in a new piece before the commencement of the cam ascent is reached again by the turret.

HIGH-SPEED SHAFTING

BY J. E. LINABURY*

One of the most significant steps in the advancement of machine shop economics, since the introduction of high-speed steel, has been the advent of high-speed lineshafting and small high-speed belts, made possible by the use of ball bearing shaft hangers. The increased friction from high rotative speed, and the low melting point of babbitt bearings have, after many years, established an average lineshaft speed of from 150 to 200 R. P. M. Occasionally, by extremely careful attention to lubrication and alignment, 300 R. P. M. has been reached, but rarely any more. This low rotative speed has made comparatively large size shafting necessary, thus adding to the weight and cost. If a motor is used for power, its speed is usually from 900 to 1200 R. P. M. It is generally conceded that a belt will give the most efficient service at a velocity of from 4000 to 4800 feet per minute. To get this the motor pulley should be 15 to 18 inches in diameter. If the main shaft turns at 200 R. P. M., its driving pulley would then be from 5 to 7 feet in diameter, with an alternative of a heavier and more expensive belt with greater tension, or a smaller pulley—usually the latter. This holds true with regard to all the pulleys on the main shaft; either the pulleys are excessively large and heavy, or the belts are not working to their best efficiency. When a 2-inch belt, costing 20 cents per foot, might be used, a 4-inch belt, costing 40 cents per foot, is required.

The ball bearing hanger, however, has changed much of this. Now many progressive engineers, looking everywhere to save installation and manufacturing charges, lay out their main and countershafting to run in ball bearings at 400 to 600 R. P. M., using light narrow pulleys and narrow belts, thus saving materially in total first cost, and from 50 to 75 per cent of the power consumed in the shafting, which in the majority of cases is not less than 40 per cent of the total power used. They also save in maintenance, for where the old type of hanger required lubrication every day, the ball bearings do not require attention oftener than once in four months.

Let us make a cost comparison of two lines of shafting, 100 feet in length, say, transmitting the same horsepower. Let the first be 2 7/16 inches in diameter, and turning on babbitt bearings at 200 R. P. M., with hangers every eight feet. Between hangers consider two 30-inch pulleys, with 4-inch belts, each 25 feet long. Each foot of this shaft weighs 15.87 pounds, or 1587 pounds in all, costing 2¼ cents per pound, or about $35.60. To transmit the same amount of power with ball bearing hangers at 600 R. P. M. will require a shaft only 1 11/16 inch in diameter, weighing 7.6 pounds per foot, or 760 pounds in all, and costing but $17.10. This means a saving of 827 pounds in weight, and $18.50 in cost. Where two 30-inch pulleys with 4-inch face were used in each bay in the first case, with the high-speed shaft, 20-inch pulleys with a 2-inch face will do the work. This saving in pulleys is about 50 per cent in their weight, and $3 a piece in their cost, or $72 in the total pulley cost of 24 pulleys. With the slow shaft, using 25 feet per pulley, 600 feet of 4-inch belt, costing about $240, would be required; while with the high-speed shaft, 2-inch belt, costing $120 would handle the same work. From this it is apparent that by the use of the ball bearing hangers, the saving in the initial cost of shafting, pulleys and belting is $210.50 in one 100 feet. While the ball bearing hangers cost more than the plain ones, the difference will not be as much as their saving in first cost. Add to this the longer life of the hanger, the freedom from dripping grease, the brighter, neater appearance overhead, the low maintenance charge, with a probable saving of 20 to 30 per cent in total power used, and one realizes the reason for ball bearing hangers becoming so generally popular. The use of high-speed shafting has not been confined to manufacturers using specialized machines, but to practically all classes of work. General machine departments, grinders, automatic machines, and the rigid and varied requirements of a toolroom, all find the application most practical, and reap the benefit of a lighter, brighter and quieter overhead construction, coupled with economy in installation, maintenance and power.

WHERE IS THE FALLACY?

The "proof" below indicates that any two unequal numbers may algebraically be shown to be equal.

Let a and b be the two unequal numbers. Let c be their arithmetical mean; that is, $(a + b) \div 2 = c$, or $a + b = 2c$.

Then:

$$(a + b)(a - b) = 2c(a - b)$$
$$a^2 - b^2 = 2ac - 2bc$$
$$a^2 - 2ac = b^2 - 2bc$$
$$a^2 - 2ac + c^2 = b^2 - 2bc + c^2$$
$$(a - c)^2 = (b - c)^2$$
$$a - c = b - c$$

Hence $a = b$

But a and b were assumed to be unequal.

* * *

A fleet of large self-propelled barges, fifteen in number, to ply between New Orleans and the coal fields of northern Alabama, is of interest in that they are the first craft of their kind in America to be propelled by producer gas engines. The barges are of steel construction, and are similar in design to those in use on the canals of Holland. Their measurements are as follows: Length, 240 feet; width on deck, 32 feet; width at bottom, 28 feet; depth, sides, 8 feet; depth, center, 8½ feet. Their capacity is 1000 tons, and the draft when fully loaded is 7 feet. They are propelled by twin screws driven by twin engines and have a speed of approximately seven miles an hour when fully loaded. The weight of each barge and equipment is close to 240 tons. The screws are driven at 300 R. P. M. by two 75 H. P. Fairbanks, Morse & Co. vertical producer gas engines. Gas for the engine is furnished by a 150 H. P. producer, made by the same company. The fuel used for the producer is what has heretofore been a waste coke from the ovens of the Birmingham district, and which consequently is secured at a low price.

LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY.

CONCERNING AN OFFSET DRILL HEAD

Fig. 1 shows the sub-base of a machine which was to be built in large quantities. Its size and weight made it very desirable to do all of the drilling on a radial drill. The holes *A* were easy enough to drill, but holes *B*, being at right angles with the others and parallel with the drill press platen, gave considerable trouble, and much time was lost by using

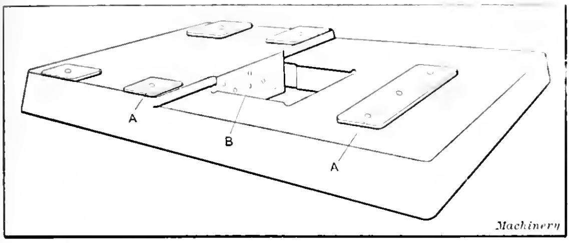

Fig. 1. Sub-base of Machine which required Special Fixture for drilling Holes B

a small ratchet drill. The saving that would be effected by drilling these holes with a power-driven drill head warranted designing and making the special tool shown in Fig. 2, which cost but $26 to make and has proved entirely satisfactory.

The yoke *D* is securely clamped to the radial drill spindle. The yoke extension *E* is hung to the yoke *D*, with a screwed-on plate *F*, so constructed that the yoke extension can be turned to any angle in relation to the radial drill arm and set by means of the lever *G* and its brass plug *H*. At *J* is shown a short drill with a taper shank which enters the collet *K*. This collet *K* is keyed to a miter gear *M*, which, in turn, is driven by gear *O*, the hub of gear *M* being freely mounted in bushing *N*. The gear *O* is fastened to the spindle

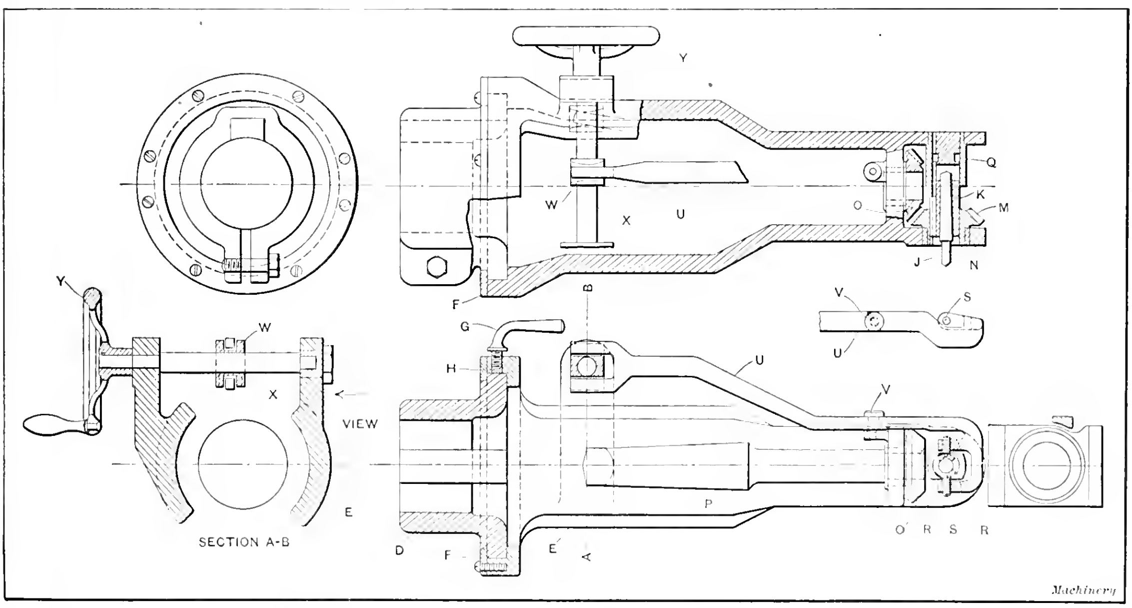

Fig. 2. Offset Drill Head designed for drilling Horizontal Holes on Radial Drill

P, which enters the taper collet in the radial drill spindle. The drill-holding collet *K* is supported by a bushing *Q*, which is slabbed off and slotted as shown in the illustration. Two small crescent-shaped pieces *R* are fitted into collet *K*, and two screw pins *S* inserted through slots in the bushing *Q*. These screws are set in the lever *U*, which is fulcrumed at *V* and propelled as shown by means of the block *W*. The screw *X* and handwheel *Y* allow the operator to feed the drill with ease.

Although at the first glance the construction of the smaller working parts of this drill head may appear frail, it must not be forgotten that it will enter an opening that is but 5 by 3½ inches in size and drill a ½-inch hole 1¼ inch from the side of the opening quite as rapidly as under ordinary conditions. This special head has paid for itself many times in the saving which it has effected in drilling the horizontal holes in the sub-bases.

RICHARD RUSSELL

TURRET LATHE SET-UP FOR A SMALL SCREW

"To cut costs, cut the cutting time and cut the time between cuts" is a slogan which has been popularized by the Bullard Machine Tool Co. This advice applies to all classes of machining operations, and scientific management is merely a "classical" title for this simple formula for cutting costs. It will be readily understood that in certain operations it is more important to make a reduction in the cutting time, while in other cases the time between cuts is more easily reduced. Of course, if both the cutting time and the time between cuts can be reduced a still greater saving will be effected.

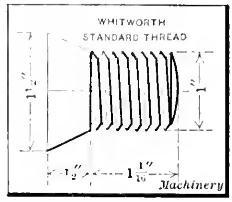

Fig. 1. Screw to be made

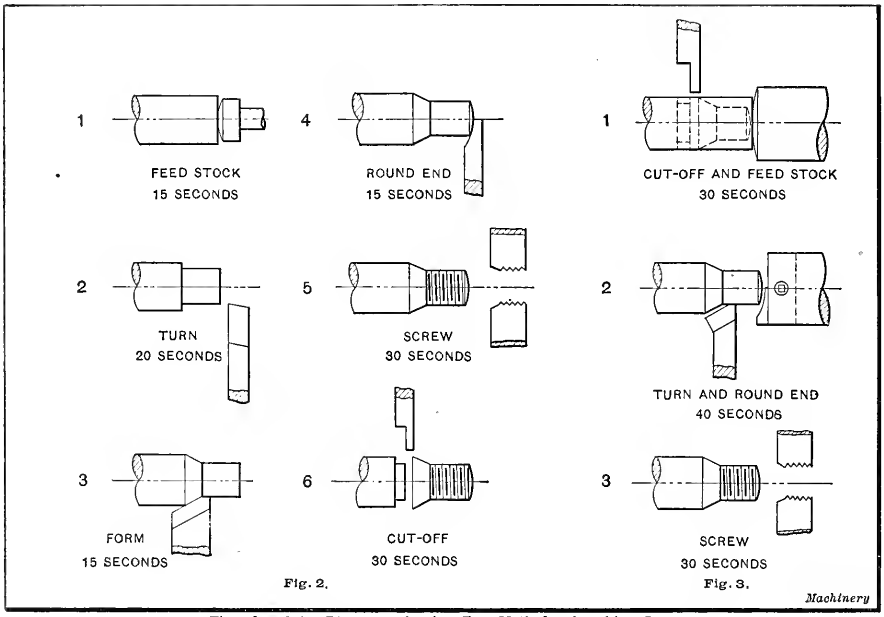
It is the purpose of this article to describe the method by which both the cutting time and time between cuts were reduced in making the countersunk head screw shown in Fig. 1. It will be evident that if a sufficient number of these screws had been required it would have been quite a simple job for the "automatic." It happened, however, that the quantity required was not large, and a more serious objection lay in the fact that the equipment of our shop did not include an automatic screw machine. Consequently the only alternative was to do the work on the most suitable hand-operated machine which was a Herbert No. 2 turret lathe, taking bars up to 2¼ inches in diameter. Fig. 2 shows what would ordinarily be the sequence of operations from feeding the stock in the first operation to cutting off the finished screw in the sixth, the time for each being given. It must be understood that each of these operations required a separate face of the turret so that it was necessary to advance and withdraw the turret

six times to complete a single screw. With a heavy turret and carriage, such as the one used on the Herbert No. 2 machine, these hand movements became decidedly monotonous and fatiguing when the machine was being operated on such short cuts.

To reduce the number of idle movements to a minimum, the tool set-up shown in Fig. 3 was adopted. By combining certain cuts this arrangement did away with three operations, so that instead of advancing and withdrawing the turret six times for each complete screw, only three movements of the turret were necessary. The operation of feeding the stock is accomplished without having to move the turret from the cut-off position, a piece of cold-drawn bar being clamped in the turret hole to act as a stop. The second operation of the new system combines the second, third and fourth operations of the original method. Referring to the illustration it will be seen that the turning tool is shaped to form the head of the screw as well as to turn the body, and a second cutter carried by a bar clamped in the turret hole forms the end of the screw. In operating the machine according to the second method the feed is tripped just before the tool which forms the end of the screw starts to cut, so that the actual ending and forming of the head is done by hand. The third operation consists of threading the screw, after which the piece is cut off and the bar fed up to the stop ready for the next sequence of operations.



Figs. 2 and 3. Diagrams showing Two Methods of making Screws

Referring to the notation showing the time of each operation according to the two methods, it will be seen that it required only 100 seconds to complete a screw when the second method of tooling was used, while 125 seconds was required by the original method. This saving may not appear very substantial, but it is certainly worth while, and it is also possible that a much greater saving could be effected on a long run because the operator would not be fatigued so soon. The only outlay involved in changing over to this new method of tooling was for the forming tool used for the second operation; the stop and the ending tool were also of special design, but as they could be used to advantage on many other classes of work they were not charged to this particular job.

ALBION

SOME EVERYDAY SHOP PROBLEMS

As it has come to my notice that some of the common operations performed in machine shops every day present apparently insurmountable difficulties to apprentices and to some so-called "journeymen," I will describe briefly my methods of doing certain work in the hope that they will be of help and benefit to some who have had troubles.

I have particularly noticed the difficulties that some machinists have in squaring up a piece in a shaper vise. I have seen machinists who had the reputation of being a little better than the average, spend a great deal of time and energy taking many cuts over a block jig which had to be planed on all six sides. Work of this kind can be done quickly and accurately if the procedure is right. My method is to plane one side with a roughing tool and then place that side against the back jaw of the vise with a round piece of stock between the opposite side and the vise jaw in order to hold it securely against the back jaw. A rough cut is taken off the side then presented to the tool. In this way, I proceed until the block is planed on four sides. Then the block is tested with a square to find two sides that are square. These are marked with chalk.

A piece of scrap cast iron about the size of the jig is then placed in the vise, pinched with the jaws, and a cut is taken from it. The jig to be finished is then placed on this false bottom using pinch parallels to hold it with the square or chalked side down. A finishing cut is taken over the block, continuing around until finished all over.

I do not pretend to say that this is the best method of doing work of this kind, but I have met success with this method of procedure and having seen so many failures when men have tried to do it other ways, believe that the reader will find my way produces satisfactory work with a minimum of labor and trouble.

Another difficult job for many mechanics is planing a pair of V-blocks so that the vees come exactly central in the blocks. I have seen many mechanics who did not seem to be able to do this simple job without spending a great deal of time at it. The way I plane V-blocks is to rough out the vees first and then finish them, placing one at a time on the false bottom of the vise. The planer head is set at an angle of 45 degrees and a cut taken down the side of the vee, being sure that the block is held down firmly on the bottom and against the back jaw of the vise. Now without moving the table run the head up for another cut and reverse the block. Take the finishing cut down the other side of the vee and finish the other block in the same way. This procedure will produce the V-blocks with the vees as nearly central as it is possible to get them.

Another kink that is sometimes found useful in turning quick tapers on a lathe is using the taper attachment in combination with the tailstock set-over. When the required taper is greater than can be obtained with the taper attachment, swing the attachment as far as it will go and then set the tailstock over sufficiently to make up the required taper.

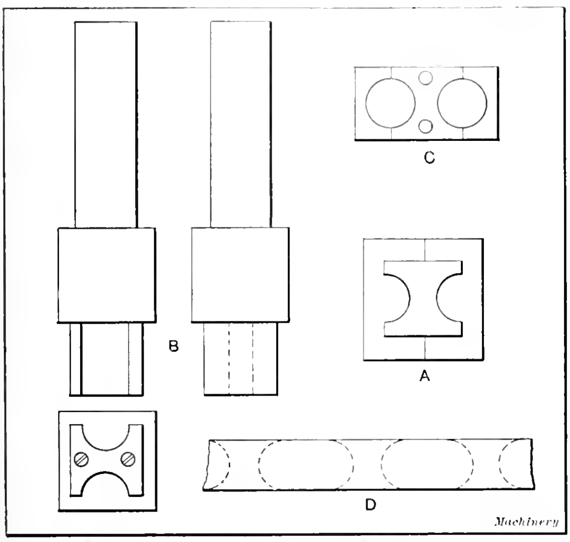
Some men seem to think that figures were invented for office use only. If they see a machinist working with a pencil and note book, they are likely to turn up their noses and say, "We don't take any stock in book learning. Experience is the best thing." Did you ever notice that "what such men lack in the head, they usually make up in the heel"? In other words, they have to do a great deal of walking and trying and cutting and fitting to accomplish what a short calculation will often do. For example, we had some square pieces that were required to be screwed in place and to stand at a certain angle when screwed in tight. The pieces were threaded eight threads per inch. Hence one complete turn would advance the piece 0.125 inch; that is, 360 degrees angular movement

would advance the piece 0.125 inch. Now, dividing 0.125 by 360 gives 0.000347 or 0.00035 inch, which is close enough for any common practice, as the advance for 1 degree. Now for the application of the figures: First, try the piece in the hole and set the bevel protractor on it, and ascertain the number of degrees it has to travel to stand at the required angle. Say, for example, it has to be turned 15 degrees. Now multiplying 0.00035 by 15 gives 0.00525 or practically 0.005 inch as the amount to be faced off in order to have the parts stand at the required angle.

Sharon, Pa. ROY B. PLATT

A LABOR-SAVING SHEAR

In an establishment where the writer was recently employed, long strips of iron, both flat and bevel-edged, were cut into shorter lengths for use on various "ironing" operations on vehicles. In order to give the ends of the pieces a more finished appearance, they were (after being cut off on an ordinary shear) rounded with a suitable die. This, of course, necessitated a second handling. Later, both the cutting and rounding were completed at one operation by the use of the special shear (or, properly speaking, punch and die) illustrated herewith. This device is adapted to cutting off a variety of widths and thicknesses, and has the additional advantage of being made entirely on a lathe and shaper, which will recommend it to many shops where the tool equipment is limited.



Punch and Die used for Combined Shearing and Trimming Operation

The die block *A* is made in two parts, doweled together. This enables the die to be cut out in the shaper, one-half at a time, and also makes it possible to readily vary the clearance between the punch and die. It can be made of almost any desired size, to suit the stock used. The one mentioned cuts the ends of the pieces with a radius of 5/8 inen, while the stock used varies in width from 3/4 inch to 1 1/4 inch, and in thickness from 3/16 to 3/8 inch.

The punch *B*, which at first glance looks like a difficult shape to produce, is easily completed by using a piece of steel considerably longer than the finished punch, and boring two holes of equal size clear through the block. Afterward, the two ends of the piece are cut off, as shown at *C*. The waste of steel made necessary by this method is more than made up by the saving in time that is effected. The punch is afterward fitted to a holder suitable for the press used.

The strips of iron are fed against stops set for the length required, and the portions of the strips *D* between the dotted semicircles are completely punched out of the strip, thus both cutting off and rounding the ends of the pieces at one handling.

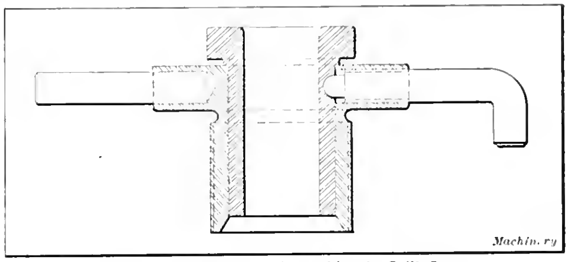
The punch may be made quite narrow in the middle and thus the amount of stock lost in cutting will be very small. Many small pieces used in "ironing" wagons, auto bodies, and on many other manufactured articles can be greatly improved in appearance by cutting off the stock in this manner, and the cost of so doing is no greater than the usual method of employing a common shear for this purpose.

Troy, Ohio. HENRY J. BECK

METHOD OF FASTENING SLIP BUSHINGS

The April and June numbers of MACHINERY contained articles and drawings of different methods of fastening slip bushings in drill jigs to prevent them from crawling up on the drills. I would like to add the accompanying example and explanation to those already given.

As slip bushings are used to a greater extent in screw bell bushings than in other styles, and as it is always necessary



Method of fastening Slip Bushing in Drill Jigs

to provide some means for screwing down the bell bushings, four pieces of drill rod inserted in the bell bushing as shown, and at right angles to each other, seem to constitute the most satisfactory way of doing this. As shown in the illustration, in place of one of the pieces of drill rod, a hole is tapped out and a form of set-screw is used with the end turned to some convenient radius, as 1/8 inch. Then the slip bushing is drilled at one point so that as the screw is turned in, it engages in the hole provided in the bushing and locks it firmly in place, thus answering the double purpose of a lock for the bushing and a prong to simplify the screwing in and out of the bell bushing.

Lima, Ohio. R. E. DODGE

THREAD CUTTING TOOLS

The process of thread cutting has been widely discussed from both practical and theoretical standpoints. The various thread forms have been described and established, but very little definite information on cutting threads has been made public, and accurate thread cutting still remains a problem for the individual to solve.

A number of threading tools are on the market which answer the purpose of screw cutting fairly well, but screw

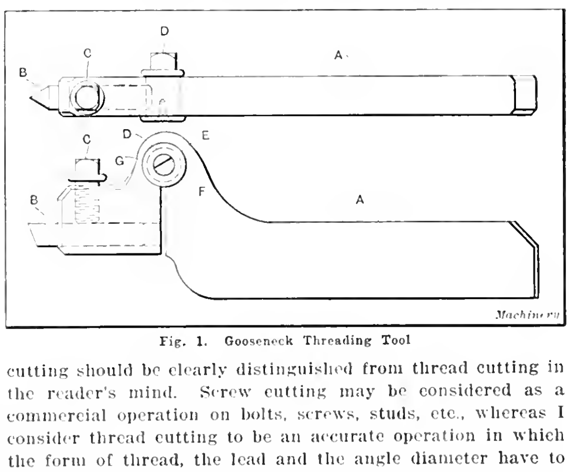


Fig. 1. Gooseneck Threading Tool

cutting should be clearly distinguished from thread cutting in the reader's mind. Screw cutting may be considered as a commercial operation on bolts, screws, studs, etc., whereas I consider thread cutting to be an accurate operation in which the form of thread, the lead and the angle diameter have to be rigidly adhered to. In the last few years the writer has been employed on accurate thread cutting and in the follow-

ing he will endeavor to describe some of the tools that have been successfully used and which may be useful to others:

Fig. 1 shows an outside threading tool of the gooseneck form. The holder *A* is forged from ½ by 1 inch tool steel stock. *B* is an inserted tool made from round stock, preferably turned down from a larger size, high quality steel rod to about $\frac{5}{16}$-inch diameter. It is held in position by the set-screw *C*. As the tool body is round, it can be set for any lead to cut the required angle. This is one of the principal requirements of an accurate thread cutting tool. *D* is a plug by which the desired amount of spring in the gooseneck is regulated. The hole in which the plug is fitted is drilled to the desired size, ½ inch being the diameter of the hole in the tool shown, and the bottom part is filed slightly, so as to produce an elongated or oval hole. The plug *D* is also made slightly oval and is fitted loosely in the hole, being held in place by a flat-head screw and washer, *F* and *E*. The hole in the stock may be countersunk, if preferred, and the wedge bolt *D* riveted over to hold it in place.

In laying out the holder, care should be taken that the hole is so placed that the weakest part of the gooseneck is at a point *G*, about midway between the horizontal and vertical, next to the tool. The thickness should gradually increase toward the back of the stock. This shape of holder causes the tool to spring away from the cut when the pressure becomes heavy and does away with all tendency to dig in. In roughing, the wedge bolt *D* is twisted, preferably so as to bring the high point to the front beneath *G*. This makes the tool quite rigid but still leaves a slight amount of spring available. When the finishing cut is taken, the wedge bolt is loosened so that the full spring of the gooseneck is available.

An objection may be offered to the design of the tool because it is not offset as ordinary gooseneck tools often are, and for that reason threading cannot be done close to a shoulder. The objection to offsetting is that it causes a sideways deflection of the tool, often resulting in roughing or tearing the thread. These tendencies are much reduced when the tool is set at right angles to the work where it gets the stiffest possible support. As to the objection that a shoulder cannot be worked to closely, the class of work on which accurate threading is required, in most cases, has either a shank or an arbor extending beyond the thread, thus giving ample space for the tool-post and tool when set in the right-angle position. Examples are taps, gages, various forms of hobs, etc.

Fig. 2 shows an inserted-cutter inside threading tool and holder. The tool-holder *A* is made of a ½-inch piece of drill rod with a $\frac{5}{32}$-inch hole drilled through the end at an angle of 30 degrees. The hole is drilled and tapped at right angles for a ⅜-inch hollow set-screw and acts as a clamp-screw. The set-

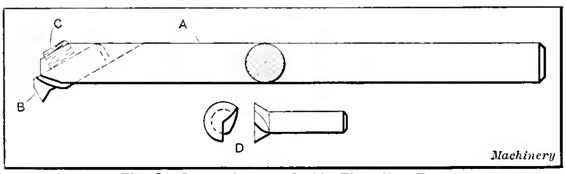

Fig. 2. Inserted-cutter Inside Threading Tool

screw must be short if limited in height to the over-all dimension of the holder, but the writer has proved out this type of holder under hard test and has found the short screw amply strong to hold the tool firmly in position. He has used a ⅜-inch standard hollow set-screw of only three or four threads length, but if desired, users can make special set-screws with finer and more threads.

The tool *B* is a round piece of tool steel ground to the shape shown in the illustration. This tool also possesses the important feature of lead angle adjustment as mentioned in connection with the description of the gooseneck holder, Fig. 1. It has another equally important feature, which is that it extends beyond the holder so as to make it convenient to reach to the bottom of a hole or to a shoulder, as is often necessary in inside threading work. *D* shows another form of cutter adapted to this holder which possesses the feature of lead angle adjustment and in addition, being circular in form, may be ground many times, the form remaining unchanged. It is at a disadvantage, however, in small openings or when working close to the bottom of a hole or shoulder, because the opposite part of the cutter projects beyond the cutting edge and thus prevents the cutting edge working as close to a shoulder as the form shown in Fig. 2.

Fig. 3 shows a center gage which the writer has found to be superior to the ordinary flat type. Its design resulted from necessity, illustrating again the fact that necessity is the mother of invention. The writer had to cut a hob having a 90-degree thread and knew of no reliable way of setting the tool correctly, until the idea of this tool was conceived. The scrap box furnished the stock which was accurately centered. The 90-degree angle groove was cut by using a compound rest. This gage is placed between the lathe centers and the tool set in the groove. The 90-degree angle groove was found to work so satisfactorily that a 60-degree angle groove, a 55-degree angle groove and a square groove were also cut. Both ends were

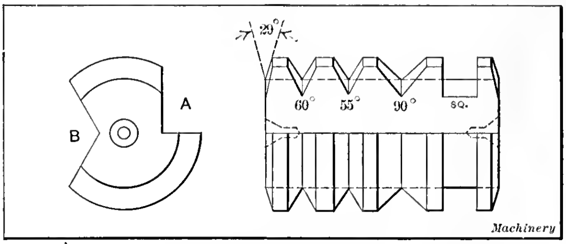

Fig. 3. Center Gage for 29, 55, 60 and 90-degree Threads and Square Threads

faced to an angle of 14½ degrees from the vertical, thus making it available for setting 29-degree angle "Acme" thread tools. The right-angle groove *A* permits the tool to be set flush with the gage and thus favors very accurate adjustment. The tool as first designed did not have the groove *B*, but the need for it was felt when a heavy piece of work between the centers would have required removal had not the gage been adapted to use *against* the work by cutting the groove *B*. The groove *B* permits the gage to be laid against a cylindrical piece of work held between the centers, and used in the same manner as when held between the centers. To set an inside threading tool, the gage is placed with one end against any surface at right angles to the line of center, such as the faceplate, chuck jaws, etc., and with groove *A* facing the threading tool.

After making the gage, the writer found a similar tool in MACHINERY's Reference Book No. 31, but inasmuch as this was original with him and has a strikingly different feature, it probably will be of interest and novelty to many readers.

Waterbury, Conn. JOSEPH WALDMAN

SETTING DIAMONDS

Referring to the article on setting diamonds in the July number, I wish to state that the diamond setting proposition was a troublesome one where I was formerly employed as foreman. The diamonds were held in the holder by a cap screwed onto a piece of ⅜-inch soft steel rod. We were always in trouble with this arrangement because of the cap loosening and the diamonds getting lost. We finally abandoned the use of the screwed cap holders and resorted to solid settings.

The method employed was to drill a hole in the end of a ⅜-inch soft steel rod just large enough to admit the diamond. The diamond was placed in the hole with the largest end at the bottom of the hole, and the end of the rod was peened around the diamond sufficiently to prevent it from falling out. The holder with the diamond in place was then given to the blacksmith who heated it to a white welding heat and with light blows, using a small hand hammer, closed the metal in over the diamond. The holder was then taken to the emery wheel and ground on the end until the diamond touched the wheel.

We found this was a very good method and used it afterwards with satisfaction. The welding heat did not appear to affect the diamond and the light blows having closed the metal around the diamond it was held very tightly when cold. With this setting, emery wheels could be trued many times before having to reset the diamond.

Montreal, Quebec, Canada. MICHAEL MCGIVERN

BLANKING, FORMING AND CUTTING DIE

The punch and die shown was designed for producing the piece illustrated in the detail view. This piece is produced from ribbon brass 0.012 inch in thickness, and at each stroke of the press one piece is blanked, another formed and a third cut off, from which it will be evident that one piece is completed for each stroke of the press. In an average working day this punch and die has a capacity for 60,000 pieces.

Referring to the illustration, the operation of the punch and die may be outlined as follows: The ribbon stock is fed into the die by means of the corrugated roll *A* which is given the required pressure by means of springs under the bolt heads in the pillow blocks *C*. The five-tooth ratchet wheel *B* is mounted on the end of the shaft which carries the feed-roll *A*; this ratchet wheel is operated by the arm *D* which is connected with the punch-holder. At each stroke of the press, the ratchet wheel *B* is rotated one tooth space, and this rotation is transmitted to the feed-roll *A*, thus advancing the stock through a distance of 5/8 inch.

The work is blanked by the punches *E*, formed by the parts *F*, *H*, *I* and *J* which constitute the forming punch and die, and cut off by the blade *G*. The blanking punches are quite simple and any mechanic will understand their operation from the illustration. The forming punch and die is interesting. Referring to the illustration, *H* is a pin about which the prongs which were produced in the blanking operation are curled. As the punch-holder descends, the punch *I* bends the ends of the prongs down around the forming pin *H*. After performing this function the punch *I* rises into the holder against the tension of a spring, and allows the forming punch *F* to come into action. This punch forces the pin *H* down into the forming die *J* and finishes curling the prongs on the work around the forming pin. When the punch-holder rises, the pin *H* is returned to its normal position by the action of a spring. During the upward stroke, the ratchet wheel *B* feeds the stock into position for the next operation, and by so doing the work is pushed off the forming pin. The shear blade *G* then comes into action and cuts off the finished piece against the edge of the forming die *J*.

Blanking, Forming and Cutting Die and Work produced in it

DETERMINING CHORDAL THICKNESS OF SPIRAL GEAR TEETH

The method of finding the dimensions of spiral gear teeth described by Arthur C. Maxfield seems needlessly complex. A simpler method is submitted in the following:

First find the normal diametral pitch. In the majority of cases this is known, inasmuch as the angles and diameters have been fixed to correspond with regular diametral pitch cutters. Then find by the usual formula, the same as that used for finding the cutter number, the number of teeth in the equivalent spur gear. Take the value given in a table of chordal thicknesses for the new number of teeth and divide by the normal diametral pitch found. The formula for determining the cutter number is:

$$\text{Cutter number} = \frac{\text{number of teeth}}{\cos^3 \text{(spiral angle)}}$$

In the case selected by Mr. Maxfield, *viz.*, 8 teeth, spiral angle 48 degrees, the number of teeth in the equivalent spur gear is found by dividing 8 by $\cos^3$ 48 degrees, which gives us 27.

Manchester, England. FRANCIS W. SHAW

ANALYZING STRENGTH OF CYLINDER HEAD BOLTS

In the July issue of MACHINERY appeared an article entitled "Analyzing Strength of Cylinder Head Bolts." With all due respect to the author, I would like to submit my view of this problem. Mr. Farnsworth, like many others, contends that the internal steam pressure must exceed the total pressure holding the cylinder head on, before any extra tension is exerted upon the cylinder-head bolts. This may be true, but at present I am not convinced.

Fig. 1 shows a sketch similar to that shown in the July number. With a tension of 10 pounds registered on each of the side scales, it is obvious that there must be a compression in the piece EF equal to 20 pounds. Now it may appear that the spring-balance at G must register 20 pounds before any perceptible difference is noticed on the side scales, but what has become of the compression on the piece EF? With no tension on the scale at G it would be difficult to remove the piece EF, but with the scale at G showing a tension of 20 pounds, the piece could be removed without altering the reading on any of the three scales.

Fig. 2 is similar to Fig. 1, with the exception that weights are used instead of the spring-balance. To illustrate more clearly, in Fig. 3 a rubber gasket I (exaggerated to illustrate more clearly) is placed between the cover and the cylinder flange. Assuming the cover to have no weight, and the gasket, in a free state, to be 3/8 inch thick, then weights W suspended from each of the six bolts, exert a pressure of 60 pounds on the gasket I and compress it to a thickness of 1/4 inch. There is a tension of 10 pounds in each of the six bolts, due to the weight on them. Now, if a spring-balance is placed at G

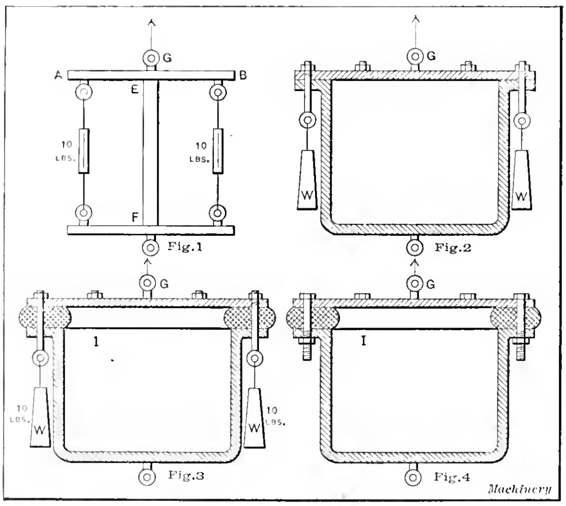

Fig. 1 to 4. Diagrams illustrating Principles relating to Stresses in Bolts

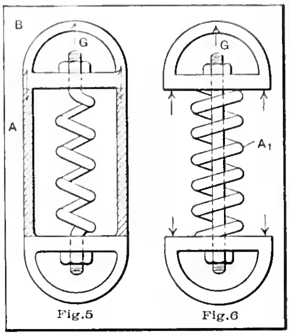
(the base being firmly secured) and a pull exerted, any tension registered on the scale must have an inverse effect on the gasket I. As the tension on G increases, the compression on the gasket decreases until the scale at G registers 60 pounds, when the gasket has regained its original thickness of 3/8 inch.

In this case, the resistance has only been transmitted from the gasket I to the spring-balance at G, which is in accordance with Newton's third law of motion: "To every action there is always an equal and contrary reaction." It will be clearly seen that there still remains a tension of 10 pounds in each stud, due to the weight W, but the cover has risen 1/8 inch due to the pull at G. Now in place of a weight being used to give a tension of 10 pounds in each stud, suppose bolts and nuts are used to compress the same gasket from 3/8 inch to 1/4 inch (as shown in Fig. 4.) Then the vital question is: If a pull is exerted at G, or an internal pressure of steam or air, or a force of any kind, acts to remove the cover, what is the result? It seems quite evident that a pull of 60 pounds at G must double the tension in the bolts, as the gasket (which is compressed to 1/4 inch) is already exerting a force of 60 pounds.

To acquire a certain tension in a stud or bolt, a similar resistance is absolutely necessary, and, if in the case in hand, the resistance of the initial tension of the bolts is taken by the flanges and gaskets, what resists any added pressure? As the compression of the flanges and gaskets is already exerting a force tending to separate the cover from the cylinder, any additional force, be it ever so small, must be added to it.



As the foregoing is only the version of a young mechanic (and perhaps a mistaken one), any light on this apparently debatable subject would be highly appreciated by mechanics in general.

Hamilton, Ont., Canada. JAMES H. RODGERS

[Whether the initial tension on a tightened bolt holding a part subjected to pressure is increased by that pressure before the initial tension is exceeded, depends upon the following conditions: When a bolt is more elastic than the material compressed, the stress in it equals either the initial stress (due to tightening the nut) or the force applied, depending upon which is greater. If the material compressed is more elastic than the bolt, the stress in the bolt equals the initial stress plus the force applied. The principles involved are illustrated by the diagrams, Figs. 5 and 6. The bolt in Fig 5 is in the form of a spring and part A is under compression. Now, while an upward pull at G would reduce the pressure between parts A and B, the tension on the bolt would remain constant until pull G exceeded the initial tension. In Fig. 6, the bolt is straight and spring A_1 is under compression. In this case, the tension on the bolt equals pull G plus the upward thrust of the compressed spring. When flanges are held together in direct contact, they are much more unyielding than bolts, and the condition illustrated by Fig. 5 exists. If they were separated by a gasket more flexible than the bolts, the total stress (as in Fig. 6) would equal the sum of the initial tension and the force applied.

Referring to Fig. 1, obviously the compression on EF will diminish as the upward pull G is increased, as our correspondent states, but the tension on the side scales (representing the bolts) remains constant until pull G, in this case, exceeds 20 pounds. The load is gradually transferred from EF to G, but without affecting the tension of the side scales, until the pressure on EF is reduced to 0; then, any additional upward pull will increase the tension on the side scales. The principle is also illustrated in Fig. 2. If the weights W weigh 10 pounds each, it is apparent that the tension of 10 pounds on each bolt will not be increased by an upward pull at G. If this same tension had been obtained by tightening the bolts with nuts, it would also remain constant until pull G exceeded the total initial tension, unless a flexible gasket were used in the joint. Any upward pull at G, however, would reduce the pressure between the flanges. If a thick flexible gasket were used, as shown in Fig. 4, the total stress would equal that due to compressing the gasket plus the pull G, because, in this case, the material compressed is more elastic than the bolts. A more complete explanation of the principles involved will be found in MACHINERY's Reference Book No. 22, "Calculation of Elements of Machine Design."—EDITOR.]

EPICYCLIC TRAINS

An epicyclic train is one in which all or some of the gears or wheels have a motion consisting of a revolution about an axis and a revolution or movement of the axis itself.

In Fig. 1, *A* is called the link or arm of the train. Rotation when right-handed will be considered as positive (+) and when left-handed as negative (−). Gear *B* has 60 teeth; *C*, 20 teeth, and *D*, 30 teeth. Gear *B* will not rotate. The problem is to find the number of revolutions made by gear *D* if the arm *A* makes + 5 turns.

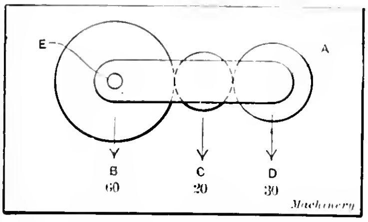


Fig. 1. Diagram illustrating Principle of Epicyclic Trains

There are several methods that can be used in solving, but I believe the following to be the most comprehensive:

	B	*D*	*A*
1. Train locked	+ 5	+ 5	+ 5
2. Train unlocked (arm fixed)	− 5	$-5 \times \frac{60}{30}$	0
3. Resulting motions (algebraic sum)	0	− 5	+ 5

First consider the train locked and turn the arm + 5 times about point *E* as an axis. This results in the gears and arm being turned + 5 times, as shown in line 1 above. The train is then unlocked and the arm assumed to be fixed. It will be necessary to turn gear *B* − 5 times in order to make its resultant movement zero, which the problem states is true. The wheel *D* would then turn $-5 \times \frac{60}{30}$ times, $\frac{60}{30}$ being the ratio of the gears. The resulting motion of each gear and the arm is shown above and is the algebraic sum.

An excellent use to which this principle may be put is shown in the example of the boring bar when used on a lathe or other machine, as illustrated in Fig. 2. Suppose the right-hand screw *A* has eight threads per inch. It is desired to find the distance the cutter bar *B* will travel for one positive (+) turn of *C*, which is the bar placed between centers. We will call the motion of *C* positive (+) when rotating in the direction of the arrow.

	H	*E*	*C*
1. Train locked	+ 1	+ 1	+ 1
2. Train unlocked (arm fixed)	− 1	$-\frac{3}{13}$	0
3. Resulting motion	0	$+\frac{10}{13}$	+ 1

With the train locked we assume *C* (arm) to be turned + 1 revolution, with the result that all the gears would be turned + 1 revolution. With the train unlocked and *C* stationary, we find it necessary to turn gear *H* minus one turn in order to have its resultant movement zero, which would be true, as gear *H* is fixed to the lathe tailstock and cannot rotate. We find that gear *E* has turned − 3/13 revolution. Adding, we find the resultant motion of *E* to be + 10/13 revolution. But this is relative to gear *H*, which is stationary and cannot move. It is necessary to find the turns of gear *E* relative to *C*, which is not stationary, but turning about the same axis as *E*, or + 10/13 − 1 = − 3/13. If the lead-screw *A* has eight threads per inch (right-handed) the cutter bar *B* will move 3/13 × 1/8 = 0.028 inch to the right for one turn of *C*.

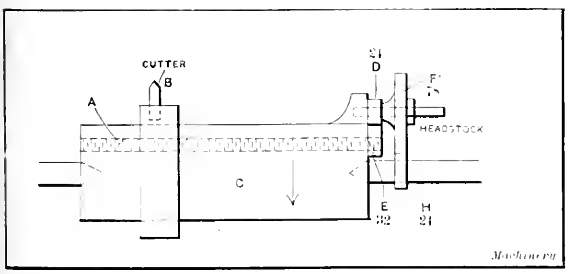

Fig. 2. An Application of the Epicyclic Gear Train

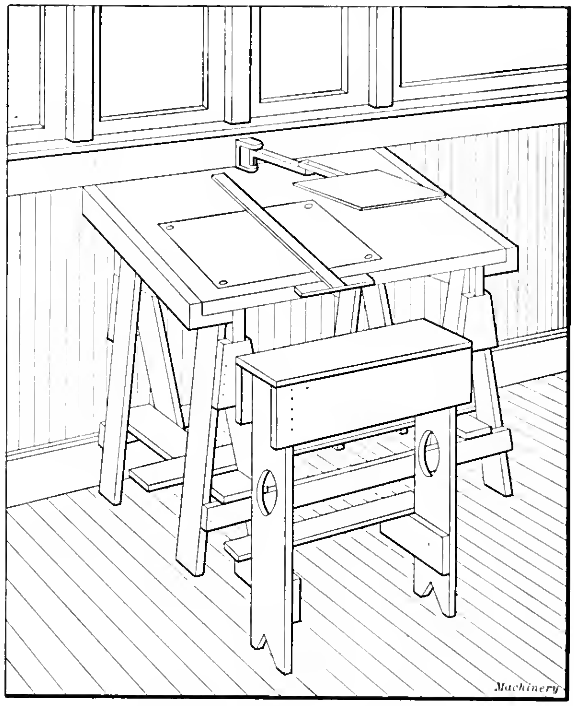
Cliftondale, Mass. I. E. Miller

DRAFTSMAN'S SEAT AND INSTRUMENT HOLDER

The illustration represents my idea of a well arranged drawing board, seat and instrument holder. I have been using this arrangement for several years and find it satisfactory. A bench seat which will accommodate two persons is convenient when the superintendent or head draftsman wishes to sit down on the seat with the draftsman for a while to inspect a drawing or to talk over matters of detail. The bench is useful also when making large drawings as one can slide along so as to keep his work in front of him. With the draftsman's stool commonly used, it is necessary to stand in order to do very large drawings, as one cannot sit on a stool and reach far.

The seat I use is 11 by 36 inches on top and 25½ inches high. The foot-rest is 8 inches from the floor. The height of the bench is right for that of the drawing board, which is



Draftsman's Seat and Instrument Holder

arranged for use either as a stand-up board or when sitting on the seat. The height of the front edge of the drawing board is 33 inches from the floor and this is very nearly right for the average man whose height is about five feet ten inches. The height is right for doing work where the draftsman has to lean over and against the board; it puts the pressure against his body where it will do him the least harm. This is an important consideration when making many large drawings.

The homemade instrument holder over the board is useful for keeping the instruments, scales, squares, etc., out of the way of the T-square, especially when it is necessary to use the T-square to draw in vertical lines. The folding arm of the instrument holder is an old square folding gas fixture. The tray is made of galvanized iron, the edges being folded over so that no square edges are exposed.

Chattanooga, Tenn. R. W. J. Stewart

A small business of some importance in New York City is the collection of steel filings from machine shops for use in fireworks. The price paid for clean filings in New York City is about twelve cents a pound.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

LANDIS ROLL GRINDING MACHINE

The Landis Tool Co., Waynesboro, Pa., has recently added to its line the roll grinding machine illustrated in Figs. 1 to 4. This machine includes a number of important features in its design and embodies the method of traversing the grinding wheel carriage, which is a distinctive feature of Landis grinders. Uniform and positive lubrication of the ways is provided and a rigid foundation for the work, no matter what its length or weight may be. There is no overhang of the work-table, as it is supported for its entire length by the column of the machine to which it is firmly clamped, thus avoiding vibration; this is a feature which is essential to rapid and accurate grinding. This machine is built in seven sizes. The smallest size is a 16 by 72 inch machine weighing 15,000 pounds, while the largest swings 52 inches, takes 20 feet between centers, and weighs 90,000 pounds.

The machine has been designed for manufacturing purposes and while it is primarily intended for grinding hardened steel and chilled rolls, it is also well suited for finishing a variety of cylindrical work such as large shafts, pistons, Corliss valves, torpedo tubes and similar pieces. The design has been worked out to make the machine entirely self-contained and no overhead works are required except when it is desired to drive the grinder from a lineshaft; in such a case an auxiliary shaft with tight and loose pulleys and a cone pulley over which the belt runs to the machine is required. Owing to the fact that the machine can be operated without any overhead works, it is convenient to place the grinder under a crane for lifting the work into place and removing it.

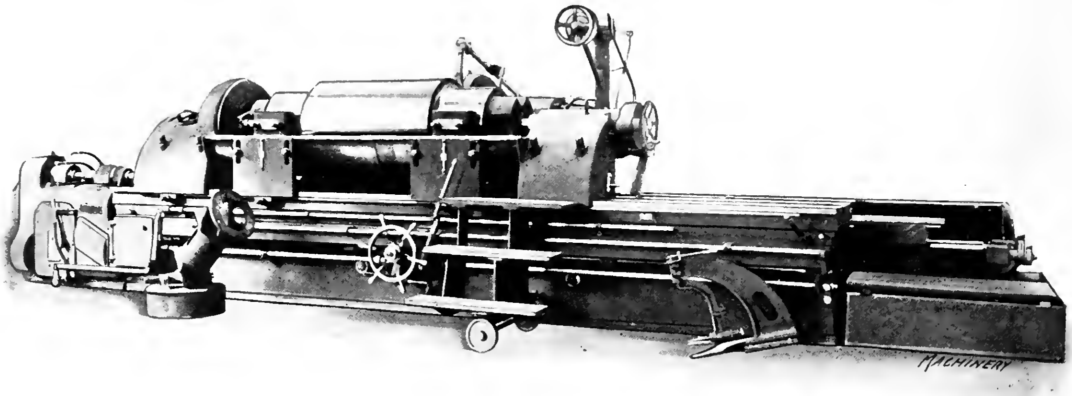

Fig. 1. Front View of Landis Roll Grinding Machine

Where electric motor drive is employed, the motor is mounted on an extension of the base and can either be connected directly to the driving shaft or power can be transmitted by a belt, as desired. The machine can also be driven by a motor placed on the ceiling or wall, in which case the extension on the base of the machine is not required. The main drive is located at the rear of the machine and consists of a shaft extending the full length of the bed. The different mechanisms are driven from this shaft independently by means of belts. The driving shaft is thoroughly protected for its entire length by means of a sheet metal guard.

The grinding wheel driving pulley traverses with the wheel carriage and is trunnioned in an independent carriage which travels on a track provided for the purpose. The pulley is driven by rolls in its hub engaging with step grooves in the main driving shaft. In traveling, this arrangement makes a practically frictionless driving connection. The grinding wheel belt passes over idler pulleys which are so arranged that its length does not change as the wheel head is moved on the cross-slide. One of the idler pulleys automatically adjusts itself for any change in the length of the belt due to stretching and at the same time keeps it under a uniform tension. The work and traverse speeds are varied independently of each other. This is an important factor in commercial grinding, as it affords the necessary traverse feed for any work speed. For grinding tapers, the table swivels and is provided with two scales which are graduated in degrees and inches per foot, respectively.

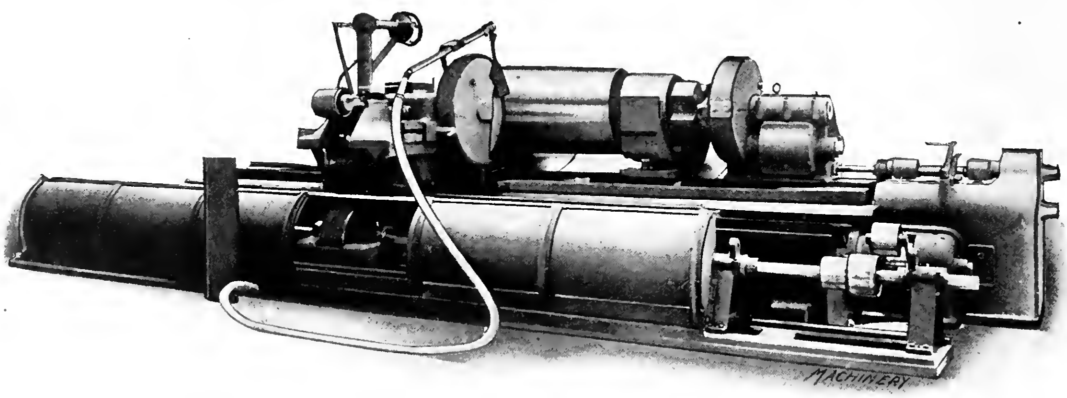

Fig. 2. Rear View of Roll Grinding Machine

The headstock is of heavy construction and powerful gearing is provided for driving the work. The speed changes are made

by an arrangement of levers at the front of the machine. The footstock is operated by a handwheel which is geared to the screw so that the center can easily be run into the heaviest piece of work that the machine will carry. The grinding wheel head is mounted on a vee and flat guide of ample proportions to provide a smooth and positive action when feeding for the lightest cut on the work. The spindle is made of steel and runs in phosphor-bronze bearings which are made with tapers to provide for taking up wear. The bearings have a ball and

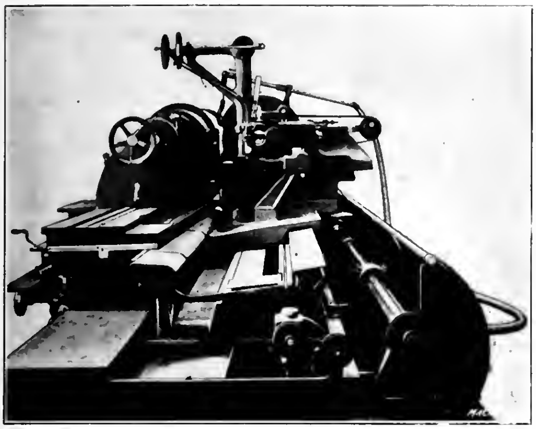

Fig. 3. Right-hand End of Roll Grinding Machine showing Driving Shaft

socket connection with the base, which makes them easy to keep in alignment with the spindle. The grinding wheel is fed to the work either automatically or by hand, and there is also a rapid power feed for moving the wheel back out of the way when changing the work and also for bringing it forward to the grinding position when the machine is ready to be placed in operation. This is an important feature as it saves a considerable amount of time as well as making the operation of the grinding machine simple and convenient. The rapid power feed is independent of the hand and automatic feed, being operated by a lever and simple arrangement of clutches. The automatic cross feed for the grinding wheel operates at each reversal of the wheel carriage and can be set to reduce the work diameter from 0.00025 to 0.012 inch at each traverse.

The grinding wheel is provided with three truing fixtures.

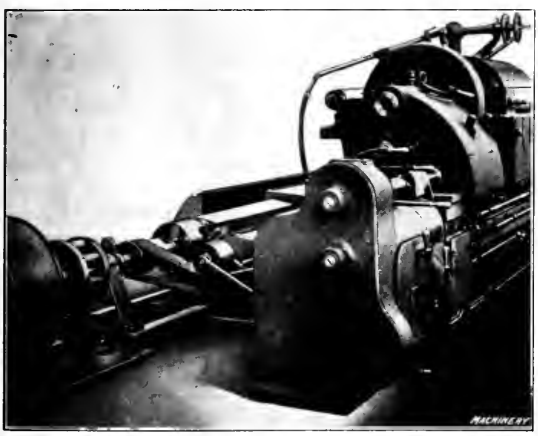

Fig. 4. Left-hand End of Roll Grinding Machine showing Arrangement of Motor Drive

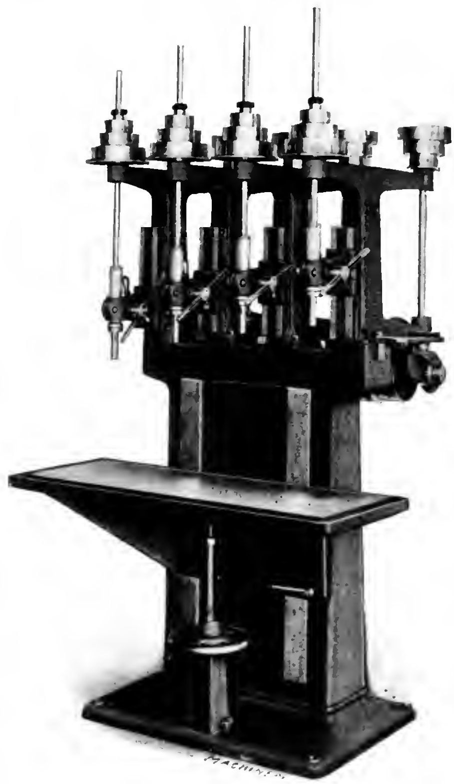
One of these fixtures is permanently mounted on the footstock, where it is in a convenient position for dressing the wheel when it is engaged in grinding necks on the rolls. Another truing fixture is located on one of the bearings which carries the roll by its neck and is used when grinding the face of the roll. The third fixture is used for forming or rounding the corners of the wheel for grinding the fillets of the necks. This truing fixture is attached to the table of the machine.

It has already been mentioned that the rolls are supported by their necks in bearings while the body of the roll is being ground. These bearings have three points of contact which are adjustable for the variation which exists in the size of the necks due to wear and regrinding. They can be quickly removed and replaced by other bearings to accommodate a different size of roll. For grinding concave work, special bearings are required. These are provided with vertical adjustment for tipping the roll to an angular position with one end above and the other below the horizontal center line of the wheel. This results in a concave form being ground. The vertical adjustments of the ends of the work are controlled by screws, the amount of adjustment secured at either end being indicated by graduated scales. These bearings can also be used for grinding straight rolls and the arrangement of the pads is the same as described in the foregoing. The concaving outfit includes a universal driver for the work.

REED MULTIPLE SPINDLE DRILL

In the March, 1913, number of MACHINERY, the improvements made by the Francis G. Reed Co., 43 Hammond St., Worcester, Mass., in its line of bench drills, were illustrated and described. Since the completion of this work, the same attention has been given to the line of multiple spindle drills manufactured by this company, a four-spindle drill of the



Improved Design of Reed Multiple Spindle Drill

improved type being illustrated herewith. The general design of the machine has been retained, but various improvements have been made to adapt these machines for the most severe classes of modern manufacturing.

Among the changes which have been made, the following may be mentioned. All of the bearings have been lengthened and the length of the belts has also been increased to add to their driving power. The top cones have been brought down nearer to the frame of the machine to reduce the strain on the bearings, which are oiled through the top of the shafts. The swing has been increased to 14 inches, while the capacity remains the same; *i. e.*, up to ½ inch drills. Gear guards have been added which practically enclose all of the gears. A new material has been adopted for the bevel gears which is very tough and possesses excellent wearing qualities combined with the ability to give a practically

noiseless transmission. The drive is so arranged that there is only one belt for each spindle, this being a straight open belt.

It will be seen from the illustration that the column of the machine has been changed to the rectangular pattern, as in the case of the improved bench drills. The table bearings are made of ample length and the table is provided with a deep oil channel extending all the way around it. The table is supported and raised or lowered by means of a telescoping screw, a binder handle being provided to lock it to the column in any desired position. This improved type of machine is known as the Reed No. 300 multiple spindle drill.

HESS EDGE PROTECTORS

In lifting heavy, finished castings the edges are frequently damaged by the chain slings, this damage being due to both the indentations produced and to the result of the chain slipping on the casting. Where rope slings are used in place of chains, the damage to the castings is avoided, but at the expense of the ropes, which are soon worn out. Both of these difficulties are avoided by the edge protectors, illustrated herewith, which are a product of the Hess Steel Castings Co., Bridgeton, N. J. It will be seen that these protectors consist of a casting having two plate members at right angles to each other and a pair of stiffening ribs to

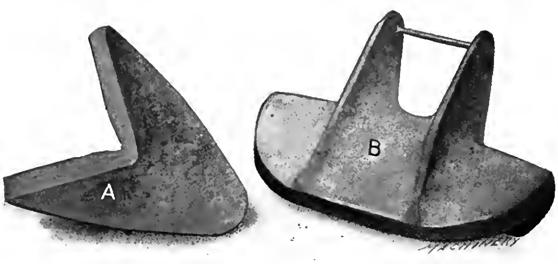


Fig. 1. End and Side Views of Hess Edge Protector

provide the necessary strength. The chain or rope rests between these ribs, the protector being thickened and rounded at this point to form a seat which will prevent the sling being damaged. The ribs are carried far enough back to receive a cotter pin which holds the protectors in place on the sling when they are not in use.

Provision is made against the slightest damage being done to castings with sharp finished edges by running a groove along the protector at the point where the two plate members join. This groove will be readily seen in the end view of one of the protectors, which is illustrated at *A* in Fig. 1, a side view being shown at *B*. The protectors are made of a very low carbon alloy, which is of essentially the same composition as pure wrought iron. This material is so ductile that there is no danger of the protectors being broken, even when they are subjected to the roughest handling. Where great care in handling is required, protectors are made with a babbitt or lead lining. This lining may be renewed as it becomes worn or charged with chips, suitable pouring dies

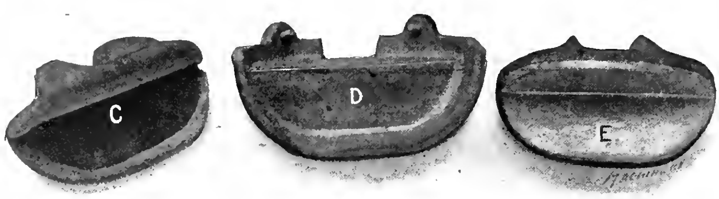

Fig. 2. Recessed Casting for Babbitt Lined Protector, Pouring Die and Finished Protector

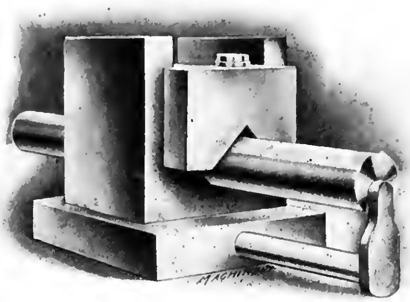
being provided for the purpose. A recessed casting for one of these protectors is shown at *C* in Fig. 2; the pouring die is illustrated at *D* and the protector with the babbitt lining is shown at *E*. With guards of this nature, finished pieces of work can be handled without any danger of marring them.

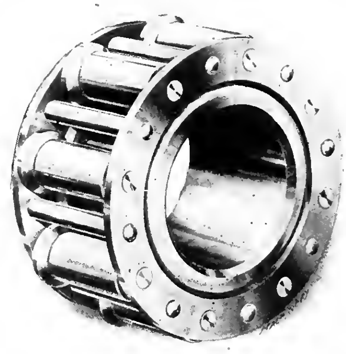
HOLTON V-BLOCK

The double V-block illustrated herewith is a product of the Holton Co., Jackson, Mich. This is a particularly useful drill press tool, and with it holes can be drilled perfectly straight through a bar, no special skill being required for the operation. The block is made of cast iron, accurately milled by means of special milling cutters designed for the purpose. The master bushing is made of steel and fitted into the upper V-block. This bushing is hardened and ground to



Holton V-block for holding Work to be drilled

¾ inch inside diameter and pressed into place. Interchangeable bushings are provided which fit into this master bushing and adapt the V-block for the use of different sizes of drills. The interchangeable bushings are also made of steel, hardened and ground in the customary manner. A set of ten interchangeable bushings forms a part of the regular equipment of these V-blocks. Referring to the illustration it will be seen that the V-block is equipped with an adjustable gage



Bower Roller Bearing for Combined Radial and Thrust Loads

which makes it a simple matter to produce duplicate pieces. The capacity of the V-block is for pieces ranging from ¼ inch to 2 inches in diameter.

BOWER ROLLER BEARING

The Bower roller bearing illustrated herewith is adapted for carrying combined radial and thrust loads, but the two components of the load are carried by individual bearing members. In this particular, the design of the Bower roller bearing differs from most forms of roller bearings designed for such service. The rollers used in this bearing consist of a long cylindrical portion upon which the radial load is supported. At one end of the cylindrical portion of each roller there is a flanged head; this head fits into corresponding grooves in the races of the bearing and the thrust load is supported upon the inclined faces shown at the left in the halftone. The heads which receive the thrust load do not come into contact with the radial raceway and therefore do not support any portion of the radial load. As the radial and thrust supporting members of the bearing are independent of each other, an increase of either radial

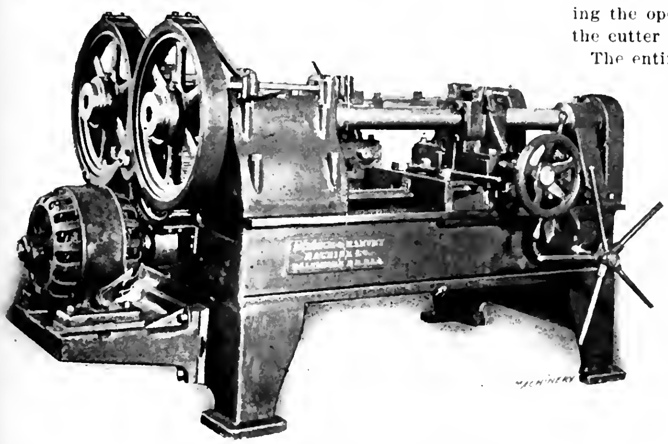
or thrust load does not affect the efficiency of the bearing for carrying the other kind of load for which it is designed.

This bearing is absolutely non-adjustable as regards radial alignment, but the end play in the bearing may be increased or diminished to suit individual requirements without in any way affecting the alignment of the shaft or spindle. Owing to the self-aligning principle which is employed, the rollers always run in a parallel path without any wedging action, and it is stated that, when correctly mounted and of the proper size, the bearing will run for years without appreciable wear. The rollers are freely mounted at one end and held at the other end by means of the heads which carry the thrust load. This bearing is manufactured by the Bower Roller Bearing Co., Detroit, Mich.

DETRICK & HARVEY BORING MACHINE

The duplex boring machine illustrated herewith is a recent production of the Detrick & Harvey Machine Co., Baltimore, Md. This machine was designed for machining car boxes, and the bed is of sufficient length to enable boxes 6 inches in diameter by 12 inches in length to be bored and faced.

The spindles of this machine are made of cast iron; they are $4\frac{1}{4}$ inches in diameter and run in bearings 17 inches in length. The spindle bearings are capped. Sliding tooth clutches keyed to the spindle and actuated by an eccentric lever engage or disengage toothed sleeves which revolve loosely on the spindles. The driving gears are made of cast iron and the pinions of either bronze or steel. The boring bars are secured to sockets in the ends of spindles and are supported at their outer ends by bearings; the two spindles can be operated simultaneously or independently as desired. The bars have no movement longitudinally.



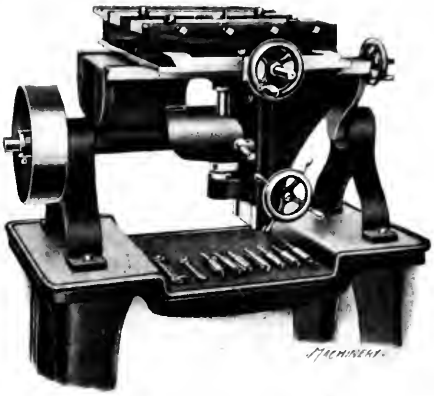
Detrick & Harvey Duplex Car Box Boring Machine

The carriages are fitted to the inner locks of the shears and are moved longitudinally by hand or power. A quick hand movement operated by the spider shown in the illustration is provided by means of the rack and pinion, while a slow hand movement is provided by means of the handwheel. Power feeds are provided by spur gearing at the end of the bed farthest from the headstock. Each carriage contains a square locked cross-slide upon which two slides are fitted, the slides being adjusted to and from the center line of the spindle by a screw, as shown in the illustration.

The change gears are located at the end of the machine farthest from the headstock. Motion is transmitted to the feed mechanisms from their respective spindles so that the feed is only in action while the spindles are revolving. Each spindle is provided with independent feed changes. The feeds to the carriage cover a range of from 1/16 to 3/16 inch per revolution of the spindle. The spindles are driven by a $12\frac{1}{2}$ H. P. motor which has a speed variation of 1 to 2 and gives spindle speeds from 25 to 50 revolutions per minute. It will be seen that the motor is mounted on a bracket at the head end of the machine so that the unit is entirely self-contained.

THURSTON DIE MILLING MACHINE

The Thurston Mfg. Co., Providence, R. I., has recently redesigned its die milling machine, a number of improvements having been incorporated in its construction which add materially to the efficiency of the machine. The illustration shows the redesigned machine, and, as in the preceding type, the die to be milled is held on a table which is carried by cross



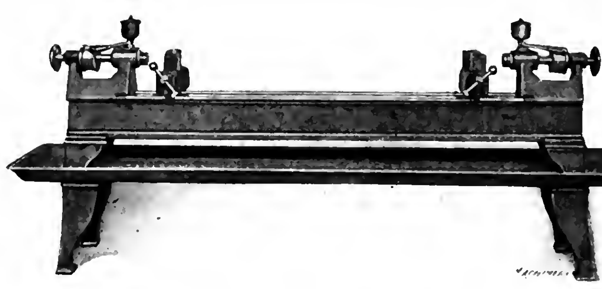
Improved Design of Thurston Die Milling Machine

and longitudinal slides. The cutter spindle projects upward through the die opening, and by manipulating the handles which operate the two slides the work is fed against the milling cutter until it has been recessed to the desired shape. Taper cutters are used, a suitable taper being employed to provide the clearance that is required for the die. In starting the operation, a hole is drilled in the die-block in which the cutter starts to operate.

The entire frame is mounted on trunnions so that the work may be inclined to the position which is most suitable for the operator. In the original machine, the cutter spindle was simply mounted in small brackets, but in the redesigned machine the cutter spindle is supported by a slide having broad bearing surfaces so that it is rigidly held; this slide also facilitates the adjustment of the position of the cutter. The raising and lowering of the cutter-slide is accomplished by means of a handwheel. The handwheels which control the cross and longitudinal movements of the work-table, are fitted with adjustable collars which provide for compensating for wear, so that backlash may be entirely eliminated. The spindle has been made much heavier than in the preceding type of machine and runs in taper bronze bushings which are carefully protected from chips and dirt. The construction of the machine has been made heavier throughout, so that it is better adapted for the heavier classes of work for which it is used.

HENDEY CENTERING MACHINE

For some time past, the Hendey Machine Co., Torrington, Conn., has been manufacturing single-spindle centering ma-



Hendey Double-spindle Centering Machine

chines. In order to enable a shaft to be centered at both ends by a single operation, this company has developed the

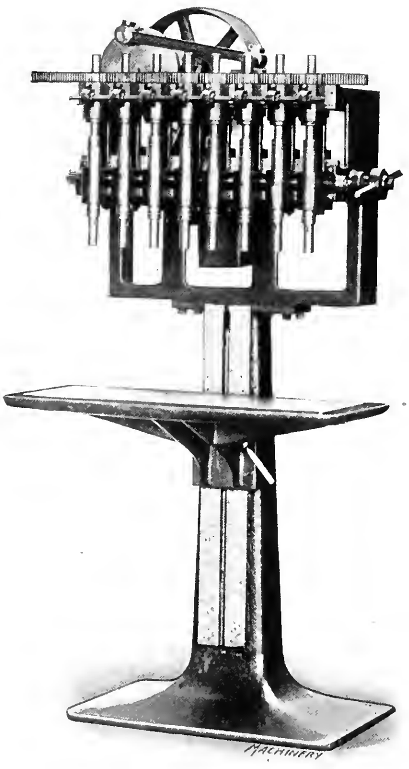
double-spindle machine illustrated herewith. The design has been worked out along the same general lines followed in the construction of the single-spindle machines, but several noteworthy improvements have been made.

The heads are rigidly clamped to the bed, thus affording permanent alignment for the spindles. The spindles run in ample bearings which are equipped with felt oilers; the front journals are made taper and have ball thrust bearings for carrying the end load. The spindles carry draw-in attachments with watch tool chucks for accurately holding combination center drills and reamers. Back locking pins working in the flanges of the pulleys are provided for use when it is necessary to remove or replace the center drills. The vise jaws are made of hardened and ground steel. The alignment of the spindles and jaws is obtained by means of a proof bar carried in the spindles. This care in providing for the alignment of the work is necessary in order to enable the machine to center stock accurately for finishing operations after it comes from the turret lathe or screw machine. No matter what the diameter of the bar may be within the limits of the machine, it will always be supported in a horizontal position.

The incline surface on the bed, sloping away from the operator, tends to direct the chips into the pan rather than have them accumulated around the heads and necessitate a frequent cleaning before being able to shift the vise carriages. Heavy parallel bars running the length of the machine serve as a rack for holding stock which is to be centered. The capacity of the machine is from 5/16 inch to 4 inches inclusive.

FOOTE-BURT MULTIPLE SPINDLE VALVE GRINDER

The adjustable multiple spindle oscillating valve grinder which is illustrated herewith is a product of the Foote-Burt Co., Cleveland, Ohio. This machine was designed for use in



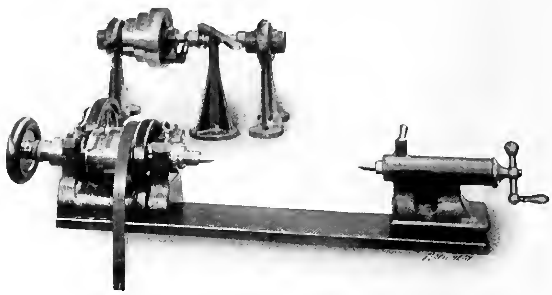
Foote-Burt Multiple Spindle Oscillating Valve Grinder

the manufacture of automobile engines and enables a complete set of valves to be seated in less time than is ordinarily required to seat one valve by hand. The spindles reverse at every one and one-quarter revolution and a cam is provided on the machine which raises and lowers the spindles at intervals of twenty revolutions to allow the grinding compound to enter the valve seat.

Machines of this type are built with from two to twelve spindles, depending upon the type of cylinder, and the spindles are made adjustable, the minimum center distance being two inches. The spindles are arranged with a ball thrust bearing on each end of the bearing and have a travel of $2\frac{1}{4}$ inches. The spindle noses are No. 1 Morse taper. The table may be adjusted up and down to enable the machine to handle different sizes of cylinders, making it sufficiently flexible to handle any type of cylinder, the valves of which might suitably be seated on this machine.

DAVIS MAGNET WINDING MACHINE

The W. P. Davis Machine Co., 305 St. Paul St., Rochester, N. Y., has recently added to its line the machine shown in the accompanying illustration which is used for winding



Davis Machine for winding Electromagnets for Automobile Self-starters

electromagnets for automobile self-starters. It will be seen from the illustration that this machine is equipped with a back-geared head and that the nose of the spindle is threaded left-hand; also that the rear end of the spindle is provided with a handwheel which is used by the operator for starting work and for making corrections.

The spindle is driven by a countershaft placed on the bench at the rear of the machine. This countershaft has a friction clutch in the cone which is so adjusted that it will slip when the brake is applied. The brake consists of a strap, shown in the illustration, which runs over the large step of the cone pulley and is actuated by means of a foot treadle. Machines of this type are built in four sizes, an 11-inch, a 14-inch, a 16-inch and an 18-inch size. The illustration shows the 11-inch machine.

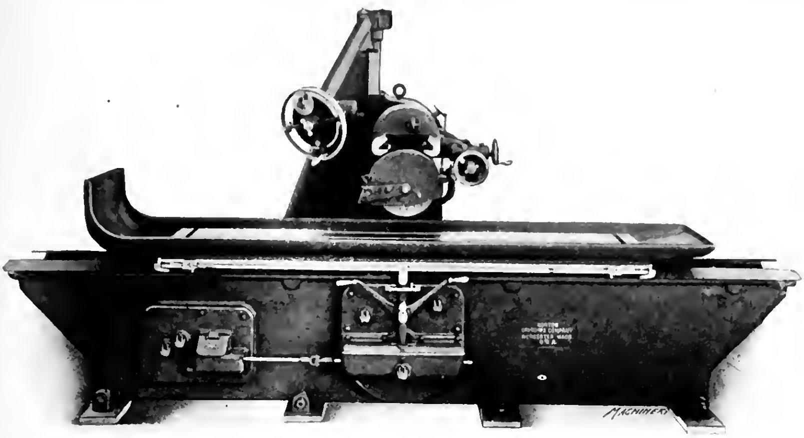
NORTON OPEN-SIDE GRINDING MACHINE

Experience has shown that in the operation of grinding wheels, the smaller the arc which is in contact with the work, the more efficient the operation of the wheel becomes, and as a result it is advisable to use wheels of small diameter. This is especially necessary when grinding plane surfaces, as the arc of contact in such cases is much greater than when round work is being ground. With a large arc of contact, the opportunity for the chips to escape is reduced. This results in heating, undue power consumption, and general inefficiency. When, for any reason, the chips cannot escape freely, a satisfactorily finished surface cannot be produced.

The open-side grinding machine illustrated herewith is a recent product of the Norton Grinding Co., Worcester, Mass. This machine is designed for grinding plane surfaces, and in order to attain the most satisfactory results, the periphery of the smallest wheel that is practical for the work in hand is used. The machine is designed to carry wheels 14 inches in diameter and for the usual class of work handled the wheel should have a 6-inch face. For special work, wheels of different widths can be used. The working surface of the table is 15 inches wide and is made in lengths of 6, 8, 10, 12 and 14 feet. The wheel head can be raised so that the distance between the surface of the table and a 14-inch wheel is 17 inches; this provides for the use of a magnetic chuck

or supplementary table when necessary. The countershaft is located in the machine base, so that the machine is self-contained. Power is transmitted to this countershaft by a belt running from the motor which is placed at the side of the machine. It will be evident from this description that all overhead works are eliminated. A 15 horsepower motor provides ample power for the requirements of ordinary work.

The grinding wheel is carried on a cross-slide operating at right angles to the travel of the table, and in order to secure the high rate of production that is made possible by the wide wheels used on this machine, no automatic feed of the wheel has been provided. A hand traverse has been designed for locating the grinding wheel in order to utilize the full width of the wheel face. Provision is also made for a slower traverse of the wheel when truing its face, this traverse being obtained through worm-gearing. The cross-slide is carried on a vertical slide, which is raised and lowered on the column by means of a ½ horsepower motor. For small distances, the vertical traverse is obtained by means of a handwheel on a shaft geared to the vertical traverse screw, and a micrometer index, which reads in quarter-thousandths, provides for making delicate adjustments.



Norton Open-side Grinding Machine for Plane Surfaces

The table is provided with T-slots of standard dimensions, which facilitate strapping work to the table or the application of a supplementary table, special fixtures or a magnetic chuck. The table traverse is obtained by means of worm-gearing which affords a perfectly uniform motion that is essential for the production of smooth, accurate work. The reversal of the table is pneumatically cushioned at the ends of the stroke. All kinds of plane surfaces which are within the capacity of the machine can be quickly and accurately ground. The machine can also be used for grinding surfaces of a variety of shapes, and for this class of work a special forming attachment is used to form the wheel to produce the shape required.

Ball bearings are employed on all shafts operated by handwheels and the worm and worm shafts are provided with ball thrust bearings. All of the worm-gearing runs in oil. The worms and wheel spindle are made of chrome-nickel-vanadium steel and all shaft bearings are ground to run in self-oiling boxes. Special equipment is used in scraping the ways in the base, which results in such accuracy of alignment that when the table has been ground in place, it presents a neat and uniform surface free from chatter marks. The inspection to which the machine is subjected requires a B. & S. straightedge the length of the finished table surface to hold pieces of tissue paper two inches apart throughout its length, with the straightedge laid at any angle on the table. The machine is supported on adjusting wedges mounted on iron plates which are imbedded in a concrete foundation; this makes it possible to realign the machine easily should such a procedure become necessary. A large tank is provided with a pump which will deliver thirty gallons of lubricant per minute to the wheel and work.

PRATT & WHITNEY 22-INCH VERTICAL SURFACE GRINDER

For several years the Pratt & Whitney Co., Hartford, Conn., has been manufacturing a small size of vertical surface grinder. The results obtained with this machine were so satisfactory that it was decided to build a larger machine along similar lines which would be suitable for heavier classes of work. The result of this undertaking is shown in Figs. 1 and 2 which illustrate front and rear views of the 22-inch vertical surface grinder which has recently been placed on the market by this company. While the design adheres to the general lines of the smaller size, the machine has been improved in many respects in order to adapt it for the severe service which is required of a grinder engaged on modern manufacturing work. Every refinement which experience has demonstrated to be essential for a machine of this type has been incorporated in the design, and although of unusual dimensions, the machine is a precision tool in every particular. It is very sensitive and easy to operate, all of the operating mechanism being contained in a single unit which is conveniently situated for the operator.

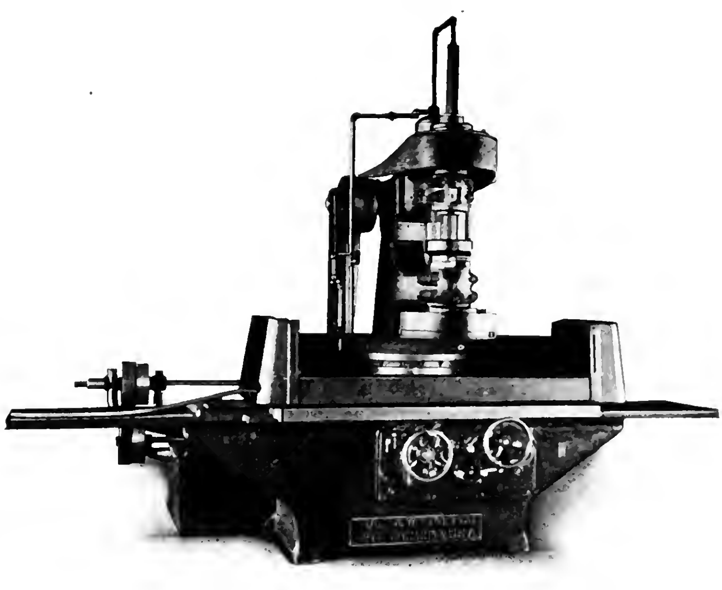


Fig. 1. Front View of Pratt & Whitney 22-inch Vertical Surface Grinder

The bed is provided with wide bearing surfaces of the vee and flat type, oil reservoirs being located in the bed for oiling the ways by means of rolls. The pan which surrounds the rear of the bed for collecting the water and receiving the chips is of liberal proportions and easily accessible for cleaning. The machine may be regularly furnished with either 4- or 7-foot tables, the bed being made in two lengths to accommodate these sizes; both the bed and table are finished perfectly true by means of masters. The table is provided

with guards which protect the bearing surfaces at all times from injury. A spacious pan is cast integral with the table for controlling the water and chips. The upright is bolted solidly to the bed, wide bearing surfaces being provided for the accommodation of the head. A taper gib forms part of the construction which makes it easy to maintain the proper relation between the head and the upright bearings. The bearing surfaces are also protected by means of very efficient wipers and guards.

The spindle is made of special steel, proportioned to resist the peculiar strains to which it is subjected. Attention is directed to the fact that the spindle is of ball bearing construction throughout. This also applies to the driving pulley which is mounted on ball bearings that are independent of the spindle. Thus the pull of the belt is absorbed by this independent bearing and is not transmitted to the spindle. This is a most important feature, without which it is practically impossible to design a head that will operate sensitively or retain its accuracy for any length of time. Furthermore, this construction places the driving belt in a protected position away from the water spray, so that it does not lose its efficiency by becoming moist. The ball bearing construction has been subjected to exhaustive tests and has proven efficient in every particular. With its use the loss through friction is reduced to a minimum and practically the entire power is utilized for driving the wheel.

The table is provided with an automatic reciprocating motion, any desired length of stroke being readily obtainable by means of adjustable table dogs. The feed mechanism is of a most efficient and substantial construction which is contained in one compact unit. The table is driven through a rack and pinion, the construction eliminating the possibility of vibrations (commonly called tooth marks) showing in the work. Two table feeds are provided, both of which may be instantly controlled through the lever *A* shown in Fig. 3. When adjusted to the right-hand station, the slow feed is engaged; and the left-hand station engages the fast feed in a similar manner. This lever, when adjusted to the central station, also serves as a means for stopping the table. The table, in addition to the two feeds mentioned, is also provided with power quick return for use in connection with rotary chucks. The power quick return becomes operative and the regular feed inoperative by moving lever *B* to the lower station. It will be noted, however, that the lever *B* is locked by means of a lock-bolt *C* and cannot be operated while the regular feed is engaged. In order to unlock lever *B*, it is necessary for the regular feed lever *A* to be in the neutral position, after which the lock-bolt *C* may be adjusted to its outward position, which has the effect of releasing lever *B* and locking lever *A*. Thus it is impossible to engage both the regular and quick return feeds at the same time. After the quick return mechanism has become operative it is controlled through lever *D*.

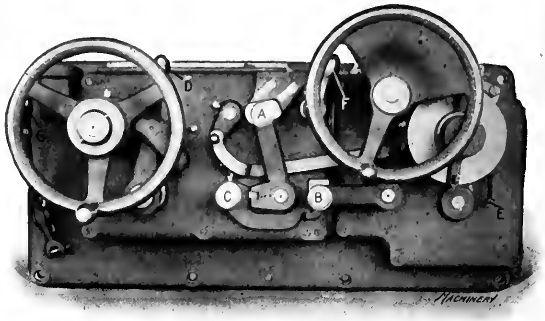

Fig. 3. Control Mechanism of Table Feed on Pratt & Whitney Surface Grinder

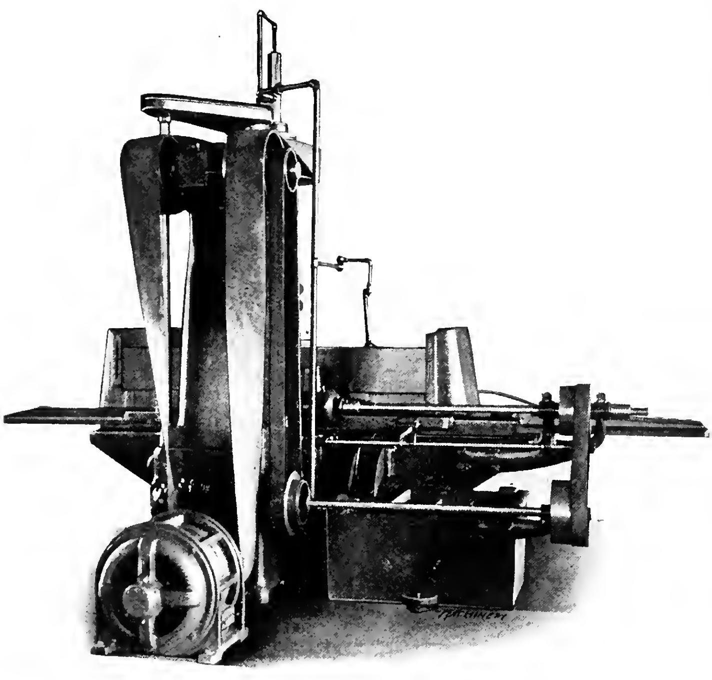

Fig. 2. Rear View of Pratt & Whitney 22-inch Vertical Surface Grinder

The wheel is provided with both hand and power feeds in addition to the rapid hand feed. The vertical adjustment is very sensitive, the head being perfectly counterbalanced and very accurately controlled through the feed mechanism. The power feed is operated through a ratchet wheel and pawl, the rate of feed being controlled by means of the adjusting screw *E*. A large micrometer dial for gaging purposes and also an automatic power feed knock-off forms part of the construction. Both the regular and rapid hand feeds are controlled through the lever *F*. This lever is operated in and out; when adjusted to its inner station, the regular hand feed is engaged, the outer station engaging the rapid hand feed. The design is such that when the rapid feed is engaged the power feed is automatically disengaged and cannot be used. The reason for this precaution is that the rapid feed is altogether too fast to be used when the machine is in operation, and if the power feed should become engaged through error the wheel would be broken. The machine is designed for motor drive only, the method of mounting the motor directly on the floor being clearly shown in Fig. 2. Provision has also been made whereby the correct belt angle from the idler to the motor pulley may be always maintained, irrespective of the diameter of the motor pulley. This is accomplished by means of the left-hand idler pulley which is so mounted that it may be swiveled to the correct angle, after which it is permanently doweled in place. The size of the motor varies from approximately 20 to 35 horsepower, according to the nature of the work for which the machine is to be used. A constant-speed motor is used, running at approximately 1200 revolutions per minute.

The machine is provided with a pump of new design which is capable of supplying an abundance of water. One stream of water is carried through the spindle, the centrifugal force of the spindle driving the water between the wheel and the work, and thus keeping both cool and free from dust. The inside stream of water is controlled through the lever *G* which is conveniently located on the front of the gear-box unit. An outside stream is also provided for conveying water to the outside of the wheel and for cleansing purposes. The wheel guard also assists in controlling the water. An exceptionally large tank is located on the back of the machine in an accessible position where it may be readily cleaned. The water is returned to the tank without being carried through pipes; in fact, the design is of such a nature that the collection of dirt or grit in inaccessible places is impossible.

Special attention has been given to the lubricating problems involved and large self-feeding oil reservoirs are provided which insure an ample supply of oil at all times. All bearings are absolutely dust- and water-proof.

A most important factor in the productive capacity of this type of machine is the cup-shaped wheel which covers the full width of the work, insuring perfect flatness, together with the greatest possible production. The wheel is protected by means of a guard, the guard being so mounted that it may be conveniently adjusted for height as the wheel wears. A wheel band is also furnished which should at all times be used upon the wheel.

The rectangular magnetic chuck affords a convenient appliance for holding a large variety of work; it may be readily applied to the table and is of water-proof construction throughout, so that water may be freely used without any danger of short-circuiting. The rotary chucks have been designed with a view of attaining the maximum efficiency as regards durability, accuracy and power consumption. They are absolutely dust- and water-proof, the drive units being located outside of the water guard, making it impossible for water to get into the chucks. The driving mechanism is so designed that it engages automatically when the chuck is brought in under the wheel and disengages when it is removed to be reloaded. The chucks are lubricated throughout by means of two large self-feeding oil reservoirs. The single rotary chuck is made either plain or magnetic. It is designed so that it may be tilted, permitting the grinding of either concave or convex surfaces. This is a desirable feature on a large variety of work, such as circular saws, cutters, and similar parts.

Special attention is directed to the duplex and quadruplex chucks which have recently been developed for use in connection with the Pratt & Whitney vertical surface grinders. Their value can readily be appreciated, as it is obvious that on work within their range the productive capacity of the machine has been practically doubled and quadrupled. A double chuck possesses all the features of the single chuck, in that it can be tilted to permit grinding concave and convex surfaces, or it may be adjusted to grind perfectly flat. The adjustment for each of the chucks is independent and when necessary they may be adjusted horizontally and reground to absolute accuracy. This chuck has proved very efficient in grinding saws and cutters with concave surfaces and is equally well suited for convex or flat surfaces. The quadruplex chuck is always horizontal and non-adjustable; thus it is only suitable for grinding flat work and will not handle concave or convex surfaces. The quadruplex chuck is by far the fastest on work such as gear blanks, washers, disks, etc.

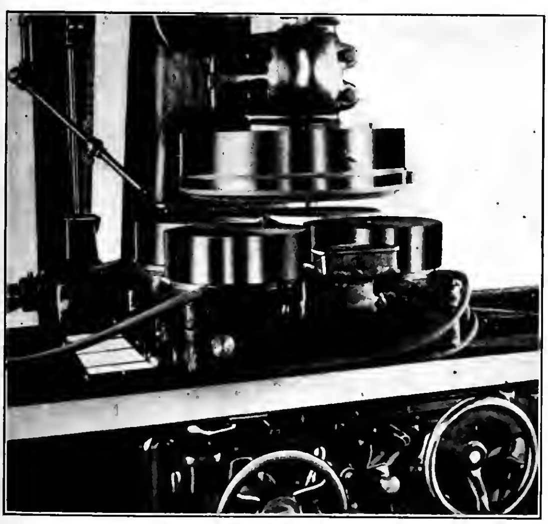

Fig. 4. Arrangement of Multiple Chucks on Pratt & Whitney Vertical Surface Grinder

LANGELIER DRILL FOR ROLLER BEARING CAGES

A special design of multiple spindle drilling head, which is illustrated in Figs. 1, 2 and 3, has been developed by the Langelier Mfg. Co., Providence, R. I., for use in drilling roller bearing cages for motorcycles. These cages, one of which is shown in Fig. 4, have eleven roller seats 0.255 inch in diameter, which are spaced equidistant from each other around a pitch circle 1 1/8 inch in diameter. The comparatively large size of the roller seats that had to be drilled on this small circle made the spacing of adjacent holes so close that it was impracticable to drill the eleven holes at one operation and at the same time retain a sufficiently strong spindle construction to enable the head to operate satisfactorily. As the layout contained eleven holes, the drilling could not be done in two operations with an ordinary multiple spindle drilling head. The head was, therefore, designed for drilling the eleven holes in three operations and to work simultaneously on three roller cages.

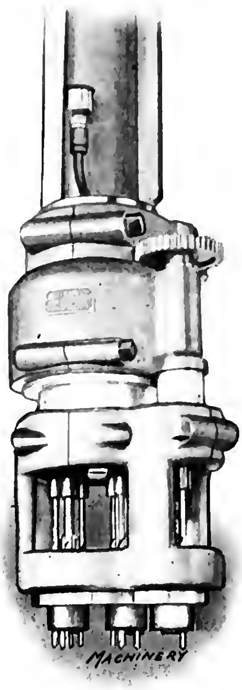

Fig. 1. Side View of Langelier Drill Head

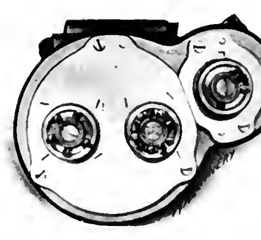

Fig. 2. End View of Drill Head showing Arrangement of Spindles

The head used for this purpose is attached to and driven by an automatic dial feed drill press having power feed and quick return to the head. The machine has a turret indexing table containing twelve chucking stations evenly spaced around a circle 9.658 inches in diameter, in which the cages to be drilled are placed by the operator. The two groups of five multiple spindles and the auxiliary spindle for drilling the eleventh hole are located in the head on an arc of a circle corresponding to the circle on which the chucking stations of the indexing turret are located. As the work in the turret indexes clockwise 1/12 of a revolution after being operated upon by the first drill head, it comes under the second head, which drills five more holes; it is then indexed a second time, bringing the work under the auxiliary spindle, which drills the eleventh hole in the cage. The eleven holes are thus drilled in three operations, which are carried on successively until one cage has been completely drilled. While these operations are going on the operator has ample time to take out the cages and put in fresh blanks.

The chucking stations in the dial feed table hold the cages freely and allow a pilot to enter the bore of the cages ahead of each set of spindles, thus bringing the work into the desired alignment. The pilots for the second group of spindles, and for the auxiliary spindle, have a number of steel locating pins which project from the drill bushings and enter the holes drilled by the first operation before the second and

third operations take place. In this way, the holes drilled in the second and third operations are properly located in relation to the holes already drilled in the cages. In Fig. 1 the drills are shown projecting from the pilot simply to show where they pass through, but while clear of the work the drills are beyond the base of the pilot, as shown in the sectional view of the drill head which is presented in Fig. 3. The multiple head consists essentially of a substantial cast-iron housing which is made to clamp around a special form of saddle on the automatic drilling machine and designed to clamp tightly over a phosphor-bronze spindle head. The spindles are located on fixed centers; they are machined from solid alloy tool steel and provided at their lower ends with chucks especially designed for receiving straight shank tanged drills. Bronze and steel washers for receiving the upward thrust are used to eliminate sliding friction as much as possible. The balance head is forged integral with the main spindle of the automatic drilling machine. The auxiliary spindle at the right is driven from a cut steel gear mounted on the main spindle of the machine through an intermediate fiber gear. The drill steadyrest with hardened and ground steel guide bushings is clamped to the lower end of the drill head and supports the drills close to their cutting end to insure having them start accurately. The drills project from the guide bushings just enough to penetrate the cage to be drilled. In order to compensate for the shortening of the drills due to grinding, the drill steadyrest may be adjusted up or down over the spindle boring head.

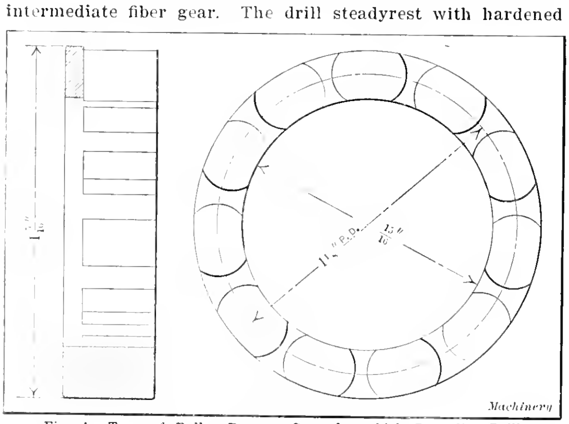

Fig. 4. Type of Roller Bearing Cage for which Langelier Drill Head was designed

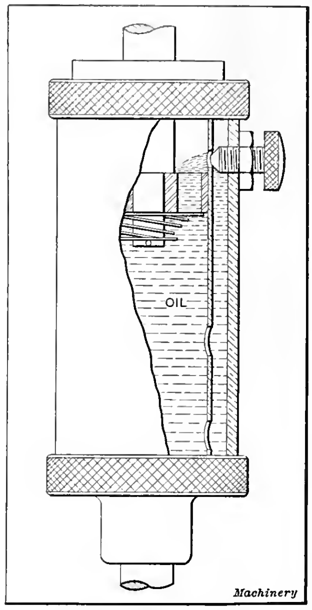
BOWDLE PUNCH PRESS SAFETY DEVICE

Power presses are generally recognized as one of the most dangerous forms of equipment used in industrial plants, and various forms of safety devices have been developed for the protection of operators of this class of machinery. The accompanying illustration shows a punch press safeguard which has recently been placed on the market by Bowdle & Co., 507 Jackson Blvd., Chicago, Ill., and it is claimed that this device will positively prevent the accidental tripping of a press. The device is connected to the rod which joins the treadle with the latch pin, a section of the rod being cut away at the point where the safeguard is attached. The illustration shows the interior construction of the device, with the different parts in position ready for operation.

The action of the safeguard may be briefly outlined as follows: A quick and decisive stroke of the treadle forces the cylinder upward, and this motion is transmitted through the oil to the piston, which, in turn, is forced up sufficiently to release the latch and allow the press to rotate. At the beginning of the pressure on the treadle, the oil starts to flow through the lower ports of the inner shell and then up through the by-pass, back into the cylinder on top of the piston. This releases the pressure below the piston, and by timing the flow of the oil by means of a cone valve in the by-pass, the piston and latch pin will resume their normal positions in time to disengage the clutch. This action is entirely independent of the action of the treadle, which may remain down. When the treadle is released, the cylinder drops back to the normal position and the oil passes down through the disk valve in the piston. In case the treadle should be pushed down in any ordinary way, instead of using a quick, decisive stroke, the oil will flow through the by-pass without imparting any motion to the piston. It is thus evident that the press can only be tripped by the deliberate act of the operator.



Bowdle Safety Device for Punch Presses

WHITCOMB-BLAISDELL TAPER TURNING LATHE

The illustrations show a lathe which has been designed by the Whitcomb-Blaisdell Machine Tool Co., Worcester, Mass., with the idea of developing a machine for taper turning operations that is capable of producing work on a manufacturing basis. The design of the machine is simple. Referring to the illustrations, it will be seen that the carriage and tool-rest are carried on the outside bed, while the inside bed carries the headstock and tailstock of the machine. The inside bed swivels on a stud at the head end of the machine and is carefully fitted to the outside bed, being supported by a broad bearing at both the head and tail end and on a cross-tie member at the center of the machine.

This lathe swings 14 inches and is built with either 5-foot or 6-foot bed, the 5-foot bed taking 2 feet between centers. Particular pains have been taken to make this a rigid and durable tool adapted for manufacturing purposes. With this idea in mind, the outside bed has been made of the dimensions used for the regular 16-inch lathes of this company's manufacture, which have exceptionally large bearings. The inside or swivel bed is of corresponding proportions, so that ample rigidity is secured. Provision is made for adjust-

ment of the swivel bed through the adjusting screws shown at the tail end of the bed in Fig. 3. On a machine with a 5-foot bed the maximum taper that can be turned is 1.6 inch to the foot.

By locating the point about which the inside bed swivels

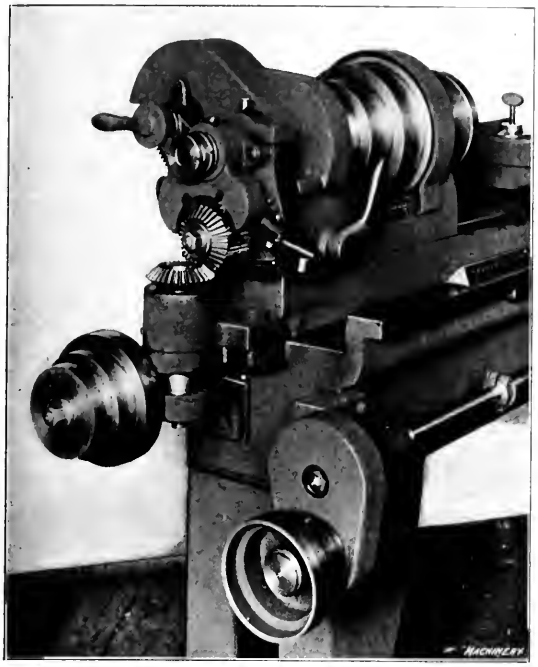


Fig. 1. Head End View of Taper Turning Lathe

at the head end of the machine, it is not necessary to change the length of the feed belt when changes are made in the feed. The feed mechanism is very simple, the feed being obtained through bevel gears and feed cones, the upper cone being driven by two spiral gears. Provision is made for adjusting the lower cone to allow for taking up the feed belt. When desired, the machine can be equipped with geared feed,

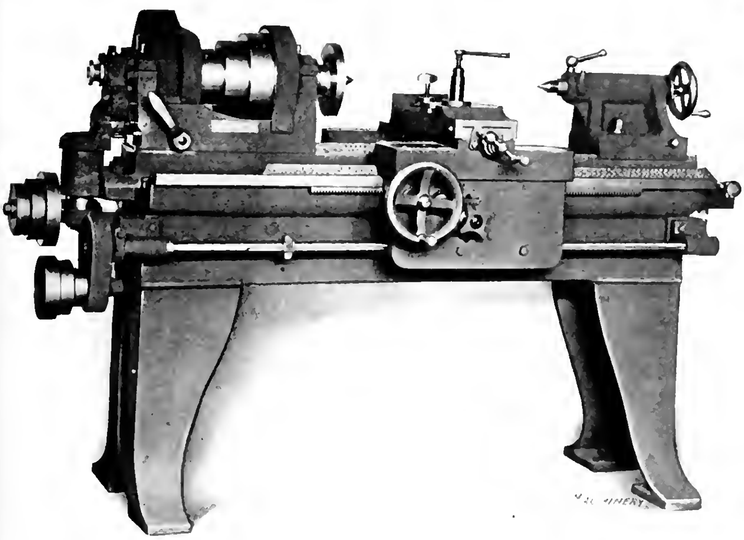

Fig. 2. Front View of Whitcomb-Blaisdell Taper Turning Lathe

providing three changes without substituting fresh gears.

The headstock on the lathe shown in the illustrations is of the three-step cone double back-geared type, giving nine spindle speeds in geometric progression. The back gears are locked in and may be shifted from the front of the machine. They are cut with a special involute cutter which gives a sharp pointed tooth, enabling them to be thrown in instantly. If desired, the machine could be furnished with a single pulley drive giving three changes through gears, the driving pulley being controlled by a powerful expanding ring friction. The tool-rest on the machine is of the elevating type which is the style regularly provided, although a plain gibbed block can be furnished if preferred. The rest is equipped with a screw gage for setting the tool, and the cross-feed is graduated to thousandths. The regular equipment

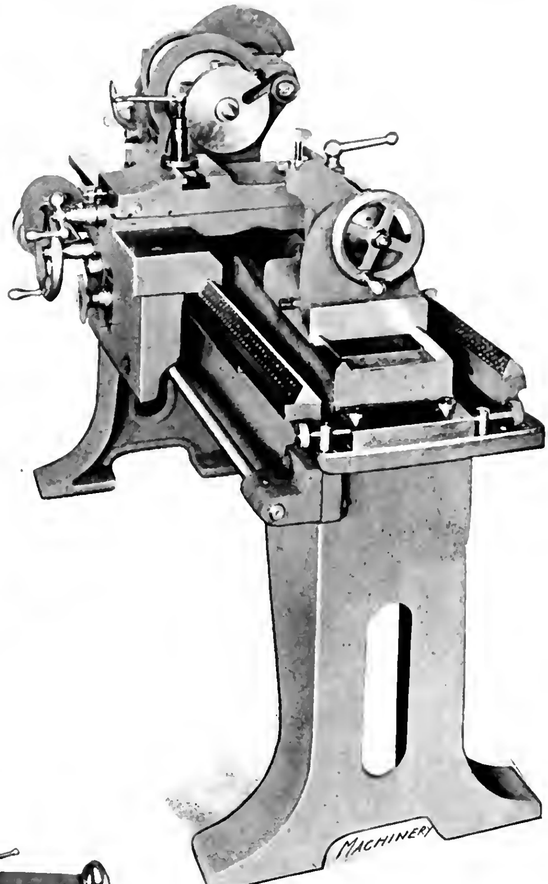

Fig. 3. Tail End of Lathe showing Bolts for clamping Inside Bed

includes an automatic stop for the longitudinal feed, a double friction countershaft and the necessary faceplates, wrenches, etc.

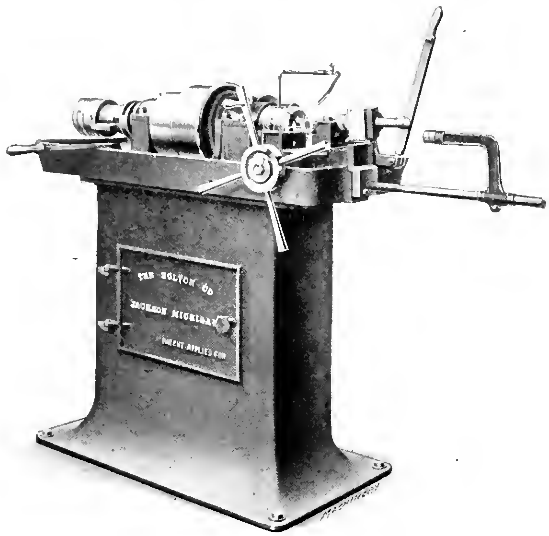
HOLTON CUTTING-OFF AND CENTERING MACHINE

The Holton Co., Jackson, Mich., has recently redesigned its cutting-off and centering machine, the improved design being shown in the accompanying illustration. The more important changes which have been made in this machine may be briefly outlined as follows: The column has been changed to the pedestal type which is more substantial and enables a tank for lubricating fluid to be contained inside the base of the machine. The improved machine has a single spindle which does away with all back gearing and a pilot wheel is provided in place of the handwheel formerly used, which enables the machine to be operated more rapidly.

This machine is designed for cutting off gas pipe, tubing and small bar stock and leaves the ends square and true. In cutting off tubing, the hole is left full size and without any burrs or other obstruction on the inside; consequently

it is unnecessary to perform a reaming operation after the stock has been cut off. Pipe or tubing can be cut to any length and as rapidly as if a rotary cutter were used. The spindle bushings are amply proportioned to insure rigidity and to withstand the most severe service to which a machine of this type should be subjected. The collets which hold the work are hardened and ground and are controlled by a lever which may be operated while the machine is working.

A new type of centering device is fitted to this cutting-off machine which makes it possible to handle centering operations most efficiently. The centering device can be attached or detached in about five minutes and if desired it may be left on the machine without interfering with cutting-off operations. The shaft to be centered revolves and the center drill and countersink are forced against it by a lever movement and then quickly withdrawn. By means of the same



Improved Type of Holton Cutting-off and Centering Machine

lever, the centering device may be drawn back on a hinged joint, leaving the front of the collet unobstructed. A long bar may be placed in the machine and pieces of any desired length may then be centered on one end and cut off. After the bar has been completely cut up, the pieces may be replaced in the collet and centered on the other end.

The oil reservoir is located directly beneath the table and can be easily cleaned by removing a plug from the bottom. The rotary pump which supplies oil or cutting compound to the tool is direct-connected to the shaft of the machine. The floor space occupied by the machine is 25 by 38 inches; the machine has a capacity for handling pipe ranging from 1/8 inch to $1\frac{1}{2}$ inch or for any size of stock up to 2 inches outside diameter. The net weight of the machine is about 950 pounds.

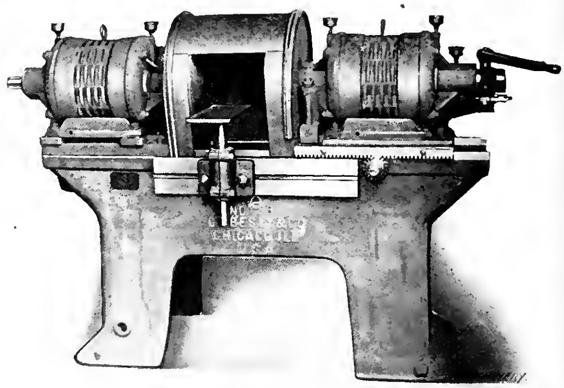
BESLY DOUBLE-SPINDLE DISK GRINDER

The illustration shows a motor-driven, double-spindle disk grinder which is a product of Charles H. Besly & Co., Chicago, Ill. This is a No. 6 machine and is equipped with 18-inch disk wheels. The double-spindle feature of this machine enables two grinding disks to be brought into contact with the work simultaneously, thus increasing the capacity and providing for grinding two surfaces of a piece exactly parallel. This type of grinder is largely used in the manufacture of wrenches, brass nuts, and for similar purposes.

The motors with which the machine is equipped are of the new pressed-steel type, which has recently been brought out by the Westinghouse Electric & Mfg. Co. These motors were described in the August issue of MACHINERY. The motors are bolted onto sub-plates, being clamped in position in a similar way to that used in securing the headstock and tailstock of a lathe. The motors develop 5 horsepower and are designed to operate at 1400 revolutions per minute on a 25-cycle, alternating-current circuit. Motors of this type can also be furnished to operate on a 60-cycle circuit. Machines equipped with these motors have disk wheels 20 inches in diameter and run at 1200 revolutions per minute, in order to give the proper abrasive speed. These disk grinders are not built with motors adapted for operation on direct-current circuits.

The left-hand head of the disk grinder is stationary, while the right-hand head can be moved along the bed by means of a gear and rack. After the head has been adjusted to the required position, it is clamped in place ready for the grinding operation. To bring the disks into contact with the work, the spindle of the right-hand head is provided with a longitudinal movement of one inch. This movement is obtained by means of a lever which actuates a rack and pinion. The rotor of the motor is displaced one-half inch from magnetic balance while grinding, but careful tests show that this displacement reduces the efficiency not more than 2 per cent, while the maximum output of the machine remains the same as when running in magnetic balance. The longitudinal movement of the sliding spindle is limited at the inner extremity of its travel by means of an adjustable micrometer stop graduated to 0.001 inch, so that the duplication of work which must be accurately ground is made possible. The work-rest is provided with vertical adjustment and is supported from a slotted pad on the front of the bed casting. The regular equipment of the machine includes ten work-rests in widths varying from 1/4 to 5 15/16 inches.

The grinder is equipped with an automatically telescoping dust hood, which is hinged at the back in order to give free access for changing the disks, and an air-tight connection in provided at the back of the machine for exhausting the grindings. The design has been worked out in such a way that a third wheel and rocker shaft may be attached to the left-hand end of the machine. A suitable work-table may be mounted on the shaft to serve the third grinding disk. The spindles are made of crucible steel and run in inserted bearing bushings of phosphor-bronze. The end thrust of the spindles is taken on hardened and ground steel collars, and the end play of the spindle is controlled by an adjustable keyed collar which is held in place by a lock-nut at the



Besly No. 6 Motor-driven Double-spindle Disk Grinder

end of the spindle. In the right-hand motor, both of the bearing bushings slide with the spindle and completely surround it; this construction reinforces the spindle when under load and protects it from emery dust. The spindle and thrust bearings are lubricated by grease from compression oil cups. The oil grooves are so placed that the oil is forced to the points where it is needed by positive feed. The movement of the grease is always outward, thus preventing grit from entering the bearings.

The geared lever feed on the sliding spindle gives the operator a leverage of 20 to 1, so that he may force the machine to the limit of its driving power without undue muscular exertion. The lever is clamped to the stud which carries the pinion engaging with the feed rack. This is an important feature of the design, because the lever may be clamped onto this stud is just the position which makes it most handy for

the workman. It is particularly desirable for this type of disk grinder to be driven by a direct-connected motor, because it is necessary to use a very large and heavy countershaft when belt drive is applied. The large size of the countershaft is mainly due to the fact that it is necessary to provide a drum pulley long enough to accommodate the full longitudinal adjustment of the movable grinder head. The countershaft employed for this size of grinder, when belt driven, is 96 inches long and weighs over 700 pounds. By using motor drive, all of these overhead works are naturally done away with. The important dimensions of the machine are as follows: Maximum opening between disk wheels, 10 inches; floor space occupied, 24 by 58 inches; weight, 2600 pounds.

CINCINNATI GEAR CUTTING MACHINE

Figs. 1 and 2 show front and rear views of the No. 7 Cincinnati automatic gear-cutting machine which has recently

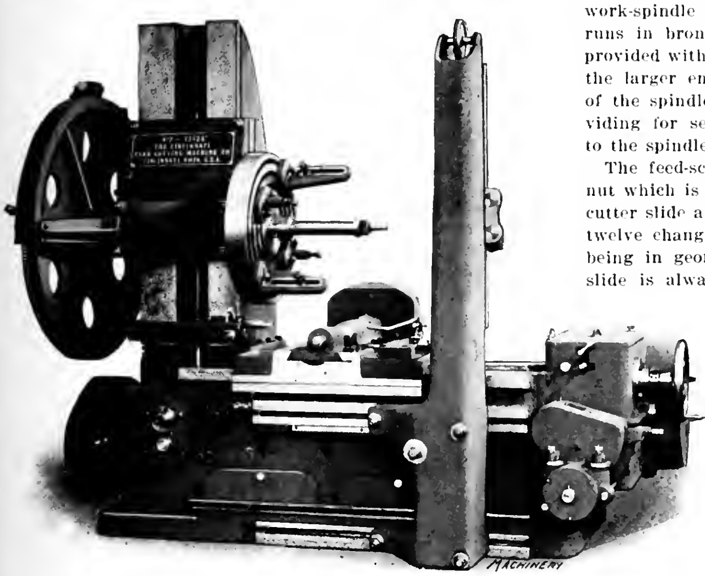


Fig. 1. Front View of Cincinnati Automatic Spur Gear Cutter

been brought out by the Cincinnati Gear Cutting Machine Co., Elam St. and Garrard Ave., Cincinnati, Ohio. This machine is designed for cutting spur gears and has a capacity for gears 72 inches in diameter by 24 inches face, being rated for cast-iron gears up to 1 diametral pitch and steel gears up to 1¼ diametral pitch. This machine is also built to cut gears 84 inches in diameter with the same face width and pitch ratings.

The bed is heavily ribbed and has rectangular guides which afford a maximum wearing surface for the cutter slide. The cutter slide has long and narrow guides provided with a handy tapered gib adjustment; three gibs are used, and as they are all located on the outside, it is an easy matter to make inspections or adjustments. The cutter spindle has both a straight and a taper bearing running in a solid bronze box. The customary bushings are eliminated, thus permitting a much larger cutter spindle to be used. The end of the spindle is No. 13 B. & S. taper and is provided with a squared recess to drive the arbor.

The positive tripping mechanism which is shown in detail in Fig. 3 is controlled by two independent shafts which are operated from the working side of the machine. These shafts are revolved by a crank-wrench; they are easily set and means are provided for holding them positively in place after the desired setting has been obtained. Brass plates are placed directly over the shafts to indicate the direction of movement of the trips. The work saddle is gibbed to the housing in such a way that loosening the clamp bolts to adjust the work does not cause the work-spindle to drop out of alignment. The saddle can be raised or lowered by either hand

Fig. 3. Positive Tripping Mechanism used on Cincinnati Gear Cutter

or power and the elevating screw for the work saddle rests on ball bearings, a micrometer dial reading to 0.001 inch being provided to enable accurate settings to be made. The work-spindle is tapered to provide for taking up wear and runs in bronze bushings. The arbor end of the spindle is provided with a special tapered hole 3.81 inches in diameter at the larger end and tapering ½ inch to the foot. The nose of the spindle is keyseated and tapped for screws, thus providing for securing a faceplate or special chucking devices to the spindle.

The feed-screw is of large diameter and runs in a bronze nut which is shielded from dirt and chips. The feeds for the cutter slide are obtained by a quick change mechanism giving twelve changes from 1 to 13 inches per minute, the changes being in geometrical progression. The return of the cutter slide is always constant. By transposing gears, the cutter spindle can be given six changes of speed ranging from 12 to 68 revolutions per minute, these changes also being in geometrical progression.

The outer work arbor support is one feature of the design of this machine. This support is made extremely heavy and is counterbalanced. A rack and pinion afford a convenient means for moving the support when chucking and taking off work. The faceplate carries two dogs and two jacks that are adjustable around the circular T-slots and radially along slots in the dogs and jacks. A safety stop of simple construction prevents the cutter slide from feeding forward until the indexing is complete, and this stop also prevents the cutter slide from being in-

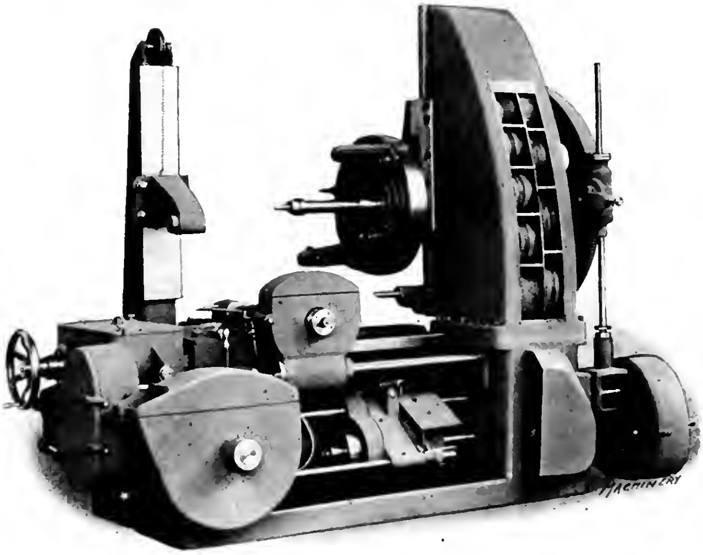

Fig. 2. Rear View of Automatic Spur Gear Cutter

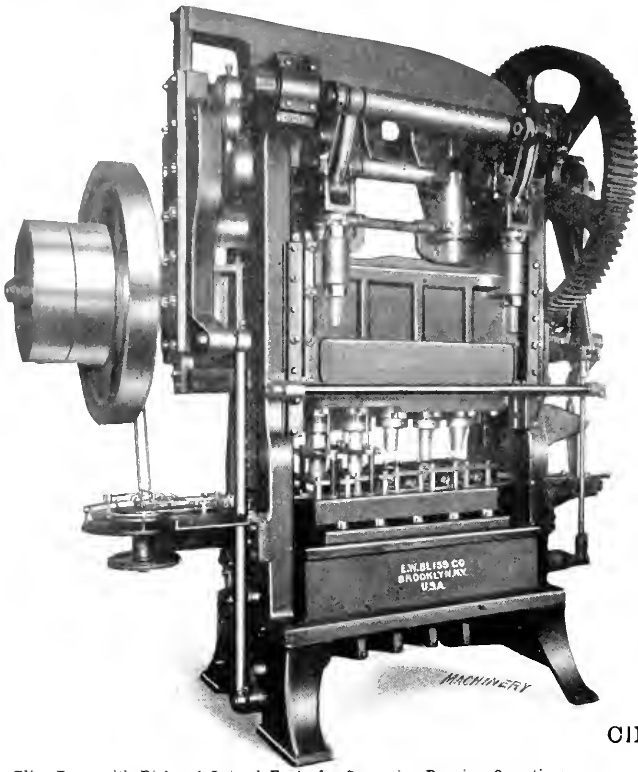
dexed by hand while the cutter is going forward. All of the shafts in the machine are shouldered and can be removed from their bearings without removing the keys and bushings

or threading keys through their slots. The machine indexes all numbers from 4 to 100 and from 100 to 450 with the exception of prime numbers and their multiples. The index wheel is 53 inches in diameter. All of the gearing in the machine is completely enclosed and the main driving gears run in an oil bath. The net weight of the machine is 19,500 pounds.



Bliss Press with Dial and Lateral Feeds for Successive Drawing Operations

BLISS PRESS WITH DIAL AND AUTOMATIC CROSS FEED

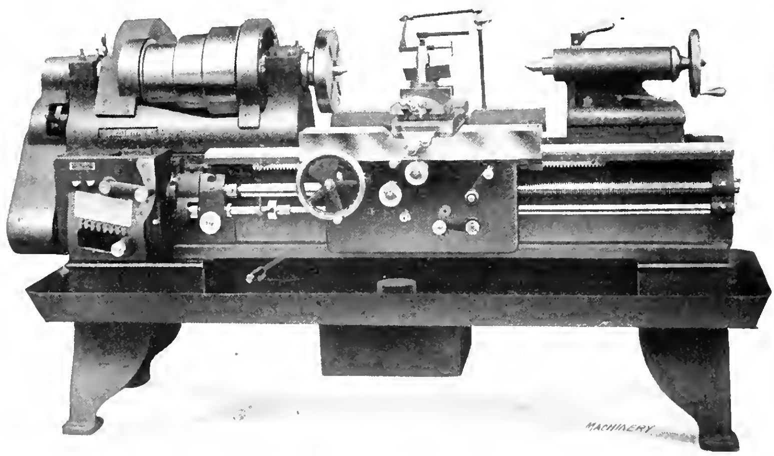
The development which has been made in methods of working sheet metal has led to the design of numerous automatic feed mechanisms for power presses as a means of increasing production. The accompanying illustration shows an automatic feed press which has recently been added to the line of the E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y. This machine is adapted for the rapid production of deep drawn, seamless shells, such as lamp and lantern bodies, oil-can bodies, drinking cups and similar articles, which require a series of drawing operations. This press is equipped with a friction dial feed and lateral carrying feed, and has five slides, each of which are independently adjustable. Five operations are performed at each revolution of the crankshaft, from which it will be evident that the output is increased and production costs correspondingly reduced over any method of doing the work in a single-slide, double-action press. Furthermore, handling of the work between operations is eliminated and a considerable saving of space is made possible, due to the fact that one press is doing the work of five single presses.

The operation of the press may be briefly described as follows: Shells which have been cut and formed from the sheet are placed on the revolving disk of the friction dial feed which carries them up and against an automatic stop gage that allows one shell to pass at each revolution of the crankshaft. On passing from the friction dial feed, the shells are gripped by the lateral feed which automatically carries them to the successive dies in which the drawing operations are performed, and finally discharges the finished piece through a chute at the right-hand end of the press. The press operates at thirty-five strokes per minute, which means 100,000 operations in a ten-hour working day.

It will be evident from the preceding description that this method of feeding work to the press does away with the danger which the operator runs in feeding work by hand, as it is merely necessary to place the shells on the revolving dial which carries them into the machine. The lateral feed has two motions—an opening and closing, and a backward and forward motion. This feed mechanism is operated by cams and links from both ends of the machine, the design affording a perfectly parallel feed motion. The bottom knock-out is cam-actuated and driven from the crankshaft through links and levers, the design being such that its travel for each slide may be different according to the depth of the drawing operation which is performed by the slide. The press is equipped with an automatic friction clutch which places its movements under practically instant control of the operator. With this type of press, the number of operations which may be performed simultaneously is only limited by the number that may be performed without annealing the work, so that wider presses having a greater number of slides could easily be used. The approximate weight of the machine with five slides, shown in the illustration, is 25,000 pounds.

CINCINNATI TOOL-ROOM LATHE WITH OIL PAN AND PUMP

The tool-room lathe equipped with an oil pan and pump which is shown in the accompanying illustration has been recently added to the line of the Cincinnati Lathe & Tool Co., Oakley, Cincinnati, Ohio. As will be seen from the halftone, the head is driven by a wide three-step cone and double back-gears, and the machine is especially adapted for heavy duty. The quill on the double back-gears is made of steel and both ends are bronze bushed. A sleeve is provided on this quill for shifting the gears from the front of the machine. When desired, this lathe can be equipped with a draw-in chuck, a relieving attachment and a taper attachment, and such attachments can be added to the machine any time that they may be required, after it has been placed in service.



Cincinnati Tool-room Lathe with Oil Pan and Pump

NEWTON 40-INCH COLD SAW

The illustrations show a 40-inch cold saw which has been added to the line of the Newton Machine Tool Works, Inc., Philadelphia, Pa. This machine has been designed especially

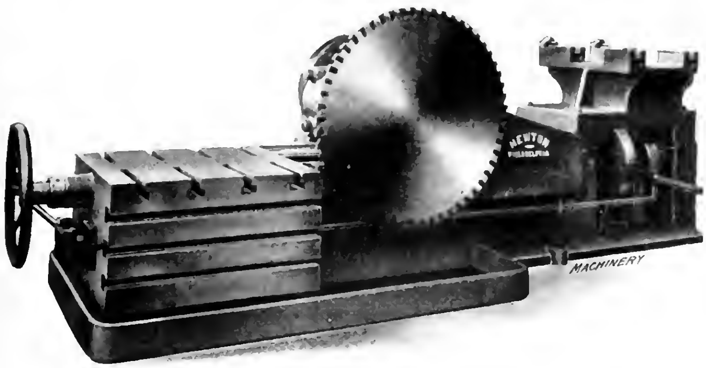


Fig. 1. Newton 40-inch Cold Saw

for use in steel foundries and for sawing operations on chilled rolls. In order to adapt it for severe service of this character, the spindle, pinion shaft and all driving gears are of exceptionally large diameter. All gears are made of alloy steel with the exception of the driving worm-wheel, which is machined from a solid bronze casting. The driving worm is

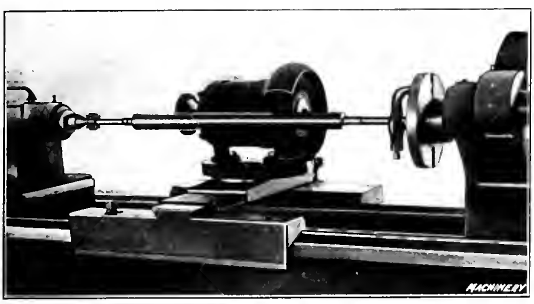

Fig. 1. Forbes & Myers Grinding Attachment in use on External Work

of hardened steel, fitted with roller thrust bearings, and the driving spline shaft is fitted with rotating auxiliary bearings, to protect the stationary bushings from the key splines and also to prevent the escape of oil. All of the bearings are bronze bushed. The spindle revolves in cap bearings and is supported at both ends.

Vertical and horizontal adjustments are made by taper shoes, and the saddle is equipped with a narrow guide bearing on the base to control its alignment and also to save power by preventing the saddle from binding on the base. In addition, the base has three shears to give an ample bearing for the saddle. The gear feed-box which is used provides six changes without requiring the removal of gears. A quick return motion is also provided which may be tripped at any predetermined point and at the end of the stroke in both directions. The entire base of the machine, including the work-table, the ways for the saddle and the extension on which the feed mechanism and motor pads are mounted, is one solid casting. This entire casting has an oil pan cast integral with it which runs all around the base. The top surface of the main work-table has T-slots running at right angles to the direction of travel, the size of the work-table being 32 by 37 inches. The vertical face of the main work-table is fitted with three T-slots in the faced portion, which is 18½ by 37 inches in size. An

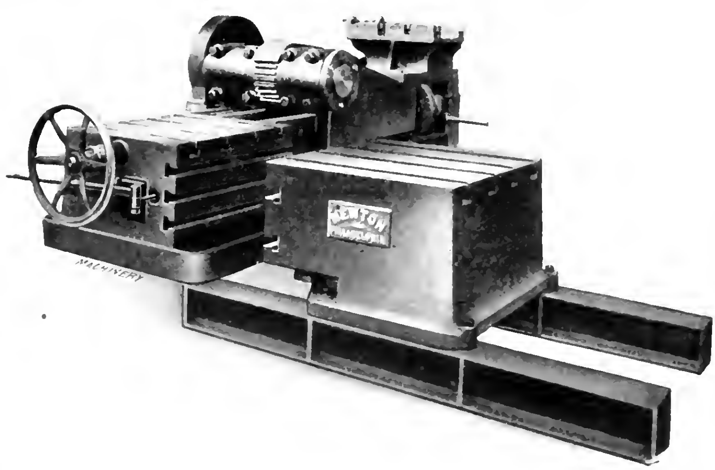

Fig. 2. Side View of Newton Cold Saw showing Auxiliary Table carried on Parallels

auxiliary table, mounted on parallels, has a top surface 36 inches square and a vertical clamping surface 24 inches deep. The use of this table is particularly convenient in handling some classes of work for which a machine of this type is used.

Particular care has been taken to obviate the possibility of "chatter" in this machine, which experience has shown to be more destructive in its effect upon saw teeth than any other defect in a cold saw. With this object in view, the feed-screw has been provided with a bearing at each end to insure having it operate in tension. The feed and fast power return are controlled from either the front or rear of the machine, which is one of the convenient features of the method of operation. A 23-horsepower motor running at 310 to 930 revolutions per minute is used for driving the machine. This motor is mounted on the bracket provided for this purpose, the motor having been removed from the machine at the time the photographs were taken. The motor transmits power to a driving pulley 30 inches in diameter by 10½ inches face.

FORBES & MYERS LATHE GRINDING ATTACHMENT

The grinding attachment for lathes illustrated herewith is a recent product of Forbes & Myers, 172 Union St., Wor-

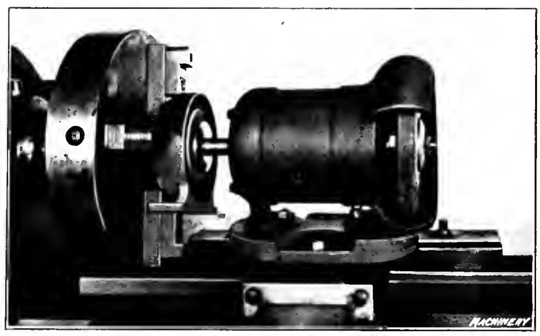

Fig. 2. Grinding Attachment working on an Internal Grinding Operation

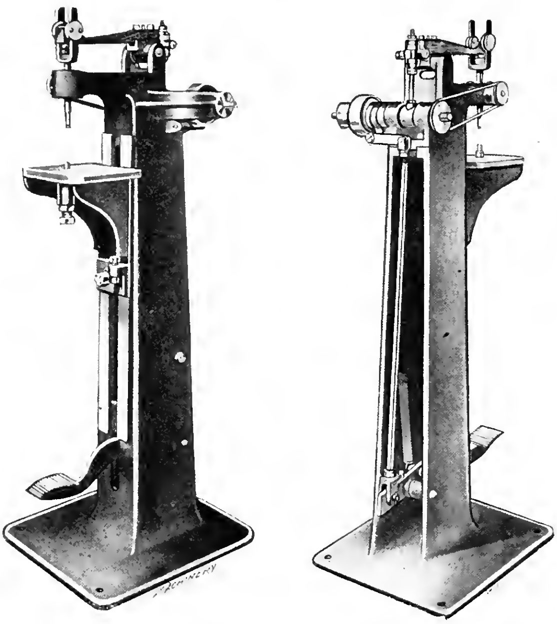
cester, Mass. It will be seen from the illustrations that this attachment is electrically driven, the armature spindle being extended at either end to enable the grinding wheels to be mounted upon it. One large wheel is provided for external work and a small wheel is carried at the opposite end of the spindle for handling internal grinding operations. This attachment is ordinarily mounted upon the tool-slide, or a

raising block made to fit special lathes may be used when such a method is more desirable.

The electric motor will give ¾ horsepower when used intermittently, as in the case of most grinding operations on lathe work. The motor is of the squirrel cage, induction type, a convenient switch being provided for starting and stopping the motor. The design of the motor has been worked out so that it is thoroughly protected against dust and grit by means of a cover which fits tightly around the shaft. The motor has no commutator, brushes, clutches or other parts which are likely to give trouble. The spindle is carried in ball bearings which insure efficient operation. The regular wheel furnished for external work is 7 inches in diameter by 1 inch face, while the internal grinding wheel is 3 inches in diameter by ½ inch face. The grain and grade of these wheels is that which experience has shown to be best suited for general classes of work, but wheels of any make or style will be furnished when so specified.

GRANT ROTARY VIBRATING RIVETER

The No. 2 rotary vibrating riveter, front and rear views of which are illustrated in Figs. 1 and 2, is a product of the Grant Mfg. & Machine Co., 80 Silliman Ave., Bridgeport, Conn. This machine has a capacity for rivets up to ¼ inch



Figs. 1 and 2. Front and Rear Views of Grant Rotary Vibrating Riveter

in diameter and has been developed for operating in close corners where it is impossible to reach the work with the regular rotating roll riveting machines of this company's manufacture. The spindle of the machine is operated through an eccentric mechanism, which is clearly shown in Fig. 2, motion being transmitted to the riveting spindle by means of a hickory helve. A rubber ball is interposed between the helve and the spindle to absorb vibration. In addition to its vibrating motion, the spindle is positively rotated by means of a worm and wheel. The worm carries a grooved pulley at one end which is driven by a round belt running over a similar pulley on the driving shaft. These pulleys are of slightly different diameters, and it is often found desirable to change them in order to vary the rotating speed of the riveting spindle.

The machine is driven by a one-inch belt which transmits power from a 10-inch pulley on the countershaft to a friction driven pulley on the machine. The pulley on the machine runs free and is engaged by a friction clutch when it is desired to operate the machine. The clutch is controlled by a foot treadle, and when this treadle is released, the pulley is once more allowed to run free, while a brake is automatically applied to the driving shaft to stop the machine almost instantly. There is also a friction stopping device connected with the machine which causes the spindle to stop at its highest point, thus permitting the work to be easily inserted or removed.

SUSPENSION BALL BEARING

Fig. 1 shows an end and sectional view of the type of ball bearing which is manufactured by the Suspension Roller Bearing Co., Sandusky, Ohio, and Fig. 2 illustrates one of these bearings mounted in a lineshaft hanger. The design of this bearing differs considerably from the form of construction which is followed by most manufacturers. Instead

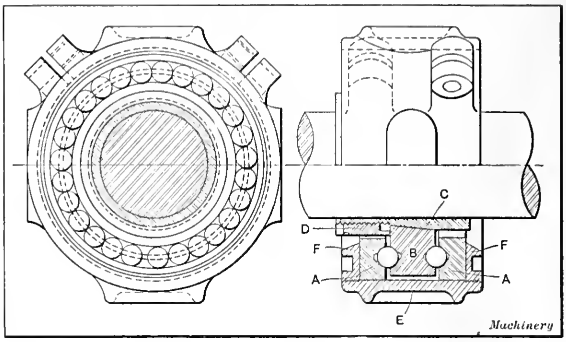


Fig. 1. End and Cross-sectional Views of Suspension Ball Bearing

of having the balls encircled by an outer race with a companion race on the inside, it will be seen that the races of this bearing consist of parallel plates A and B between which the balls are carried in race grooves. The construction is clearly illustrated in Fig. 1, where it will be seen that a collet C surrounds the shaft and holds the inner race on its tapered section. The inner race B is held in position on the tapered collet C by means of the binding nut D. The bearing is assembled in a case E in which the parts are held in place by means of the adjusting nuts F.

The construction of this bearing causes the pressure to be applied to the balls in such a way that they rotate on an axis inclined at an angle of about 45 degrees to the horizontal. In this way, the effect of radial or thrust loads upon the action of the balls is practically the same so that the

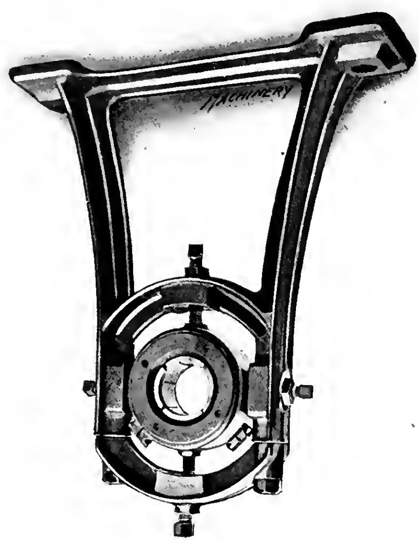

Fig. 2. Suspension Ball Bearing mounted in Lineshaft Hanger

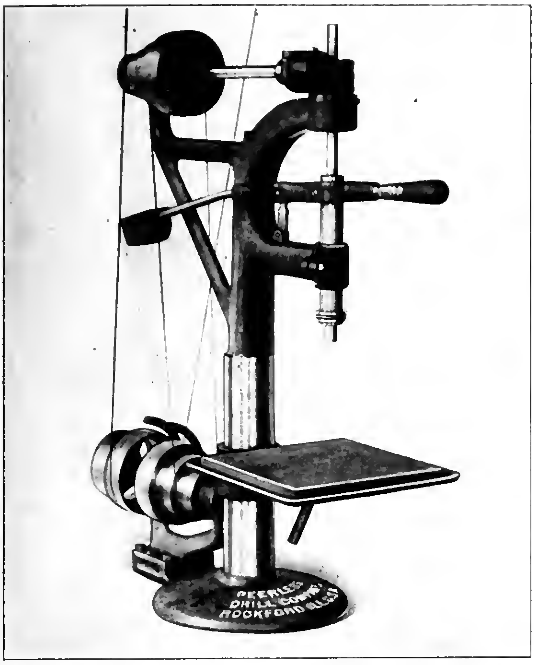
bearing has an equal capacity for supporting either kind of load. The "suspension" principle on which this bearing is designed causes the load to be distributed over all the balls in the bearing.

Fig. 2 shows the bearing supported in the style of hanger which is used for lineshaft service. It will be seen that

this hanger is provided with the usual style of adjusting screws for regulating the alignment of the shaft. The construction of the bearing case is such that it is dirt- and dust-proof and the bearing runs without requiring frequent lubrication. Enough oil is kept in the bearing case to protect the parts from rust, the oil playing little, if any, direct part in the mechanical action of the bearing.

PEERLESS TWELVE-INCH BENCH DRILL

The 12-inch ball bearing bench drill shown in this connection is a product of the Peerless Drill Co., Rockford, Ill.



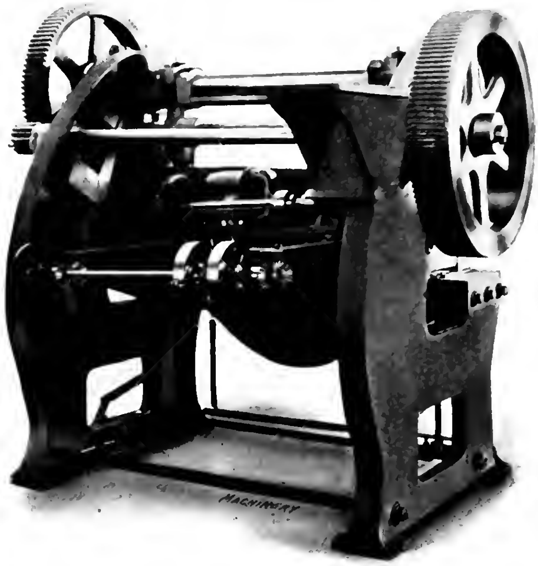
Peerless 12-inch Ball Bearing Bench Drill showing Use of Twine in Place of Driving Belts

It will be seen that this machine is equipped for hand feed, a small steel link being used between the feed lever and the frame of the machine to afford the required vertical movement for the coupling on the drill spindle bushing. The arrangement will be readily understood from the illustration, where it will be seen that the counterweight used on this machine provides for the return of the spindle when the feed lever is released. Spiral gears are used to transmit power from the pulley shaft to the drill spindle, these gears being completely enclosed. The table is of unusually large size for a machine of this type, thus affording plenty of room for any jig that may be used. An oil channel is provided which runs all the way around the table. The machine shown in the illustration is equipped with ball bearings and machines of this type are also built with plain bearings instead of the ball bearings, the style of plain bearings used being made adjustable and self-oiling.

One of these ball bearing drills was recently subjected to rather an unusual test in the manufacturers' shops. Light twine was used in place of the usual driving belts, and with this arrangement a No. 31 drill was driven through a piece of cast iron one inch in thickness in forty-five seconds. During this test the spindle was driven at 1000 revolutions per minute. The ability of the machine to do work when driven in this way shows the high degree of sensitiveness which has been attained by the manufacturer in the bearing construction.

NIAGARA SQUARING SHEAR

The power squaring shear illustrated herewith is a recent product of the Niagara Machine & Tool Works, Buffalo, N. Y. The important feature of this machine consists of a device for adjusting the back gage by means of an electric motor.



Niagara Squaring Shear with Motor-driven Back Gage Attachment

The motor used for this purpose is mounted on the back web of the bar that carries the upper knife and drives an intermediate shaft which transmits power to the bevel gear shaft by means of straight and crossed belts. The motion of the bevel gears is transmitted to the back gage by means of two feed-screws, and a reversing clutch controlled by a hand lever is provided on the pulley shaft to provide for moving the back gage to the required position. In this way the

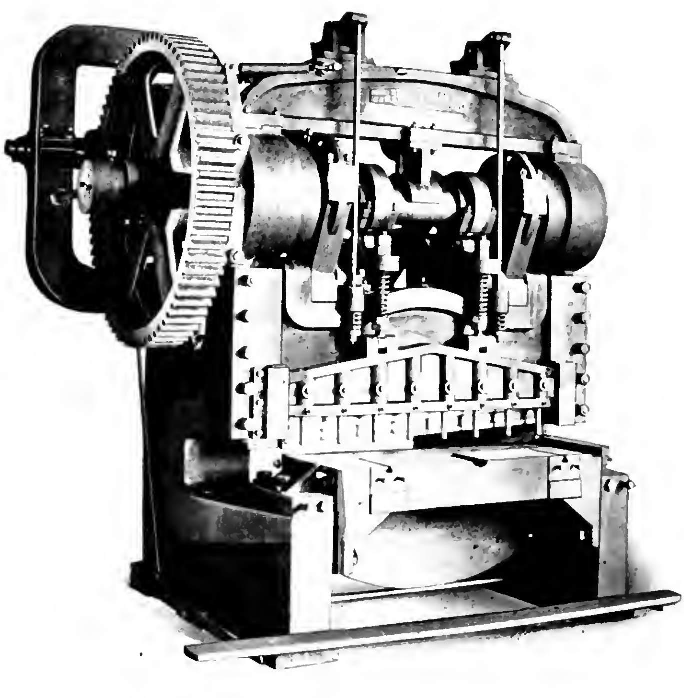


Fig. 1. Left-hand Side of Bertsch Five-foot Gate Shear

width of the stock to be cut off by the machine can easily be controlled. The back gage brackets are fastened to the

cutter bar and there is a graduated scale mounted on one of the arms to facilitate setting the gage. This attachment is of particular benefit where it is necessary to adjust the back gage frequently in order to cut strips of different widths.

BERTSCH FIVE-FOOT GATE SHEAR

Bertsch & Co., Cambridge City, Ind., have recently added to their line the five-foot gate shear shown in Figs. 1 and 2. This machine is adapted for shearing operations on plates up to 1¼ inch in thickness and is built along massive lines to adapt it for heavy work of this character. The shafts are made of forged steel and run in liberal sized bearings. All of the gears in this shear are machine cut. The clutch has steel jaws and a cast-steel switch ring which acts against a hardened tool-steel roller on the plunger. The action of the clutch is automatic and positive. In addition to the table, the machine is built with two heavy cross-tie members bolted to the end housings, one of these cross-ties being at the top and the other at the rear of the crosshead. This design adds greatly to the rigidity of the machine.

The form of hold-down used on this machine does not obstruct the shearing line in any way. The hold-down feet or gags can be easily and quickly disengaged, either for the purpose of removing the top blade or for operating the shear without a hold-down. The removal of the gags does not require the entire hold-down frame and its connections to be removed. It will be seen from the illustrations that the machine is equipped for direct motor drive. A five-foot machine is shown in the illustrations, but machines of this type are built in lengths up to 12 feet and equipped with motor, belt or hydraulic drive.

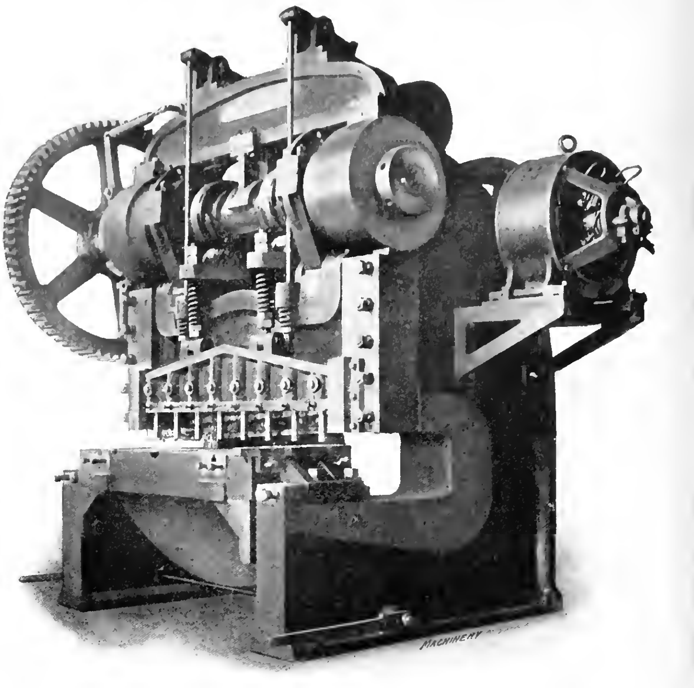

Fig. 2. Right-hand Side of Bertsch Shear showing Application of Motor Drive

NEW MACHINERY AND TOOLS NOTES

Drilling Machine: Canedy-Otto Mfg. Co., Chicago Heights, Ill. A 20-inch drilling machine, the spindle of which is 1¾ inch in diameter and provided with a No. 3 Morse taper hole. Either hand or power feed may be used as desired.

Vertical Milling Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. A milling machine especially adapted for milling railway-motor spiders; this machine may also be used to advantage for machining keyseats. In the latter operation only end mills are used.

Improvement on Cowan Transveyor: Cowan Truck Co., Holyoke, Mass. A release check for the Cowan transveyor which enables the operator to release the load independently of the handle. This check lowers the heaviest loads for which the truck is adapted without shock.

Steel Pipe Threading Die: Pipe Machinery Co., Cleveland, Ohio. A pipe threading die which will thread open-hearth steel, Bessemer steel or wrought-iron pipe with equally good results. The die is of the expanding type, the chasers being opened and closed by means of a thread movement in the die body.

Pneumatic Pyrometer: Uehling Instrument Co., Passaic, N. J. An improved type of pneumatic pyrometer adapted for furnishing a continuous autographic record. This instrument is particularly designed for use in connection with blast furnaces and can be provided in the single, double, triple or quadruple form.

Flow Meter: General Electric Co., Schenectady, N. Y. An improved type of meter adapted for measuring flow of steam, water, air and other fluids through pipes. This meter is designed to meet the demand for a strong and serviceable instrument which can be used not only as a testing instrument, but as a stationary meter for the continuous measurement of the flow of either gases, liquids or vapors delivered through the pipes in an industrial plant.

Electric Tachometer: Electric Tachometer Co., Broad and Spring Garden Sts., Philadelphia, Pa. This tachometer was originally designed for use on motor boats, aeroplanes, etc., but has been adapted for use on machine tools. It consists of a small direct-current magneto-generator and an indicating volt meter. The instrument operates on the well-known principle that when a system of coils is rotated within a permanent field, an electric voltage is generated which is proportional to the speed of rotation.

Hydraulic Forcing Press: Hydraulic Press Mfg. Co., 84 Lincoln Ave., Mount Gilead, Ohio. A hydraulic press capable of exerting pressures up to 1000 tons, which has been designed for general forcing work in the machine shop. The largest diameter which can ordinarily be handled between the strain rods of the press is 48 inches. On classes of work where a greater space is required, but where the pressure need not be excessively high, the press may be adapted for handling work up to 84 inches in diameter.

Cutter Grinder: Cincinnati Milling Machine Co., Cincinnati, Ohio. A machine which retains the features of this company's established type of cutter grinder, but in which the design has been modified to make the present type more rigid and to extend its capacity for larger sizes of cutters. The centers swing 10 inches in diameter and have a capacity for work up to 17 inches in length. The table has a longitudinal movement of 16 inches, a vertical movement of 7½ inches and a cross movement of 9½ inches.

Manufacturing Milling Machine: Cincinnati Milling Machine Co., Cincinnati, Ohio. A milling machine designed to handle the class of work for which the Lincoln type of millers has been almost exclusively used. The design of the machine has been worked out along the generally established lines followed in the construction of Lincoln millers, but has been improved in many details. It is made in three different styles which comprise a regular machine having one head and outboard support for the arbor; a duplex miller; and a machine in which the bed has been shortened and the tailstock left off, thus adapting it for face milling operations.

Double-crank Toggle Drawing Press: Ferracute Machine Co., Bridgeton, N. J. The ram is driven by toggles, actuated by a cam groove in a large gear at the left-hand side of the machine, and a yoke connected with the toggle shafts. The arrangement is such that the ram reaches its lowest position and remains stationary while the plunger completes the last half of its downward stroke and makes the first half of the return stroke, thus giving a dwell of 180 degrees to the blank-holders. The press is adapted for producing seamless work as deep as 15 inches; it exerts a pressure up to 500 tons and weighs about 135,000 pounds. Two larger and four smaller presses of the same type are being manufactured by the Ferracute Machine Co.

* * *

Moreau, a Frenchman, has succeeded in developing an aeroplane in which the difficult problem of automatic stability is practically solved. In a recent flight made under military auspices, the aeroplane remained in the air for 35 minutes during which time the pilot did not have to touch any of the steering parts; in fact, Moreau stated before ascending that he would make the entire flight with folded arms, and this condition he fulfilled.

THE EFFICIENCY ENGINEER AND THE CONTINGENT FEE

John Archibald was an efficiency engineer—at least that is what he called himself. There is no question but that he was very efficient in making his presence known whenever he was around. He made a business of placing old-fashioned plants upon a basis where they could double their dividends—at least that is what he said he did, and on the strength of what he said about himself, he was called into consultation by the owners of the Smith & Brown Co., which has done a profitable business for the last twenty-five years. The president thought that there might be something in this new efficiency hobby after all, and it might be worth while investigating.

Thus it came about that one sunny morning Mr. Archibald appeared at the Smith & Brown plant and began taking notes of the very inefficient methods that they were using; and he was quite frank about letting them know that he could see opportunities for improvement right and left. He studied the conditions for a week or so and then he made his report which was to the effect that he saw chances for decreasing costs to the extent of $40,000 or $45,000 a year. He also reported that this improvement could be made if he were hired as efficiency expert and given two assistants of ordinary training and intelligence. (Mr. Archibald's training and intelligence, it is understood by this time of course, was above the average.) He further intimated that his services would be worth $5000 a year, and as his assistants could be hired for very little money, a saving of at least $40,000 a year could be accomplished with an almost negligible initial expense. This report ought to have pleased the Smith & Brown Co., and it undoubtedly did, but the prospects of the coming prosperity somehow burst so suddenly upon the owners that they were unable to decide right away as to what to do. They agreed however, to write to Mr. Archibald within a few days stating their intentions. In a few days Mr. Archibald received the following letter from Mr. J. P. Smith, the president of the Smith & Brown Co.:

Mr. John Archibald,
24 Blank St., New York City.

Dear Sir: We have carefully considered your report regarding the possibilities for increased efficiency in our plant. We think, however, that the compensation which you expect for your services is entirely too modest and is not commensurate with the great saving that your knowledge and ability would accomplish in our plant. We therefore propose that instead of paying you a fixed salary of $5000 a year, as stated in your memorandum, we share with you the entire resulting savings of the first year, after the system which you will install has been put into operation, you receiving one-half of this saving. We think that this arrangement will be entirely agreeable to you and expect to hear from you at an early date. Yours very truly,

J. P. Smith, Pres.

It has always seemed very peculiar to Mr. Smith that he never heard from Mr. Archibald in answer to this proposition. Of course he has a high regard for Mr. Archibald's honesty and personality, seeing that he refused to accept $20,000 for his services when he, himself, had placed a value of only $5000 a year on them. But Mr. Smith's partner, Mr. Brown, who is less of an idealist, suspects that if all efficiency engineers (so-called) were to be paid on the basis proposed by Mr. Smith, there would not be one-half as many of Mr. Archibald's type running around loose as there are—but then, of course, Mr. Brown never believed in this efficiency business anyway, so his opinion is naturally prejudiced. E. O.

* * *

A quick and satisfactory method of coloring drawings requires the use of ordinary wax crayons and gasoline only. Crayon of the color desired is applied and then rubbed with a piece of cloth wet with gasoline until the color is even and extended to the limits desired. If it overruns the lines it can be erased with a pencil eraser. Some colors, particularly the yellows, purples, greens and light blues, produce much better results than others. It is believed that the gasoline dissolves the wax from the crayon, leaving the pigment as an impalpable powder, which when rubbed over the paper colors it uniformly. The method is applicable with equal success to eggshell and smooth drawing papers and to white prints on both paper and cloth.—*Engineering and Mining Journal.*

A BULLDOZER DIE

A very simple but efficient die designed and built by Williams, White & Co. of Moline, Ill., is shown in the illustration attached to one of this company's bulldozers. This die is used to bend stirrups for locomotive springs in one heat. Three strokes are required. The ends of the bar are scarfed and bent around before being placed in the bulldozer die. The first operation is bending the bar to a U shape. This is done in the right hand part of the die. Next one leg

Bulldozer equipped with Die for forming Locomotive Spring Stirrups

of the U is bent at right angles across the top, in the left-hand part of the die; then a piece *A* is removed from the traveling die equal to the thickness of the stock. The incompleted stirrup is now turned over on the same part of the die and the other leg is bent across the top, thus completing the stirrup as shown at *B*. The stock is spring steel, 5/8 inch by 2 inches, and the stirrup when completed is about 6 1/4 inches by 11 inches over all. The machine runs at ten strokes per minute and three strokes are caught in succession for bending a stirrup.

* * *

STEEL FOR PERMANENT MAGNETS

Steel containing 5 1/2 per cent tungsten makes excellent permanent magnets. The steel should be heated above the recalescence point and when quenched should show a fine-grained fracture. After magnetizing a magnet should be "aged" by prolonged heating in boiling water or steam. A short bar magnet tends to lose its magnetism quickly; the coefficient of demagnetization for a bar magnet twenty-five diameters in length is 0.05 while that of a magnet five diameters long is 0.5, or ten times as great. A bar magnet five hundred diameters long is supposed to be permanent. The magnetic force of the best magnets is considered by Prof. S. P. Thompson to be only 60 to 80 per cent of what may be eventually attained.

* * *

MOVING PICTURE TARGETS

New zest has been given to shooting in rifle galleries by the introduction of moving pictures as targets. The apparatus projects animals, birds, vehicles, etc., in rapid motion on the screen, and by ingenious means the marksman is shown how close his shots come to the object aimed at. At least two systems have been developed for registering hits on moving pictures, description of one of which, taken from the *Saturday Evening Post*, is substantially as follows: For the success of the apparatus it is essential that means be provided for stopping the film when a shot is fired. Without such control it would be impossible to determine accurately where the bullet struck and consequently the principal element of rifle-range pleasure would be lost. The sound of the shot stops the film automatically. A delicate microphone that responds to any sound is violently vibrated by the sound of the shot and the vibration causes it to throw on an electric current which puts brakes on the moving picture machine, or in other words to press a button and stop the machine. The stop is almost

PLAIN GRINDING MACHINE

NOTE how quickly and easily the operator can make feed and speed changes without leaving his position, or without shifting belts. To obtain any one of the available speeds or feeds he simply shifts an index slide and moves a lever as far as it will go. Consider what a saving in time this means on manufacturing work. Duplicate pieces having several different diameters can be ground more rapidly, since the correct speed and feed for each diameter can be instantly obtained. When changing from one job to another the speed and feed is also quickly and easily adjusted. Any change of feed can be made without stopping the wheel or table. The operator is also able by the simple movement of a lever to change from a fast feed for roughing to a slow feed for finishing, without disturbing the setting of the feed levers. All changes of wheel speed are made on the machine, by means of split pulleys of various diameters which are readily changed without removing the belt.

RESULT OF THE NEW DESIGN
EASIER OPERATION—INCREASED PRODUCTION

Read Page 75

instantaneous. Often the stop comes on the next picture succeeding the one fired at, but as the pictures succeed one another at the rate of sixteen a second, the difference between them is slight and the following picture shows closely enough the location of the illuminated bullet hole in relation to the object fired at.

The construction of the screen is ingenious. It is made of three thicknesses of heavy paper. One thickness of paper unwinds from a roll of paper at the top of the screen and winds up on a roll at the bottom and these rolls are given a slight turn occasionally by an attendant. The other two thicknesses slowly but continuously unwind from rolls on one side and wind up on rolls on the other side, but they travel in opposite directions. A few seconds after the shot has penetrated the sheets, the movements have automatically closed the hole. Back of the screen is an electric light so placed as to be out of the range of shots and still shine through the hole in the sheet and thus disclose its location relative to the arrested picture on the screen.

The chief difficulty met with in the operation of these machines has been to prevent the film from catching fire when stopped. A fan is provided to blow the hot air away from the film when it stops and thus prevent the temperature rising to the igniting point.

* * *

PERSONALS

E. F. Lake, who conducted a metallurgical engineering business in Bayonne, N. J., has moved the same to 1453 Waterloo St., Detroit, Mich.

J. E. MacArthur of the Pierce Arrow Motor Car Co., Buffalo, N. Y., has resigned his position to become superintendent of the Keystone Mfg. Co. of Buffalo.

William H. MacGregor, president and general manager of the National Twist Drill & Tool Co., Detroit, Mich., recently returned from a two months' business and pleasure trip in Europe.

W. G. Dunkley of Salford, Manchester, England, an occasional contributor to MACHINERY, has received the Bachelor of Science degree in engineering at London University as an external student.

A. M. Powell, president of the Powell Machine Co., Fitchburg, Mass., returned from a European trip on the *Laconia* August 19. Mr. Powell made the trip abroad in the interest of the Powell "Hy-Speed-Cut" planer.

John Goetz has been appointed superintendent of the Kempsmith Mfg. Co., Milwaukee, Wis., manufacturer of milling machines. Mr. Goetz was for several years in charge of the company's tool-room and light manufacturing operations.

C. R. Burt has resigned the position of superintendent of the Barber-Colman Co., Rockford, Ill., and becomes factory manager of the Russel Motor Car Co., Toronto, Ontario, Canada, September 1. E. W. Billings, formerly general foreman, succeeds Mr. Burt as superintendent of the Barber-Colman Co., and F. G. Hoffman will have charge of sales of small tools and the machine tool departments.

Prof. Albert Sauveur of Harvard University, Cambridge, Mass., has been awarded the Elliott Cresson gold medal by the Franklin Institute of the State of Pennsylvania, acting through its committee on Science and the Arts, in recognition of his numerous and important contributions to the science of metallography and the influence he has exerted in bringing this science into practical and useful application in the iron and steel industry.

Charles H. Moyer, for twenty years traveling manager of the George V. Cresson Co., Philadelphia, and of its successor, the Cresson-Morris Co., for the last three months, has resigned his position. Mr. Moyer, who is widely known as a specialist in power transmission machinery, was connected with the George V. Cresson Co. since boyhood and held various positions at the works before opening the New York office. He contemplates going into business as a special engineering representative and manufacturers' agent, with an office at 90 West St., New York City.

Dr. W. H. Tolman sailed for Europe July 29. The United States State Department has accredited Dr. Tolman as a delegate to the Tenth International Housing Congress which will meet at The Hague September 8, 1913. He is also the secretary of the American Section of the Congress. Dr. Tolman will go directly to London in the interest of the International Exposition of Safety and Sanitation to be held in New York City next December under the auspices of the American Museum of Safety; while in England he will seek to obtain exhibits, particularly such as will show the work done by the factory inspection section of the Home Office in the prevention of occupational diseases and industrial poisons.

Isaac P. Richards

Samuel Porcher has been appointed purchasing agent of the Pennsylvania Railroad system, succeeding Daniel S. Newhall, who died July 12 after having been in the company's service thirty-one years. Mr. Porcher is a graduate of the University of Virginia and entered the machine shops of the company in 1882. He went through a full shop course and was transferred from the mechanical engineer's office to the office of the superintendent of motive power in Jersey City in 1888. In that year he was appointed assistant engineer, motive power department, United Railroads of New Jersey Division, in which position he remained until 1894, when he was made assistant purchasing agent of the Pennsylvania Railroad Co.

Samuel S. Eveland of the Eveland Engineering & Mfg. Co., Philadelphia, Pa., owner of the Hunter and other tractor truck patents, covering the use of two-, three- and four-wheel tractors with fire apparatus, wagons, trucks, etc., has closed a contract with the Martin Tractor Co., Springfield, Mass., and has become identified with that company. The president of the Martin Tractor Co. is Harry G. Fiske of the Fiske Rubber Co. Under the agreement, all the patents of the Martin Tractor Co. and those transferred by Mr. Eveland are consolidated under one control. The Martin Tractor Co. will immediately erect a factory for the manufacture of tractor trucks for the trade. The Knox Co. of Springfield, Mass. will continue to make them under a license agreement.

* * *

OBITUARIES

Isadore Van Huffel, who has been in the employment of the Dodge Mfg. Co., Mishawaka, Ind., for about thirty-five years, died August 4. For almost twenty-five years Mr. Van Huffel has had charge of the paint and oil department of this company. He was born November 19, 1842, in Belgium, and came to this country forty-one years ago. He resided in Mishawaka ever since his arrival in the United States.

ISAAC P. RICHARDS

Isaac P. Richards, president of the I. P. Richards Co., Providence, R. I., died July 18. Mr. Richards was born in Ashford, Conn., June 15, 1834. At the age of seven, he was put on a farm in Pomfret, Conn., where he worked for eight years for board and clothes. He received a country schooling by doing chores late at night. Later he worked on farms at various places in Connecticut, until at the age of seventeen, he went to Plantsville, working for the Plants Mfg. Co. Returning to the farm for a couple of years, he began, in 1853, to learn the machinists' trade in the shop of Paul Whitin & Son. In April, 1856, he finished his apprenticeship, during which he had received $2 a week, out of which he had paid $1.88 for board. He worked now for two years in Whitinsville, Mass., and in 1858 he went to Providence to work for W. T. Nicholson and later for J. R. Brown & Sharpe. He moved about during the next few years, and in 1864 went back to Whitinsville to take charge of the screw department. In 1867 he was granted a patent for a spindle boylster. In 1869 he patented an improvement in punches for iron and steel, and two years later he went to Providence to manufacture these punches in the machine shop of W. T. Nicholson. In 1885 he built his own shop at 23 Pemberton St., Providence, for the manufacture of punches and dies. The business was incorporated in 1908. The quality of the punches which Mr. Richards manufactured is well known all over the country. His motto was "Quality" and he wanted everybody to live up to it.

COMING EVENTS

September 18-20.—Eighth annual convention of the Federation of Trade Press Associations in the United States, at the Hotel Astor, New York City. W. H. Ukers, chairman of the committee of arrangements, 79 Wall St., New York City.

October 7-10.—Convention of American Society of Municipal Improvements in Wilmington, Del. George H. McGovern, secretary, Chambers of Commerce, Wilmington, Del.

October 10-17.—Eighth annual foundry and machine exhibition in the International Amphitheater Bldg., Chicago, Ill. This exhibit, which was started eight years ago to show foundry equipment only, has broadened out considerably in the past few years and now includes all classes of machine tools and shop equipment as well as foundry equipment and supplies. One hundred and eight concerns were represented in the exhibition held in Buffalo, N. Y., last year and over one hundred and twenty-five concerns have taken space for this year and two hundred are expected. C. E. Hoyt, secretary, Lewis Institute Bldg., Chicago, Ill.

October 13-17.—Annual convention of the American Institute of Metals at Chicago, Ill. W. M. Corse, secretary, Lumen Bearing Co., Buffalo, N. Y.

October 14-16.—Annual convention of the Allied Foundrymen's Association. Hotel La Salle, headquarters. Richard Moldenke, Watchung, N. J., secretary.

October 19-25.—Seventh annual convention of the National Society for the Promotion of Industrial Education, in Grand Rapids, Mich. The convention promises to be the greatest yet held by the society in point of attendance, importance of questions to be discussed and interest in the work. C. A. Prosser, secretary, 105 East 22nd St., New York City.

October 20-26.—Convention of the American Mining Congress in Horticultural Hall, Philadelphia, Pa. James F. Callbreath, secretary, Munsey Bldg., Washington, D. C.

December 3-6.—Annual meeting of the American Society of Mechanical Engineers. Headquarters Engineers Bldg. 29 West 39th St., New York City. Calvin W. Rice, secretary.

December 11-20.—First International Exposition of Safety and Sanitation under the auspices of the American Museum of Safety, 29 W. 39th St., New York City. Dr. William H. Tolman, director. Safety and health in every branch of American industrial life—manufacturing, trade, transportation on land and sea, business and engineering, in all of their subdivisions, will be represented at this exposition. Exhibits from Europe and other foreign countries will be admitted free of duty by special act of Congress. European employers have cut their accident and death rate in half by a persistent campaign of safety. There are twenty-one museums of safety in Europe, and all these will contribute to the American Exposition.

NEW BOOKS AND PAMPHLETS

Reinforced Concrete Wall Footings and Column Footings. By Arthur N. Talbot. Published by the University of Illinois, Urbana, Ill., as Bulletin No. 67. Price, 50 cents.

Progress Reports of Experiments in Dust Prevention and Road Preservation, 1912. 51 pages, 6 by 9 inches. Published by the U. S. Department of Agriculture, Washington, D. C., as Circular No. 99.

Investigations of Detonators and Electric Detonators. By Clarence Hall and Spencer P. Howell. 73 pages, 6 by 9 inches. Illustrated. Published by Department of Interior, Bureau of Mines, Washington, D. C., as Bulletin 59.

First Series of Coal-Dust Explosion Tests in the Experimental Mine. By George S. Rice, L. M. Jones, J. K. Clement and W. L. Egy. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Bulletin No. 56.

The Determination of Internal Temperature Range in Concrete Arch Bridges. By C. S. Nichols and C. B. McCullough. 101 pages, 6 by 9 inches. Published by the Iowa State College of Agriculture and Mechanic Arts, Ames, Iowa, as Bulletin No. 30.

Theory of Loads on Pipes in Ditches and Tests of Cement and Clay Drain Tile and Sewer Pipe. By A. Marston and A. O. Anderson. 181 pages, 6 by 9 inches. Published by the Iowa State College of Agriculture and Mechanic Arts, Ames, Iowa, as Bulletin No. 31.

Legal Specifications for Illuminating Gas. By E. B. Rosa and R. S. McBride. 31 pages, 7 by 10 inches. Published by Department of Commerce, Washington, D. C., as Bulletin No. 14 of the Technologic Papers of the Bureau of Standards. S.W. Stratton, director.

Determination of Phosphorus in Steels Containing Vanadium. By J. R. Cain and F. H. Tucker. 11 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Bulletin No. 24 of the Technologic Papers of the Bureau of Standards. S. W. Stratton, director.

Logarithms for Beginners. By Charles N. Pickworth. 49 pages, $4\frac{3}{4}$ by $7\frac{1}{4}$ inches. Published in America by the D. Van Nostrand Co., New York City. Price, 50 cents.

This little book gives a more detailed and practical explanation of logarithms and their various applications than is to be found in most mathematical text-books. The present edition is the fourth, and a table of hyperbolic logarithms has been added which will make the work of still greater value.

The Boy Mechanic. 469 pages, $7\frac{1}{2}$ by $9\frac{1}{2}$ inches. 800 illustrations. Published by Popular Mechanics Co., Chicago, Ill. Price $1.50.

This work for boys, amateurs and all interested in construction and operation of machinery, scientific apparatus, etc., was compiled largely from the "Popular Mechanics Magazine." Seven hundred articles tell how to construct wireless outfits, boats, camp equipment, aerial gliders, self-propelled vehicles, engines, motors, electrical apparatus, cameras and hundreds of other things. The book is one that will be highly appreciated by the average boy as a birthday or Christmas gift.

Journal of the Municipal School of Technology, Manchester. Vol. 6. Containing a record of investigations undertaken by members of the teaching staff and students of the school. Published by the University of Manchester, Manchester, England.

The volume contains, among other valuable contributions, a paper on cutting tools, by Dempster Smith, which will be found of interest to all concerned with the design and operation of machine tools. The paper reviews the experimental investigations of forces acting on cutting tools of the form best adapted for durability. It also reviews some durability experiments. The paper covers fifty-three pages of the volume and is illustrated with folding charts, diagrams and halftones.

The Gas Engine Handbook. By E. W. Roberts. 323 pages, $4\frac{1}{4}$ by 7 inches. 85 illustrations. Published by the Gas Engine Publishing Co., Cincinnati, Ohio. Price $2.00.

This is the seventh edition of a handbook which was first published in 1900. The new edition is entirely rewritten and the subjects are treated from the standpoint of the latest practice in this field. The book throughout is practical rather than theoretical in its nature. The principles of operation of the various cycles of gas engines are first dealt with, after which the gas engine fuels, the mechanism of the gas engine and the various details of gas engine construction are described. The book is divided into three parts, the first section being mainly descriptive, while the second part deals specifically with the design of gas engines, chapters being devoted to each detail of the engine. Besides the descriptive section and that on design, about fifty pages of the book are devoted to the operation and testing of gas engines, and suggestions are also given for selecting an engine to fit the requirements of the buyer.

NEW CATALOGUES AND CIRCULARS

Ohio Valley Pulley Works, Maysville, Ky. Card advertising "Limestone" pulleys.

T. W. G. Cook, 88-90 Walker St., New York City. Circular advertising presses, dies, molds and patterns.

Production Engineering Co., 1716 Spring Garden St., Philadelphia, Pa. Circular advertising structural steel column crane.

Rockford Iron Works, Rockford, Ill. Folder advertising high-duty Rockford punch presses and illustrating the company's patented automatic brake.

H. Bickford & Co., Lakeport, N. H. Circular illustrating and giving general dimensions of motor-driven boring and turning mills in from 4- to 7-foot sizes.

Adolph Muehlmatt, Fifth Ave. and Elm St., Cincinnati, Ohio. Circular of the "Rex" universal ball vise for tool-makers, die-sinkers, stamp-cutters, mold-makers, etc.

Sprague Electric Works of General Electric Co., 527-531 West 34th St., New York City. Bulletin of motor-driven exhaust fan outfits with direct- and alternating-current motors.

Chicago Pneumatic Tool Co., 1010 Fisher Bldg., Chicago, Ill. Bulletin E-29 (superseding E-24) and 34-B on Duntley electric grinders, heavy-duty portable type and "Chicago Pneumatic" power-driven compressors, respectively.

George Von Rottweiler, chief engineer, Western Metal Products Co., Inc., Waterloo, Iowa. Pamphlet entitled "Draftsmanship and Mechanical Engineering," advertising correspondence school course in mechanical drawing.

Brown Hoisting Machinery Co., Cleveland, Ohio. Catalogue K, 1913, on Brownhoist locomotive crane with grab bucket. The catalogue contains numerous illustrations showing the application of the crane in various industries.

James Rees & Sons Co., Pittsburg, Pa., builder of engines, boilers and steamboats. Catalogue of the various products of the company, showing interesting illustrations of the development of river steamboats in the United States.

Chicago Pneumatic Tool Co., Fisher Bldg., Chicago, Ill. Bulletin No. 34R on enclosed self-oiling, single-stage, steam and belt-driven compressors. Also Catalogue No. 43 illustrating and describing "Rockford" railway motor cars.

National Tube Co., Frick Bldg., Pittsburg, Pa. Booklet on "Kewanee" pipe unions, hose unions, air pump unions, flange unions, union ells, union tees, boiler couplings, ball joints, boiler fittings, brass cocks, check valves, globe valves, etc.

Duryea Motor Co., Saginaw, Mich. Leaflet containing testimonials from various users of the company's product, and also a number of reprints from various publications bearing on the subjects of the two-cycle motor, air-cooling and similar features.

U. S. Electrical Mfg. Co., 459-461 East Third St., Los Angeles, Cal. Bulletin "A" illustrating and describing type "FR" constant speed polyphase induction motors from $\frac{1}{4}$ to 15 horsepower. Also circular showing in line engravings the design of the type "FR" motor.

Dodge Mfg. Co., Mishawaka, Ind. Catalogue D-Z 25 on the Dodge-Zimmer conveyor, intended for economical transportation of raw, finished and waste materials. The catalogue is illustrated with excellent halftones and line engravings showing many different applications of the conveyor.

Berger Mfg. Co., Canton, Ohio. Catalogue of sheet metal products including roofing, siding, eaves troughs, conductor pipe, gutters, ventilators, skylights, metal ceilings, metal furniture, metal lumber, metal stock room equipment, cornices, finials, reinforcing and furring plates, metal lathes, metal shingles, tin plate, metal tile, etc.

Tate, Jones & Co., Inc., Pittsburg, Pa. Circular No. 142 entitled "Fuel Oil Data." The circular contains considerable information for those who use fuel oil, particularly for metal heating, tempering, etc. Much of the data is carefully tabulated, and a great deal of information is given on the heating values of various fuels.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. Booklet illustrating and describing electrical equipment for automobiles. Folder of Westinghouse 3-inch meters. Pamphlet entitled "Small Motors," showing their application to washing machines. Circular illustrating and describing squirrel-cage induction motors.

General Electric Co., Schenectady, N. Y. Bulletins Nos. A4093, on Generators for Electrolytic Work; A4124, on Automatic Starters for Alternating-Current Motors; A4130, on Adjustable Speed Direct-current Motors; A4135, on Lightning Arresters for Electric Railways; and A4139, on Central Station Oil Switches of High Rupturing Capacity.

Atlas Ball Co., 203 Glenwood Ave., Philadelphia, Pa. Circular of Atlas ball gages for measuring internal diameters ranging from $\frac{1}{4}$ inch to 2 inches diameter. The gages consist of steel balls, guaranteed accurate within 0.0001 inch and electrically welded to suitable handles. These gages are furnished in various combinations according to the wants of users.

Michigan College of Mines, Houghton, Mich. Year book for 1912-1913 and announcement of courses for 1913-1914. The book, comprising 130 pages, gives a mass of information for prospective students, and a program for the year 1913 and 1914. Complete information is contained regarding admission to the college, either on certificate from accredited schools or by examination.

Lapointe Machine Tool Co., Hudson, Mass. Bulletin No. 13 illustrating and describing the Lapointe broaching machines, and giving, in addition, brief descriptions of work done on these machines, the descriptions being illustrated both with halftones and line engravings. Many interesting illustrations of broaching operations of difficult work are shown, and a table of dimensions of Lapointe standard cutter bars is included.

Garvin Machine Co., Spring and Varick Sts., New York City. Catalogue illustrating and giving the dimensions of wrenchless chucks. In addition, the catalogue contains a number of illustrations with accompanying description relating to the operation of Garvin turret machinery. The chucks are operated on two systems: compressed air and spring power. The air system is recommended as being the most powerful and convenient.

Suspension Roller Bearing Co., Sandusky, Ohio. Catalogue illustrating and describing Boyer suspension ball bearings. The catalogue contains a description of the method of construction of these bearings, calling attention to their advantages and the particular services for which they are suited. It also illustrates hangers provided with these ball bearings and gives tables and dimensions and load capacities of bearings for combined radial and thrust loads as well as for plain and grooved ball thrust bearings.

Standard Electric Tool Co., Cincinnati, Ohio. Bulletin U8, superseding Bulletin U7 on standard high-power universal portable electric drills operating on both direct current and alternating current. These drills can run from a lamp socket or power circuit, using either alternating or direct current of the same voltage. It is claimed that they operate satisfactorily on low frequency circuits from 0 to 60 cycles without any special feature or change in winding. These electric drills are furnished in seven sizes, having a capacity in steel ranging from $\frac{1}{4}$ inch to $1\frac{1}{4}$ inch, respectively.

Peck, Stow & Wilcox Co., Southington, Conn. Catalogue 10-A of P. S. & W. tinsmiths' tools and machines, comprising squaring shears, curved shears, slitting shears, scroll shears, parallel shears, circular shears, cornice brakes, folding machines, forming machines, brace and wire benders, grooving machines, turning machines, burring machines, wiring machines, elbow-edging machines, setting down machines, beading machines, swages, stovepipe crimpers and beaders, corrugating machines, gutter machines, double-seaming machines, elbow seam closers, tucking machines, punches, wire feed and cutter, tinners' hand shears or snips, stake-holders, stakes, shear-holders, vises, roofing tongs, cross-lock seamers, hammers, soldering coppers, etc.

TRADE NOTES

Benson Brothers, 51-53 Druitt St., Sydney, Australia, dealers in American tools, would like to receive catalogues from American machine tool builders who are not represented in Australia.

Ferracute Machine Co., Bridgeton, N. J., celebrated its semi-centennial August 16 by a garden party given by President Oberlin Smith and wife at their home "Lochwold" adjoining the works.

Goldschmidt Thermit Co., 90 West St., New York City, announces that the San Francisco office of the company has been removed from 432-436 Folsom St. to 329-333 Folsom St.

MACHINERY

OCTOBER, 1913

WORK HOLDING ARBORS AND METHODS FOR TURNING OPERATIONS

A TYPICAL COLLECTION OF DEVICES ESPECIALLY DESIGNED FOR HOLDING WORK IN THE FAY AUTOMATIC LATHE

THE developments in the design of machine tools during the last ten or fifteen years have brought these machines to a high degree of perfection. Many are provided with features which make great precision possible, and a workman who understands how to get the most out of one of these modern machine tools can produce very accurate work. It should be remembered, however, that no matter how accurate and how well adapted to rapid production the machine may be, if the methods of holding the work are not equally well thought out there is comparatively little gained. As a matter of fact, this point is neglected in a great many machine shops. In a few instances, we find planning departments and efficient tool-designing departments where the methods and appliances to be used in manufacturing are carefully considered. In the majority of shops, however, the workmen, or at best the foremen, are left to devise for themselves the methods by which the work is to be held in the machines. In the few cases where the workman is unusually ingenious, this may be of advantage, but it is seldom possible for the man at the machine to consider both the accuracy required and the rapidity of production with anything like the care that can be done by a designer especially detailed to do this work.

Therefore, it is becoming generally recognized that in order to take advantage of the full capacity and adaptability of modern machine tools, it is necessary that the work-holding and machining methods be worked out by designers of equal ability to those who actually design the machine. In the following article a few methods will be shown for holding different classes of work for turning and facing operations in the lathe. The arbors and devices shown were designed under the direction of Mr. Ralph E. Flanders of the Jones & Lamson Machine Co., Springfield, Vt., for use in the Fay automatic lathe; but as far as the methods for holding the work are concerned, they may be employed with equal advantage in any engine lathe, and are therefore capable of wide application. The tooling arrangements shown in each case are, of course, especially adapted to the Fay automatic lathe with its front and rear tool-holders, but by means of a special tool-block many engine lathes could be rigged up to perform the work in a similar manner. These tooling arrangements will probably suggest other machining methods.

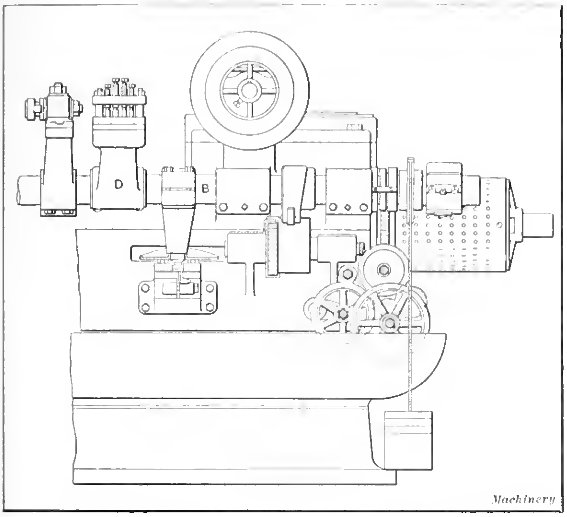

Fig. 1. Rear View of Head End of Fay Automatic Lathe

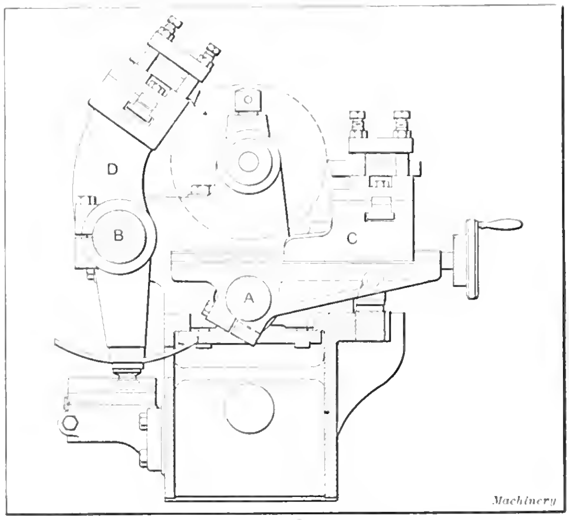

Fig. 2. Cross-sectional View of Fay Automatic Lathe

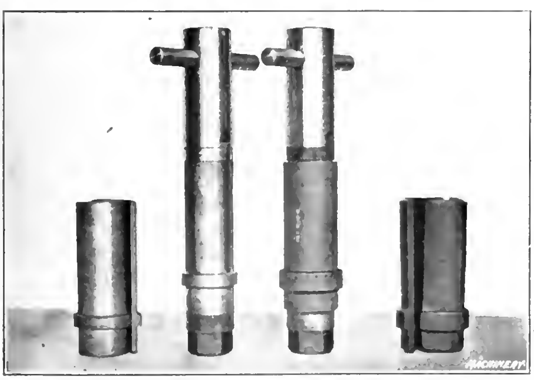

Fig. 3. Half-bushings to be machined and Arbor used for holding them while turning Outside

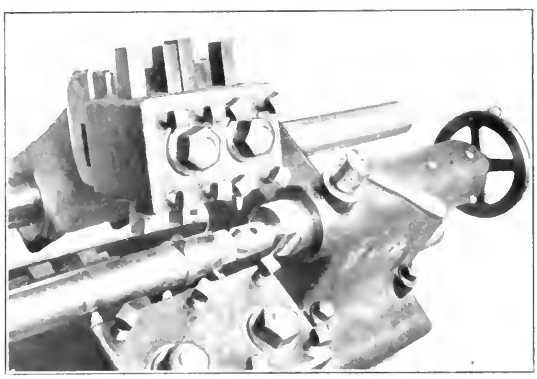

Fig. 4. Tools illustrated in Detail in Figs. 3 and 5 set up on Fay Automatic Lathe

Principles of Arrangement of the Fay Automatic Lathe

In order to make the following article intelligible in so far as the arrangement of the tools is concerned, it will be necessary to refer briefly to the construction of the Fay automatic lathe. (A general description of this machine was

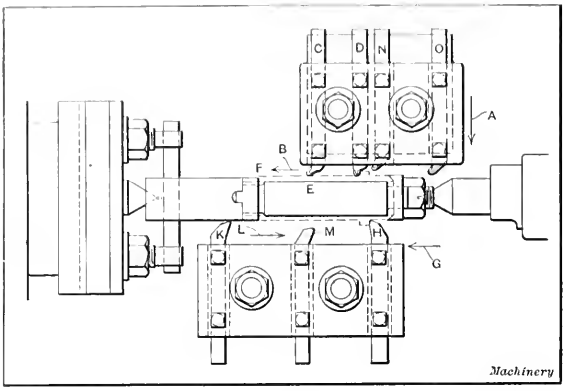

Fig. 5. Tool Arrangement for turning Half-bushings shown in Fig. 3

published in the June, 1909, number of MACHINERY.) The line engraving Fig. 1 shows a rear view of the head end of the machine; Fig. 2 shows a sectional view. The main or work-spindle is driven by worm gearing from a cone pulley mounted

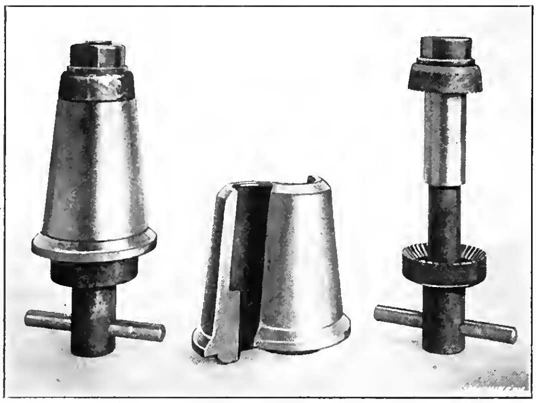

Fig. 7. Arbor for turning Tapered Bushings and Work for which it was designed

at right angles to it. A series of cams is provided for controlling the cutting tools, and by means of a clutch mechanism operated by adjustable dogs, the cam-shaft may be given a slow feeding movement or a rapid idle movement over any

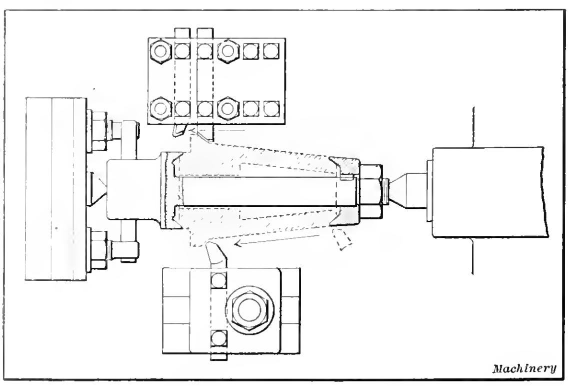

Fig. 9. Finishing Tool Arrangement for Bushings shown in Fig. 7

portion of the periphery of the cam. Two heavy bars, *A* and *B*, extend the full length of the machine and on these the various carriages and tool-holders are mounted. Each of these bars is controlled by a cam both as regards the longitudinal and the rocking movement about their axes. The rocking movement of the front tool-holder *C* is caused by templets or cam surfaces on the slide or former bar at the front of the bed on which the outer end of the carriage rests. These templets may be given any desired shape which will be copied by the tool as the carriage is fed longitudinally.

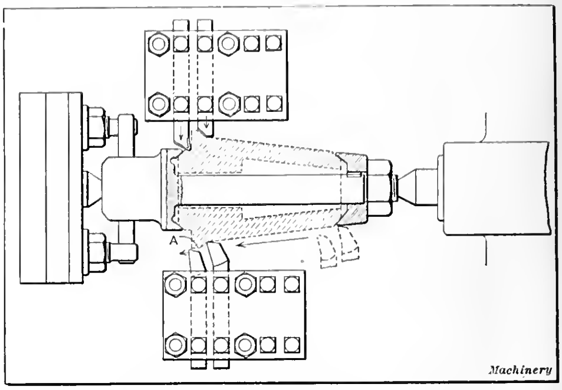

Fig. 6. Method of holding Tapered Bushings shown in Fig. 7

The carriage may also be held stationary and the former bar carrying the templet may be fed to the right or left, thereby causing the tool to feed directly in or out at right angles to the axis of the work. The main tool bar is operated

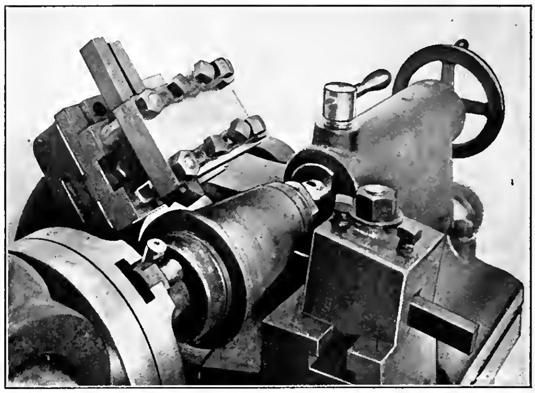

Fig. 8. Tools shown in Detail in Figs. 6 and 7, set up on Fay Automatic Lathe

longitudinally by an internal cam surface within the cam drum shown to the right in Fig. 1, and the tool slide at the rear is rocked by a cam beneath the headstock. It will be understood from this description that the front tool-block *C*

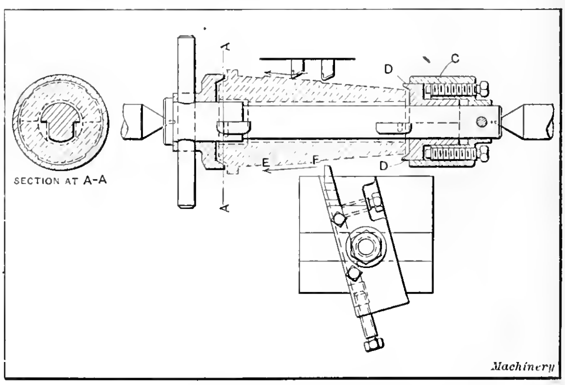

Fig. 10. Arbor for holding Tapered Bushings with Rough Ends

is especially adapted to straight turning, taper turning and forming operations, while the rear tool-holder *D* is intended for operations requiring the tool to be fed in toward the center of the work after which, of course, the tool-bar can be fed longitudinally for ordinary straight turning operations.

Arbors for Holding Bushings made in Halves

The arbor shown in Fig. 3 is used for holding the type of half-bushings illustrated while turning the outside. When performing this operation, it is necessary that the bushings be so held that the parting line comes exactly in the center, so that the two halves are interchangeable. At the same time, they must be held so that the outside will be true with the inside, which has already been finished by a formed convex milling cutter. When the inside has been finished, the two halves are clamped to an arbor and the ends are finished to a beveled surface by a hollow mill. The half-bushings are then ready to be placed on the arbor shown in Figs. 3 and 5, where they are held in place by beveled collars slightly corrugated on the tapered surfaces to form an effective drive. By holding the bushings in this manner the whole of the outside can be finished at one setting. The rear tool-block carries the roughing tools and is first fed inward in the direction of arrow *A*, Fig. 5, and then to the left in the direction of arrow *B*. The roughing cut is divided

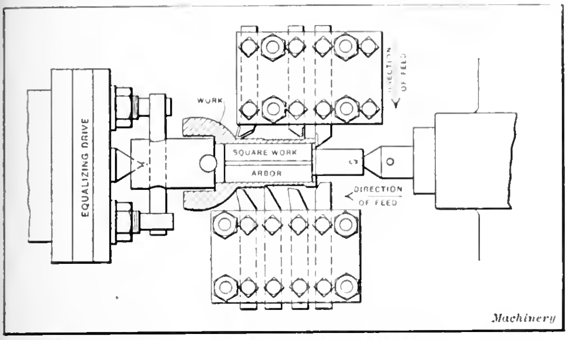

Fig. 11. Turning Work carried on Arbor passing through Square Broached Hole

between the tools *C*, *D*, *N*, and *O*, so that the tool slide needs to feed from *E* to *F* only in order to complete the roughing cut. The tool *N* roughs out the top of the shoulder on the bushing, while the tool *O* roughs out the part of the bushing to the right of the shoulder.

The finishing tools are held in the front tool-holder. Tool *H* is first fed in the direction of arrow *G*, finishing one end of the bushing, and then tool *K* is fed in the direction of arrow *L* to finish the other end of the bushing; at the same time, tool *M* finishes the collar or shoulder shown. The roughing is entirely completed before the finishing cut begins. The finishing cut on the long surface to the left on the

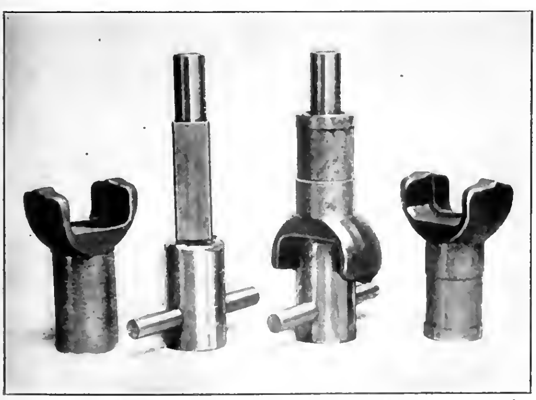

Fig. 12. Square Arbor for carrying Work with a Square Broached Hole

bushing is done by one tool *K* and not by two tools as in the case of the roughing cut, because if two tools were used for finishing it would be difficult to avoid a slight mark on the turned surface at the point where the two cuts meet. Fig. 4 shows the work and tools as arranged in the machine.

In Fig. 6 is shown an arbor used for holding a tapered bushing while finishing the outside; the bushing is shown in Fig. 7, and Fig. 8 shows the work and tools set up in the machine. In this case the hole in the bushing, which is made in halves as in the preceding case, is rough. The joint between the two halves must, however, come exactly in the center of the finished bushing so that the two halves may be interchangeable. The first operation is to plane the joints; then the two halves are clamped together and the ends are finished by a hollow mill to form a bevel bearing for the clamping collars of the arbor. When milling the ends, the joint must be held central in a jig especially designed for the purpose. The half-bushing is then clamped on the arbor shown in Fig. 7, the beveled surfaces of the collar and shoulder holding it true. Fig. 6 shows the arrangement of the roughing tools, the arrows indicating the direction in which they are fed. The front and rear tools are in action simultaneously. The front tools are guided by a taper former on the former bar. In the roughing operation the small surface at *A* will, of course, be turned on a taper, but this will be corrected by the finishing operation, the tooling arrangement for which is shown in Fig. 9. In this case the tools in the back tool-holder finish the short taper on the shoulder and

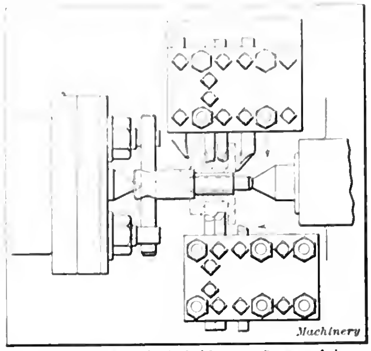

Fig. 13. Gear Blank held on a Square Arbor

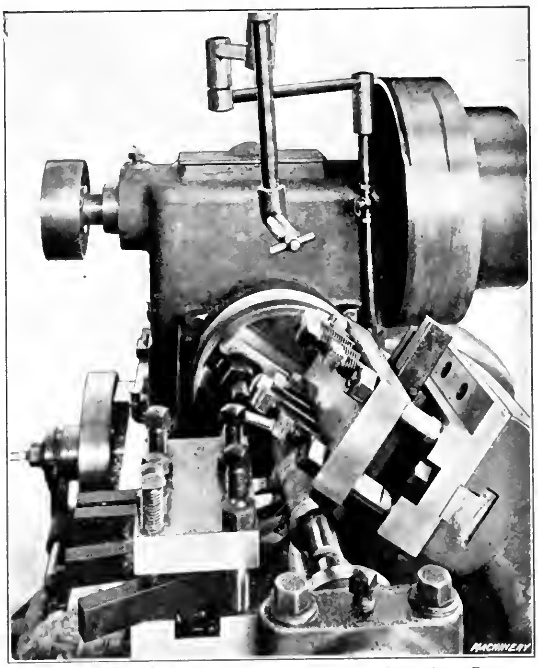

Fig. 14. Turning Work carried on a Square Arbor in a Fay Automatic Lathe

the top of the projection. The long taper surface of the bushing is finished by the tool held in the front tool-holder. Arrangements are made for relieving the tool on the return.

Fig. 10 shows another tapered bushing made in halves, which is turned on the outside before the inside is finished. Here the ends are not finished because other means are available for holding the work so as to locate the joint in the center of the finished bushing. There are lugs on the inside of one of the half-bushings, which bear against shoulders on the arbor, as shown by the section to the left. After the two halves are finished by planing, the half provided with the lugs is first placed on the arbor so that the lugs bear against these shoulders, which insures a correct location. As the ends are rough, the clamping arrangements must be made to

take care of any adjustment necessary to provide a full bearing. A bushing *C* is therefore provided within which slide two half-bushings *D*, operated by adjusting screws. By means of these screws each half of the bushing to be turned

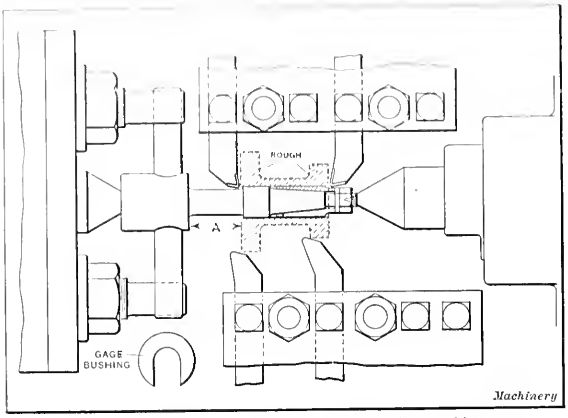

Fig. 15. Example of Work held on Expanding Bushing

can be clamped tightly against the collar at the other end of the arbor; at the same time the joint in the center will be held in correct relation to the center of the arbor. The roughing cut is divided between the two tools in the rear tool-

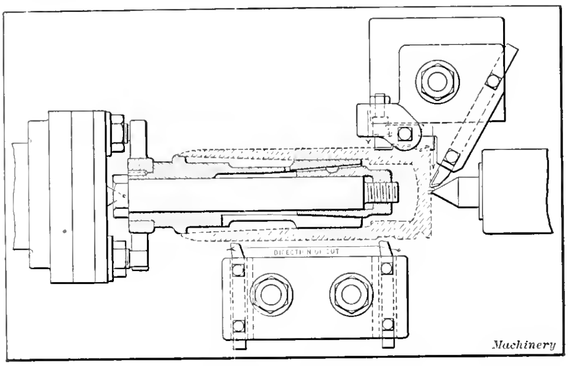

Fig. 17. Combination Threaded and Expanding Arbor for holding Shrapnel Shell in Lathe

holder and the finishing is done by the tool in the front tool-holder. Only the short surface from *E* to *F* is finished.

Holding Work with Square Holes

A piece of work with a square broached hole by which the

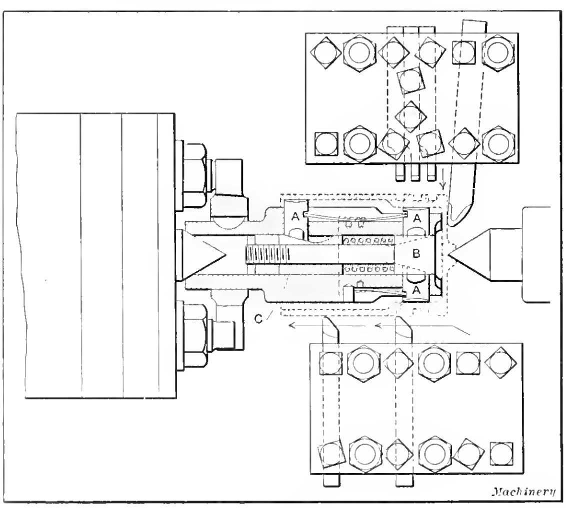

Fig. 19. Arbor for holding Pistons to be turned

piece is held on a square arbor is shown in Fig. 11. In this case the cutting is all done in one direction so that it is unnecessary to provide for clamping the work for endwise motion. An illustration of the piece of work and the arbor, also showing the work in place on the arbor, is given in Fig. 12. The tools, as inserted in their respective holders, are shown in place on the machine in Fig. 14.

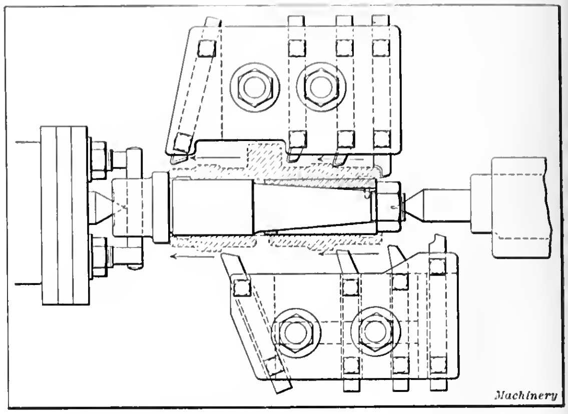

Fig. 16. Another Method of clamping Work on Expanding Bushing

Fig. 13 shows a simple method for holding a gear blank with a square hole. The hole in the blank is first bored, after which the piece is roughed all over except on the large diameter and on the face next to it, as it is held by these

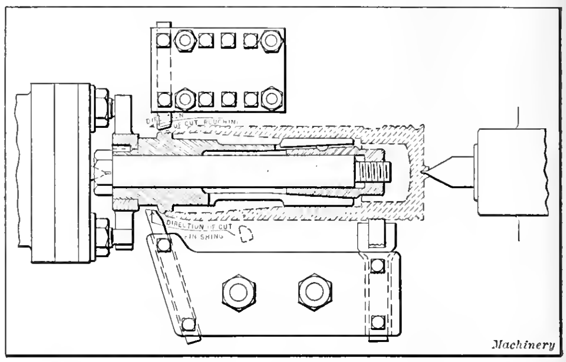

Fig. 18. Tool Arrangement for turning Shrapnel Shell Point and knurling Groove at Closed End

surfaces in the turret lathe. Then the hole is broached, two keyways being provided at the same time, after which the piece is placed on the arbor, the keys being driven in just tight enough to hold it in place. The tooling arrangement

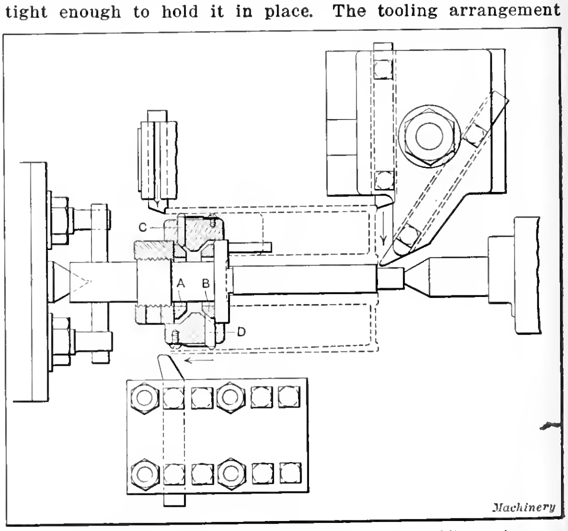

Fig. 20. Method of supporting Pulley from Inside while turning

used for finishing the surfaces is shown in the illustration.

When a piece of work is to be finished on the Fay automatic lathe, or in any lathe with multiple tools and fixed stops,

it is necessary that the endwise location of the work be always the same; hence when work with a round hole is to be finished, it cannot be held on an ordinary arbor with a slight taper unless the hole is so accurately finished that the piece will come to a driving fit at a given place on the arbor, in which case the point to which the work is to be driven

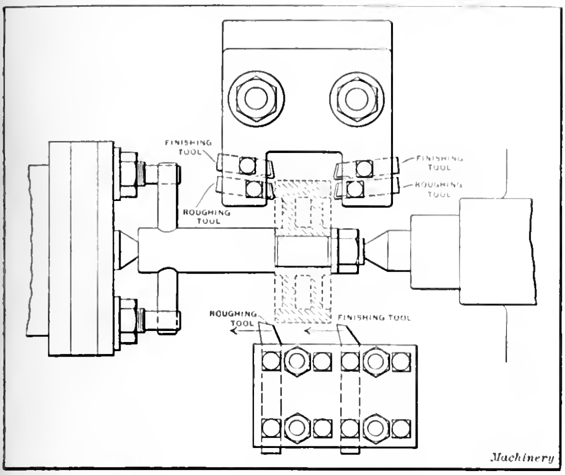

Fig. 21. Example of Arbor designed to hold Two Pieces of Work at One Time

may be determined by means of a simple gage which acts as a stop. As a matter of fact, some firms make it a point to machine the holes in work of this kind so accurately that the work can be driven onto an arbor and come to a driving fit at a given point. This can almost always be done with bronze bushings, as there is enough elasticity in this material to permit the pieces to be forced down to a certain

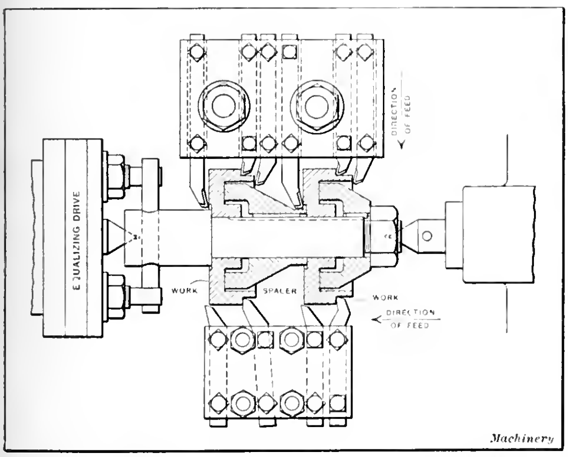

Fig. 22. Example of Two Pieces clamped on Arbor, illustrating Use of Spacer

position. With this method of holding, both ends of the work can be faced, as there are no clamping arrangements to obstruct the path of the tools.

Holding Work by Means of Expanding Bushings

One of the simplest methods for holding work with a finished hole is by means of expanding bushings. This method makes it possible to chuck the hole in a drill press and still hold it at a given position on an arbor without obstructing the ends of the work, and in such a way that both ends of the work can be faced. In the case shown in Fig. 15 the hole was too long to fit a split bushing the entire length, as the thickness of the bushing would have been rather excessive at one end, or else the taper would have had to be made too small; therefore part of the arbor is turned straight and to fit the hole in the gear blank to be turned. In order to insure that the piece be placed in the same position longitudinally each time, a gage bushing, an end view of which is shown in the lower left-hand corner of the illustration, is used to gage distance A. The piece of work is dropped onto the arbor and secured loosely against the gage; then the gage is withdrawn and the nut is tightened to hold the work firmly in place. The arrangement of the tools for finishing this piece is clearly indicated in the illustration.

In Fig. 16 is shown another example of an arbor for clamping work by means of a split bushing. The work here shown is an armature bearing box. No gage is necessary in this case, as the work is located by a shoulder at one end of the arbor, only one end of the work being faced off. The roughing is done by the tools in the rear tool-holder and the finishing by the tools in the front holder. Another interesting method of holding work while machining is shown in Fig. 17. The work here shown in position on the arbor is a shrapnel shell. The work is threaded on the inside at one end and can thus be screwed onto a threaded portion of the arbor. The end of the arbor is split and provided with an expander. The rear tool slide holds the roughing tool which

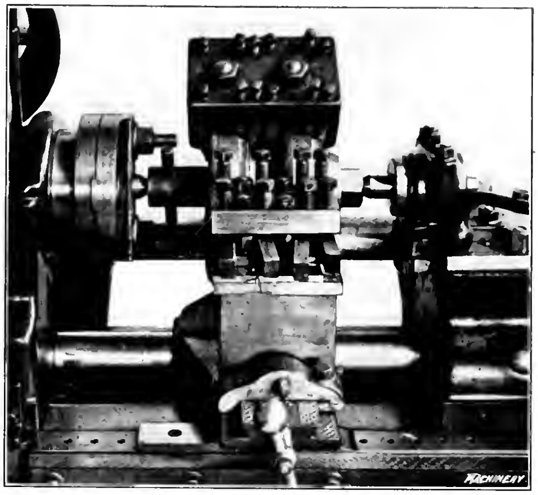

Fig. 23. Two Pieces of Work on Arbor mounted in Fay Automatic Lathe

faces the end, and also a forming tool which comes into a surface free from scale that has been roughed off by one of the tools in the front slide. The direction of the cut of the tools in the front slide, first inward, then parallel, and then slightly outward, is shown by the arrow. Fig. 18 shows

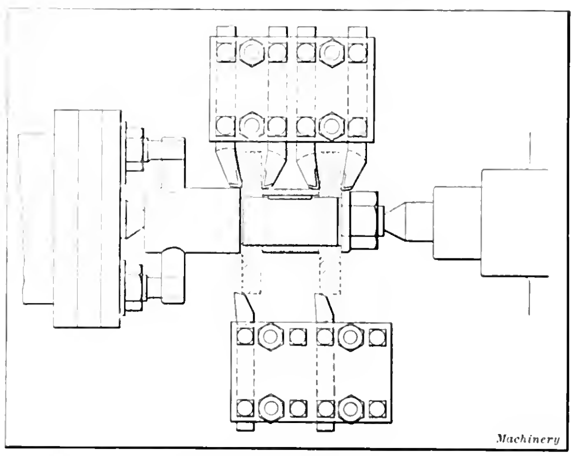

Fig. 24. A Simple Case of Two Pieces of Work held on an Arbor with Spacer between them

the arrangement of the tools for roughing and finishing the tapered end of the shell and for knurling a groove at the closed end. In this case a special grooved former must be used in place of the taper attachment of the machine at the rear. When the front tool at the left has completed its cut the finishing tool-holder drops in, permitting the tool to the

right to perform the knurling operation. In this case a former is clamped to the former bar of the machine.

Supporting Thin Work from the Inside

The most interesting holders for work that is to be machined in the lathe are, perhaps, those that are arranged to support thin work from the inside. In Fig. 19 is shown one example of a piston held by an equalizing arrangement. This arrangement is applicable only to pistons which are not to be ground. The usual method is to bore a hole for a short distance inward at the end of the piston and then drill the wrist-pin hole. The bored portion is used for locating the work in position by means of a stud through the wrist-pin. The method shown in the present illustration, however, permits the work to be done in one operation without any counterboring, and with the assurance of an even thickness of metal all around the piston. One end of the piston is centered in a centering machine. If the piston is heavy it may be held by the outside during this operation. If the metal is thin, it is preferable to center it with reference to the inside, holding the work in a jig like the fixture used in the machine. The holding device consists of three plungers *A* at each end of the piston, which slide in slots cut in the head of bolt *B* and in collar *C*, and which thus both center the work and support it on the inside. In the case of small pistons only two plungers are used at the closed end, because

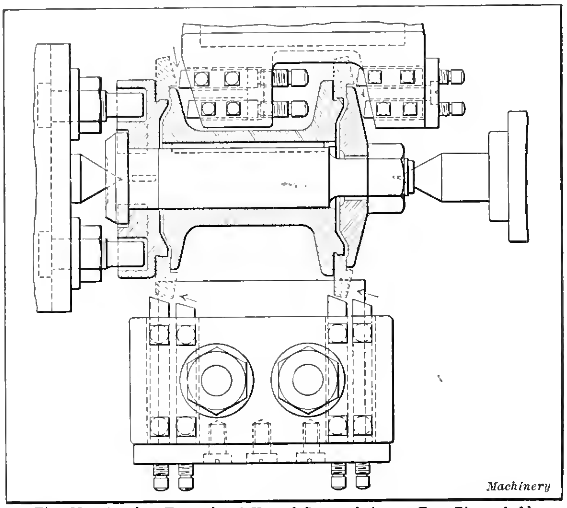

Fig. 25. Another Example of Use of Spacer between Two Pieces held on the Same Arbor

there is not enough room for three on account of the bosses for the wrist-pin. The bolt with the tapered slot is tightened by means of a nut having a slot in it, which can be reached from the end of the arbor when the fixture is taken out of the machine, by means of a special screwdriver. The tooling arrangement shown in the illustration is that provided for roughing the piston. The two tools in the front holder divide the roughing cut between them so that the feed motion needs to be only one-half of the length of the piston.

Fig. 20 shows a method used for supporting the overhanging rim of a long pulley. In this case the pulley is centered by the hole which fits the arbor, and the support must simply act as an equalizer. As will be seen, two floating collars, *A* and *B* are provided which are tapered on one side. This tapered side bears against pins *C* and *D*. As the collars are perfectly free to locate themselves with relation to the arbor, it is evident that the pressure on the pins (of which there are three for each collar) will be the same, and there will be no tendency to throw the work out of center, but to merely support it with equal pressure at the six bearing points.

Holders for Two Pieces of Work

In many instances it is possible to hold two pieces on the same arbor, thus practically cutting the time of machining in half. The simplest illustration of this is probably that shown in Fig. 21, where two gear blanks which have been faced on one side and have had the holes bored, are clamped together and faced on the other side and turned on the outside. The arrangement of the tools is of interest; the arrows shown give the direction of the feed and indicate the method of procedure. Fig. 22 shows another case where two pieces held on the same arbor are machined at the same time. A spacer is provided between the two pieces so as to locate the one to the right in position, the one to the left being located against a shoulder on the arbor. In order to use this arrangement for location, it is necessary for the work to have shoulders finished on two sides and also that the finishing be done accurately enough so that it can be used for locating

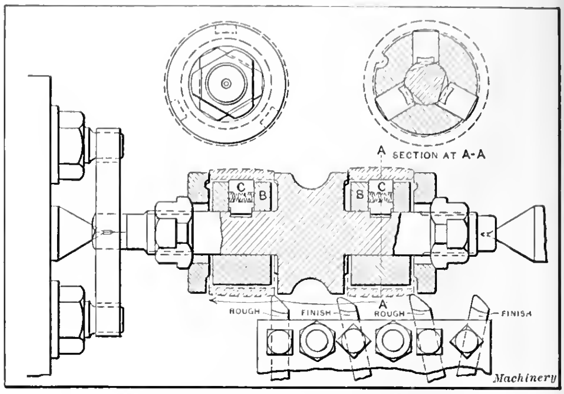

Fig. 26. Arbor for holding Two Pieces of Work which must be supported from the Inside

the two pieces. In this case both the clamping collar and the spacer are keyed to the arbor to make the drive more positive. In Fig. 23 this job is shown set up in the machine.

In Fig. 24 is shown another case of clamping two pieces using a spacer between them. It is evident that if the two sides of the hubs of the gear blanks had not previously been machined, this method could not be used as the gear blank to the right would not come in an accurate position to permit being machined by the tooling arrangement indicated.

In Fig. 25 is shown still another example of holding two pieces by means of a spacer. Here the roughing and finishing are done at the same time. The tools in the rear and front holders operate simultaneously, the taper attachment being used for the rear holder. A taper former is used on the former bar for the front tool-holder. Fig. 26 shows an especially interesting arrangement for holding two pieces and for sup-

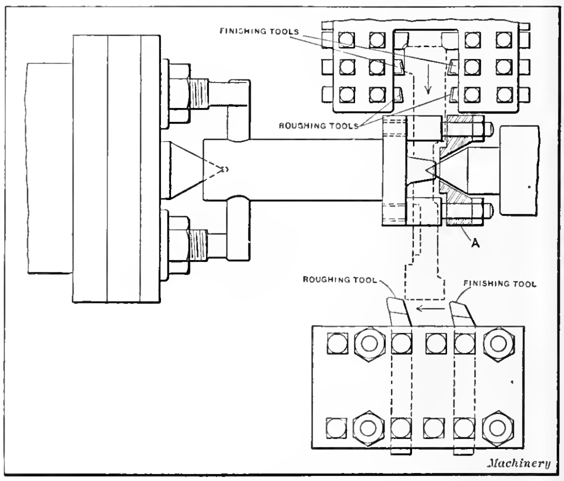

Fig. 27. Arbor for holding Small Flywheel while machining the Rim

porting the thin walls of the bushings while machining. In this case the ends and the inside of the bushing are rough. The only difficulty that was met with was to machine them without distorting them on account of the thinness of the metal. The bushings are both centered and supported by the rough inside surface. For this purpose bushings *B* are provided on the arbor. These bushings hold plugs *C* which are prevented from falling out of their seats by springs

when the pieces to be machined are to be removed from the arbor. The arbor itself is provided with three flat spots or bearings, as shown in the sectional view at the top. These act as cam surfaces when the arbor is turned and force the plugs outward, thereby centering and supporting the work on the inside. This arbor shows a different method than those shown in the previous examples for holding two pieces at once. Here the middle portion of the arbor is solid and provided with three bearing points on each side for the work. Then collars are provided at each end of the arbor with nuts for clamping the work. One disadvantage is present with this arbor. The dog at the driving end must be removed to take off the pieces nearest to the head. In practically all the other cases shown a driving pin driven into the arbor can be used, as the work is removed in the other direction.

Method of Holding a Narrow Flywheel

Fig. 27 shows an interesting method for holding a narrow flywheel for a motorcycle while machining the sides and the face. It is necessary to hold this piece in such a manner that it is not thrown out of true sidewise. At the same time the sides of the rim must be left partially free for machining. The difficulty of holding the rim true is due to the fact that the hole in the wheel is very short and provided with a short taper. If an arbor is made which projects through, it will be so small in diameter that it is likely to break off under a heavy cut, particularly if threaded on the end. The method by means of which this difficulty was overcome is shown in the illustration. The arbor is made with a projecting tapered end into which the tail center enters, and an equalizing collar *A* is provided which presses the wheel onto the tapered end of the arbor. One of the studs by means of which the equalizing collar is held against the end of the shoulder of the arbor acts as a drive for the flywheel by bearing against a central fin of the drop-forging. The studs pass through openings in the web of the wheel.

These examples indicate in a general way the various types of holding devices that are likely to be required in turning operations. While they do not cover special cases, they show principles that can generally be applied. It is apparent that if devices of this kind were more generally provided, the full advantage of the facilities offered by modern machine tools could be better realized. In cases of interchangeable manufacture, the arbors and methods of arranging the tools and operations can hardly be left to the decision of each individual workman, as there is much to be gained by a thorough study of the subject by those who give their entire attention to work of this character. E. O.

ADJUSTABLE FIXTURE FOR HOLDING IRREGULAR SHAPED WORK

Irregular shaped castings which must be machined, often present no apparently good means of holding by ordinary gripping appliances for drilling, shaping or milling. An ex-

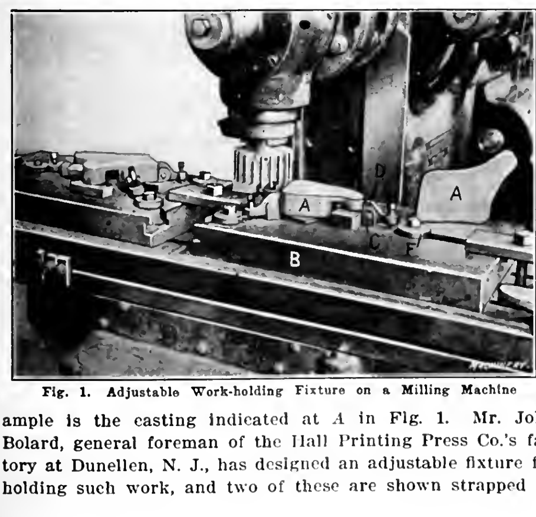

Fig. 1. Adjustable Work-holding Fixture on a Milling Machine

ample is the casting indicated at *A* in Fig. 1. Mr. John Bolard, general foreman of the Hall Printing Press Co.'s factory at Dunellen, N. J., has designed an adjustable fixture for holding such work, and two of these are shown strapped on the milling machine table in Fig. 1. The fixture consists of a base block *B*, which is T-slotted, three slots radiating from a central point. In each of these slots is fitted a gripping dog, illustrated in detail in Fig. 2. The base block *C* of the dog is slotted to receive jaw *D*, which is fulcrumed on a cross-pin. In the tail of the dog is threaded a set-screw *E*, and by turning in this set-screw the jaw is caused to "bite" inward and downward at the same time, firmly gripping the casting and forcing it down on the table. A back-stop *F* is bolted behind each dog so that there is no chance for slipping away from the work.

In Fig. 1 an efficient method of using this type of fixture is shown. Two fixtures are in use, and while the cut is being taken across one of the castings the second fixture is

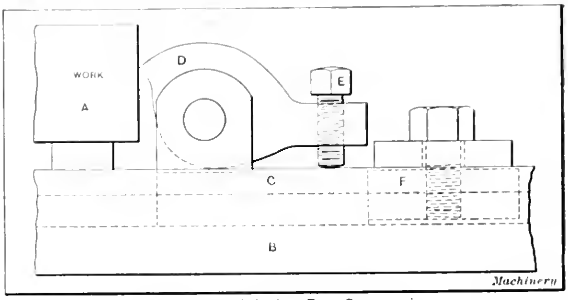

Fig. 2. The Gripping Dog Construction

being loaded and made ready for the milling operation. Similarly when a cut on the second casting is under way the casting previously milled is removed and a new piece inserted. It is only necessary to loosen one dog for removing the work. C. L. L.

"SWAT THE FLY" IN THE DRAFTING-ROOM

The common house fly is becoming recognized as one of the most deadly enemies of the human race. He is a carrier of germs of many diseases and filth of every kind. Experiments conducted in England with marked flies showed that they travel long distances and that sources of contagion may be far removed from the homes of those who become infected through them. "A single fly caught in a refuse can in a suburb of London gave no fewer than 116 colonies of bacteria and ten colonies of fungi, the germs being all collected from the bristles of the insect's legs and body or on its proboscis, as gathered while feeding on the refuse in the can. Flies are active carriers of tuberculosis, ophthalmia, anthrax cholera, infantile diarrhea, etc." Flies are pests in the drafting-room. They not only trouble the draftsmen, but feed on India ink, and have been known to damage tracings by sucking up the inked lines before they become dry. An instance showing how the fly may be responsible for errors in dimensions was recently brought to our attention. A drawing had been made with the dimensions 12", but when sent into the shop the dimension had mysteriously changed to 1.2". Investigation showed that a fly was responsible for the "decimal point." The moral is "swat the fly" in the drafting-room, but, better still, screen the drafting-room to prevent fly-specked drawings and to preserve the health of the draftsmen.

TWENTY-FOUR-HOUR TIME SYSTEM

A twenty-four-hour time system was recently introduced in France and is said to have given rise to some curious results. One of the troubles the Frenchmen have met with is the striking of the hour. It is apparently not practical to have clocks strike twenty-four strokes or thereabouts in succession because of the difficulty of counting. Numerous peculiar proposals have been made to avoid this trouble, for example, using a double chime, one bell for units and one for tens, the two bells to have different tones. It would seem that it would be feasible to permit the clocks to continue to strike in the same way as hitherto, as this could hardly cause confusion, but that does not seem to suit the French time reformers.

APPLICATIONS OF ELECTROMAGNETIC TRIPPING DEVICES

MECHANISMS WHICH PREVENT DAMAGING MACHINES OR PRODUCING DEFECTIVE WORK

BY GEORGE M. MEYNCKE*

In designing automatic machinery or automatic feeds for standard machines, the designer often faces the problem of providing a suitable device that will make his machine absolutely fool-proof and reliable. This is particularly true in the case of automatic machines where one operator looks after several units. While it is not claimed that purely mechanical means cannot accomplish the same results which are secured through the use of electromagnetic tripping devices, the mechanisms would necessarily be so complicated—as compared to the electrical devices described in this article—that they would be a source of endless trouble, if not impractical. Another advantage of the electrical devices lies in the fact that they may be used as a check on the accuracy of preceding operations and thus avoid finishing pieces of work that are defective. The application of electricity to automatic machines may be regarded as a complication in itself, but this is far from being the case if these tripping devices are properly applied.

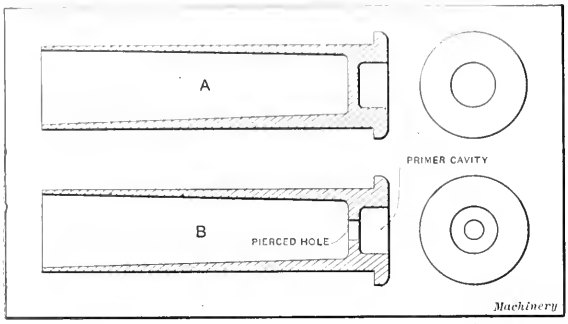

Fig. 1. Cross-sectional Views of Shell before and after piercing Primer Hole

The following examples are typical applications of electromagnetic tripping devices to automatic machines, and by studying these designs the reader will readily appreciate how similar tripping mechanisms could be applied to other classes of machinery; he will also appreciate how these devices put a check on the operation of the machines to which they are applied. In most of these examples, the tripping devices constitute part of attachments for standard machines that were converted into "automatics," thus dispensing with the necessity of an operator for each machine. Electricity performs the vital part of the work; it takes the place of the eyes of the operator and is far more satisfactory than eyes because electricity is more nearly infallible.

Fig. 1 shows a metallic cartridge shell A as it is received by the machine which pierces the primer hole, and a shell is illustrated at B on which the piercing operation has been performed. After the hole has been pierced, the primer is inserted in the primer cavity by the machine. These operations are performed on a standard Waterbury-Farrel cartridge primer. The shells were formerly placed on dial pins by hand and indexed under the crosshead for piercing and inserting the primer; they were then removed from the dial pins automatically. An improvement was made in the method of operation by applying an automatic feed mechanism to place the shells on the dial pins, but this did not dispense with the necessity of an operator for each machine, as there are three possible conditions that may result in the production of imperfect work: First, the feed mechanism might fail to deliver the shell to the dial pin, or the supply of shells might become exhausted, while primers would continue to feed and thus be wasted. Second, the piercing punch might break and the machine would then continue to place primers in the cavities of shells which had not been pierced, and such shells would obviously be useless. Third, the primer feed might fail to work properly, or the supply of primers might become exhausted.

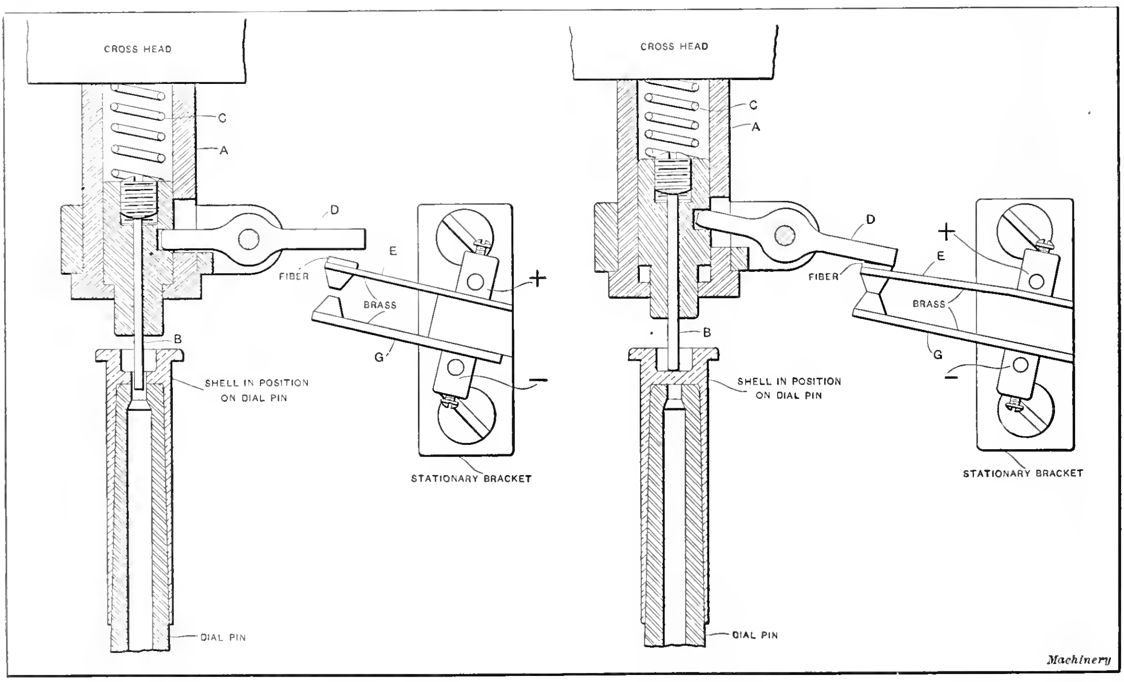

Fig. 2. Tripping Device which acts in Case of Failure of Punch to pierce the Shell, as shown in Right-hand Illustration

The application of a suitable electromagnetic tripping mechanism to this machine now takes care of all of these contingencies. First, we will consider the possibility of the feed mechanism failing to deliver a shell to the dial pin. Referring to Fig. 3 it will be seen that the shells are carried on index points of the dial which carry them under the punch A. If a shell is in its place on the dial pin it con-

* Address: 125 Lehman St., Dayton, Ohio.

tracts the spring *B* when the ram descends, but should the mechanism fail to deliver a shell to the pin, the sleeve *G* passes down over the dial pin and pushes the upper contact *D* of the tripping mechanism down upon the lower contact *E*. This closes the electrical circuit and stops the crosshead on the up-stroke. The contacts are fastened to the frame of the machine and the method by which the tripping mechanism operates will be described in detail later. The way in which the piercing operation is safeguarded by the electromagnetic tripping mechanism is illustrated in Fig. 2. The punch holder *A* is located at the index point immediately after the completion of the piercing operation. If a shell is pierced, the pin *B* descends through the hole in the shell, as shown at the left-hand side of the illustration; but if the piercing operation does not take place, the punch is held in the position indicated in the right-hand illustration, thus contracting the light spring *C* and throwing the lever *D* against the contact *E*. This closes the electrical circuit and causes the machine to be stopped so that shells cannot have primers inserted in them when the primer hole has not been properly pierced. The failure of the machine to feed a primer into the primer cavity of the shell is guarded against by the mechanism illustrated in Fig. 4. The design

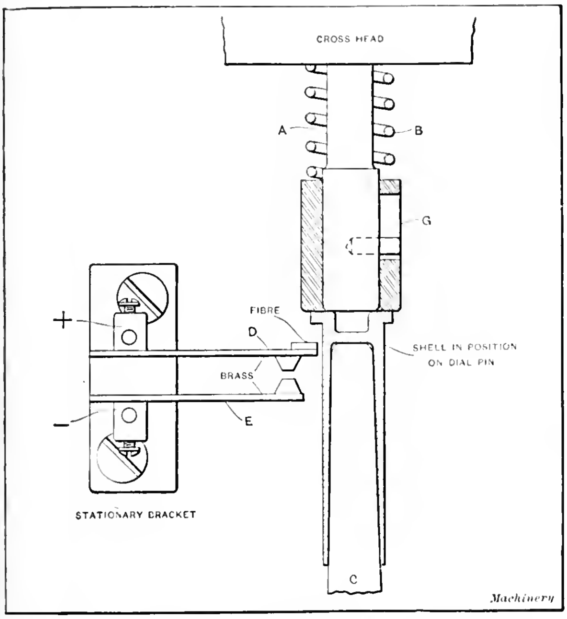

Fig. 3. Tripping Device which acts when a Shell has not been placed on Dial Pin

of this tripping mechanism is practically the same as that used to control the piercing operation and will be readily understood without further description.

Fig. 5 illustrates a press which is used for assembling the brass cups *A* and *B*, the cup *A* being inserted in the cup *B*. These cups are held in hoppers on each side of the machine from which they are taken by notched dials. The cups *A* are dropped into holes in the machine dial which passes over the dial carrying the cups *B*. We will not go into the method by which the machine operates here, it being sufficient merely to state that a plunger descends in such a manner that the cup *A* is forced into place in cup *B*. It will be readily seen that several conditions may occur that will result in loss or damage, *i. e.*, the feed mechanism could fail to deliver either one or both cups to their respective dials, or it could deliver them to the dials in an inverted position. Fig. 5 illustrates how either the absence or inversion of either or both cups is detected by an electromagnetic tripping device which automatically stops the machine until the error has been corrected. The punch *C* is located at an index point preceding the assembling punch and is carried by a bracket which is fastened to the crosshead. In the case of an inverted cup, the punch *C* is held on the bottom of the cup and pulls the rod *G* down through the action of the pinion, which engages with rack teeth cut in the rods *C* and *G*. The descent of the rod *G* causes the contact closer *F* to pull down the upper electrical contact until it closes the circuit and causes the machine to be stopped. The right-hand illustration shows a detail of the punch and die when the feed mechanism has failed to deliver a cup to the dial plate. In this case, the upper electrical contact is pulled

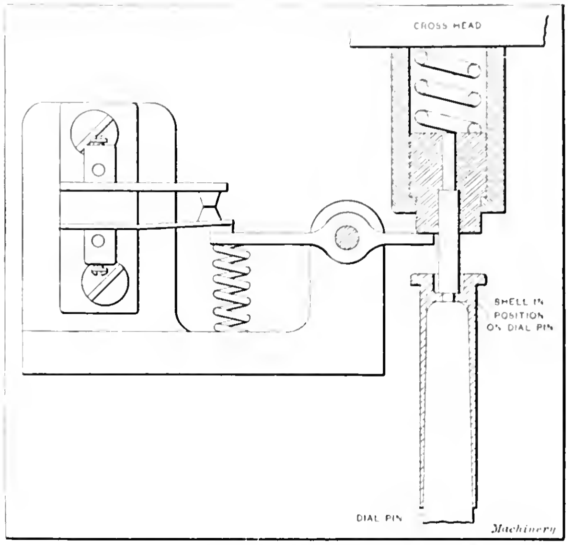

Fig. 4. Trip which prevents passing on a Shell without a Primer

down by the contact closer *H* and causes the machine to be stopped as previously described.

Fig. 6 shows the electromagnetic tripping device used on the machines referred to in the preceding paragraphs. In this illustration, the tripping device is shown in place on a power press equipped with a Horton clutch. The design and contraction of the tripping mechanism will be more readily understood by referring to Fig. 7, which shows an end and

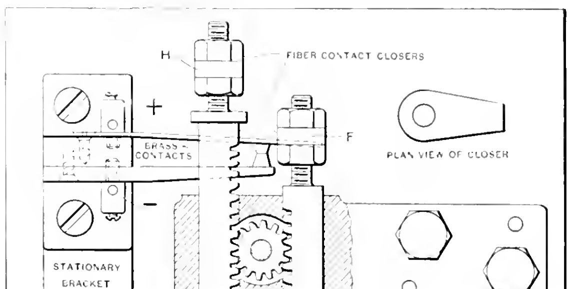

Fig. 5. Trip used on Machine for assembling Shells A and B

cross-sectional view. This tripping mechanism is self-contained and can be applied to any style of press or type of machine. It will be seen that the bracket *A* carries the magnet *B*, pole-piece *C*, and levers *D* and *E*. The brass pole *G* is wound with No. 14 double-covered wire and the lead wires are carried off through the back of the spool. The

brass pins H help to support the pole-piece C and provide adjustment for different widths of air gap which should be as small as possible. In order to start the press, the lever E is pulled down. This pulls out the flywheel clutch (see Fig. 6) and allows the spring J to pull the lever D over the hardened knife-edge, thus setting the pole-piece C at the proper working distance from the magnet. The inside dimensions of the device are given in Fig. 7, and when the magnet is energized by two dry cells, it gives an initial pull or jerk of from twelve to fifteen pounds. As the dry cells are used on open-circuit—except for the fractional part of a second during which the contacts meet—they have a long life.

The initial pull provided by an electromagnet of this kind varies with the material used for the magnet and pole-piece. Where cast iron is used, the pull of the magnet can be calculated by the formula:

$$NI = 3000\ Z\ \sqrt{P \div D}$$

in which N = number of coils of wire on spool (ampere-turns);
I = current in amperes;
P = pull in pounds;
Z = air gap in inches;
D = diameter of plunger in inches.

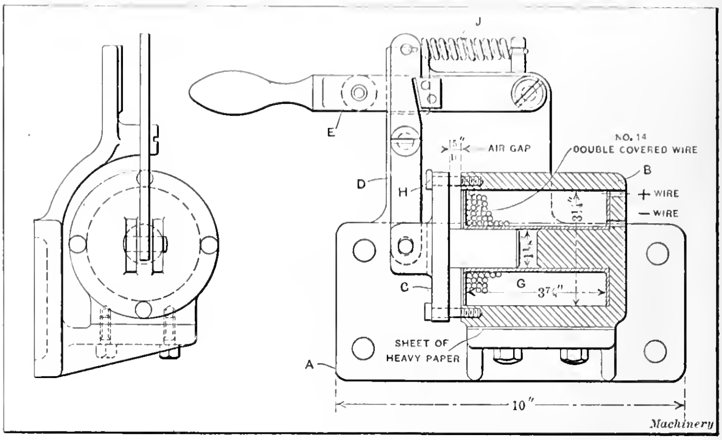

Fig. 7. End and Cross-sectional Views of Electromagnetic Controller

The electromagnet shown in Fig. 7 was designed to give a pull of fifteen pounds, and it will be seen that $Z = 5/16$ inch and $D = 1.125$ inch. Then $NI = 3000 \times 5/16\ \sqrt{15 \div 1.125} = 3423.19$ ampere-turns.

Assuming that there are 375 turns of wire on a spool, the amount of current required will be found to be $\frac{3423.19}{375} = 9.14$ or, say, ten amperes. Two good dry cells connected in series will average fifteen amperes during their useful life and give a considerably higher current when new. As ten amperes is sufficient to enable the electromagnet to do the work required of it, it will be seen that an ample factor of safety is provided. When designing devices of this kind, moving wires and moving contacts should be avoided and the mechanism should be made as simple as possible. The dry cells should be used on open circuit, the contacts carefully insulated from the machine and covers provided for contacts and terminals.

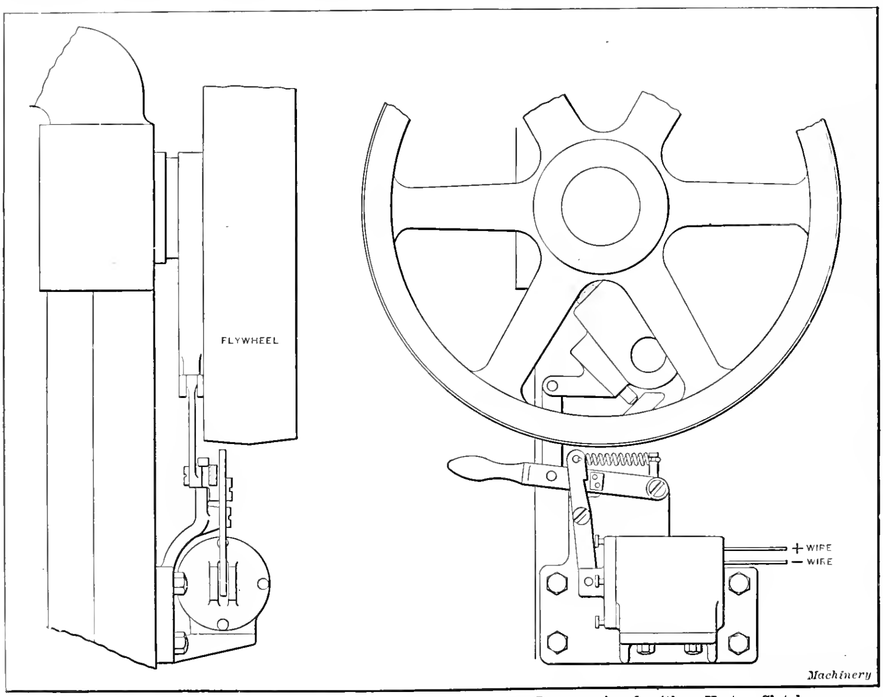

Fig. 6. Electromagnetic Tripping Device applied to Power Press equipped with a Horton Clutch

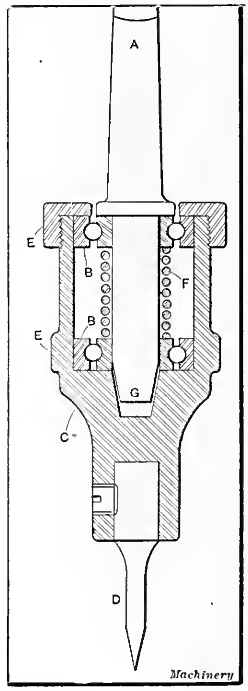
FRICTION DRIVEN POWER SCREWDRIVER

BY W. ALTON

The following is a form of screwdriver that will be found useful where there are a large number of screws to be put into parts that are small enough to handle under a drill press. It consists of an arbor with a taper shank A fitted to the drill press spindle in which it is desired to use the tool. The opposite end G of the arbor is tapered to fit a corresponding recess in the body C of the tool. The arbor runs in ball bearings B, the outer race of the left-hand bearing being a sliding fit in the body C and the inner race of the right-hand bearing being a sliding fit on the mandrel. The tapered clutch end G of the mandrel is kept out of engagement when the tool is not in use by the spring F.

The body of the tool can be stopped to engage the screwdriver D with the slot of the screw by grasping it around the knurled portions E, but in practice this is hardly necessary as the screwdriver will usually engage the screw if fed down on it. A further advantage is that the clutch will release when the screw is driven in. This tool is easily made and will be found a time saver in doing the class of work for which it was designed.



Screwdriver used in Drill Press

MACHINE FORGING—6

DIES AND METHODS EMPLOYED IN THE FORMING, WELDING AND UPSETTING OF MACHINE AND ENGINE PARTS

BY DOUGLAS T. HAMILTON*

The forming and welding operations illustrated and described in the following represent some of the interesting applications of upsetting and forging methods to the production of locomotive and car parts. Three methods of welding parts are given, which practically covers the entire range handled. Mention is also made of the important part filled by bulldozers and steam hammers in the production of many parts, and of their close connection as manufacturing auxiliaries to the forging machine.

Fig. 70. Miscellaneous Examples of Lap-welding and Forming Operations accomplished on a 6-inch Ajax Universal Forging Machine

Miscellaneous Lap-welding and Forming Operations

The miscellaneous welded and formed parts shown in Fig. 70 were secured in the Chicago shops of the C. & N. W. Railway through the assistance of A. L. Guilford, manager of the Chicago office of the Ajax Mfg. Co. The forging dies and tools shown in the following illustrations constitute a few of the many interesting examples to be found in the shop mentioned, and represent the results of the endeavors of T. E. Williams, master smith, to decrease the cost of forged engine and car parts. All of the examples shown in Fig. 70 were produced on the 6-inch Ajax universal forging machine shown in Fig. 71.

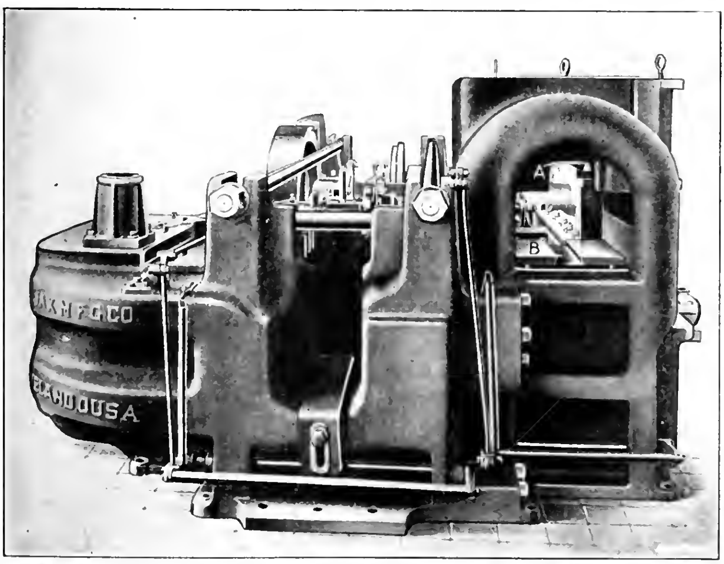


Fig. 71. Six-inch Ajax Universal Forging Machine used in the C. & N. W. Railway Shops for making the Forged Parts shown in Fig. 70

Universal Type of Upsetting and Forging Machine

The universal type of upsetting and forging machine shown in Fig. 71 has a much greater range of possibilities for producing machine-made forgings than the regular upsetting and forging machines previously described. This machine has the features common to the regular forging machine in combination with those of a powerful vertical press operated independently of the other part of the machine. The universal forging machine is designed especially for forming such forgings as require squeezing, punching or trimming operations either before or after upsetting. This often makes it possible to prepare and complete large upsets and difficult shaped forgings in one handling, and thus utilize the initial heat.

In construction, it consists mainly of a double-throw crankshaft from which are operated two header slides—one for the standard upsetting mechanism and the other for the vertical press. The upper die-holder *A* of the vertical press is operated by two heavy steel side links, the lower ends of which connect with eccentrics on an oscillating shaft. This die-holder is provided with means of adjustment so that the squeezing dies can be brought together or separated as requirements demand. The lower member of the dies used in this auxiliary part of the machine is held on the stationary die-holder *B*.

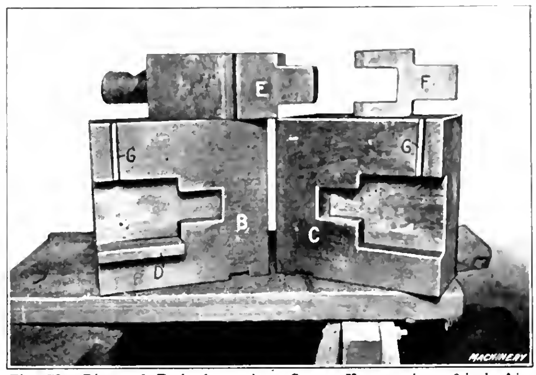

Fig. 72. Dies and Tools for making Spring Hangers in a 6-inch Ajax Universal Forging Machine

Dies and Tools for making Spring Hangers

An interesting example of the utilization of scrap metal for making engine parts is the spring hanger *A*, Fig. 70. This part is made from old arch bars 1 by 4 by 5 inches, with the dies and tools shown in Fig. 72. Six blocks cut off from the arch bars are piled together and riveted as shown at *A* in Fig. 73, the old holes in the arch bars serving as a means for riveting them together. This is done to hold the separate blocks in place while a welding heat is being taken. After the parts have reached the proper temperature they are taken to the universal forging machine shown in Fig. 71, and placed between squeezing dies held in the vertical press. The machine is then operated, welding the pieces together and converting them into a solid block as shown at *B* in Fig. 73.

After the separate pieces have been welded and shaped, the solid block is again taken to the furnace and heated to a welding temperature. Then it is removed and placed between the opposing faces of the gripping dies *B* and *C* shown in Fig. 72, these being held in the forging machine shown in Fig. 71. The stationary gripping die *B* is provided with the shelf *D* on which the heated block is placed, this serving to hold it while the dies are coming together. As soon as the dies close on the work, plunger *E* advances and displaces the stock in

*Associate Editor of MACHINERY.

such a manner as to form the tail on the end of the forging *F* by simply forcing the center portion of the block back into the rear impressions in the gripping dies. This is accomplished in one heat, and when the piece is removed from the dies it is finished complete. Vent holes *G* are provided in the opposing faces of the dies to allow the excess metal to escape.

Another example of a spring hanger forging is shown at *B* in Fig. 70, the dies and tools used being shown in Fig. 74. The first operation in the production of this spring hanger is drawing the 2-inch wrought-iron bar *A* down to the shape shown at *B* in Fig. 75 in a Bradley steam hammer. This piece, after being drawn down is heated and placed in a bulldozer, where it is bent into a U-shape as shown at *C*, the heaviest part of the piece being located at the bent end. The one-inch hole is punched through the bent end at the same time that the work is being formed. The body or shank of the hanger is made from a 1 by 4-inch piece of round edge iron *D* which is swaged down on a 4-inch forging machine to $1\frac{3}{4}$ inch round for a length of about 7 inches on one end, as

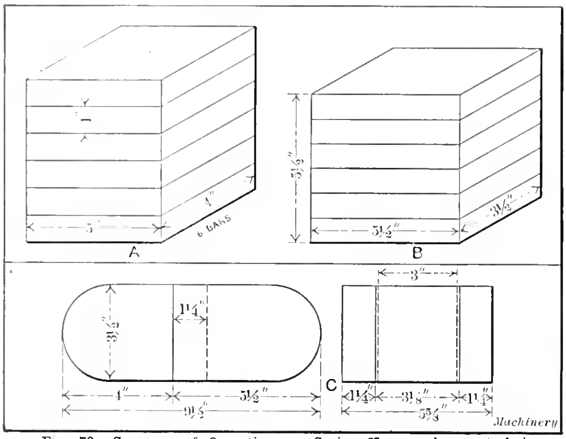

Fig. 73. Sequence of Operations on Spring Hanger shown at A in Fig. 70 and also in Fig. 72

shown at *E*. The bar is then heated, placed in the forging machine and upset to 2 inches in diameter in order to completely form the reinforced portion on the flat part, and at the same time reduce the end to one-inch in diameter by $2\frac{1}{4}$ inches long. The reduction on the end of the bar is accomplished with the plunger held in the ram of the machine.

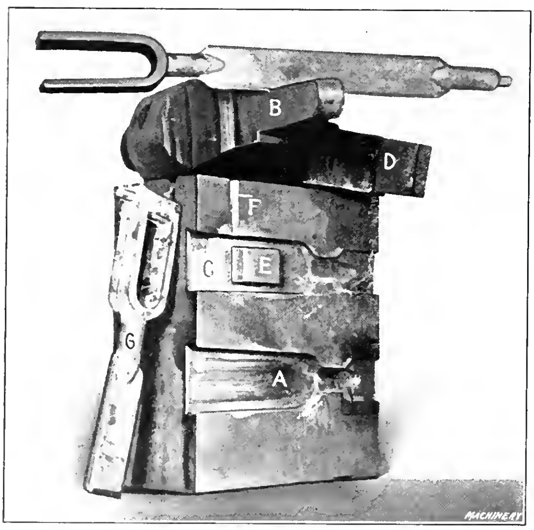

Fig. 74. Dies and Tools used in making Spring Hanger shown at B in Fig. 70—also illustrating Pin Welding Operation

The loop *C* is now placed on the reduced end of the rod as shown at *G* and is riveted cold, just enough to hold the two pieces together while a heat is being taken. The work is then raised to a good welding heat, and is quickly placed in the lower groove *A* (see Fig. 74) of the dies held in the 6-inch forging machine shown in Fig. 71, where the work is formed by plunger *B*. The reason for doing this work in a 6-inch forging machine is that the plunger travel necessary is 14 inches, and this would be impossible on a smaller machine than that having a 6-inch capacity. This 14-inch travel, of course, is after the dies have been closed on the work. After the two pieces are welded together as shown at *H* (Fig. 75) a block *a* of 2-inch square iron 3 inches long is placed in the

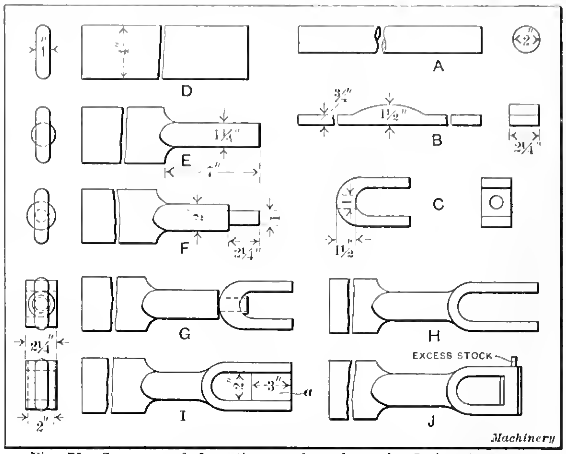

Fig. 75. Sequence of Operations performed on the Spring Hanger B shown in Figs. 70 and 74

U-end of the forging as shown at *I* and a welding heat taken. The work is then placed in the upper groove *C*, Fig. 74, of the dies and as the plunger *D* advances it upsets the forging to the proper shape around the embossed center portions *E*, the excess metal flowing up through the vent holes *F* provided in the gripping dies. The finished forging is shown at *J* in Fig. 75.

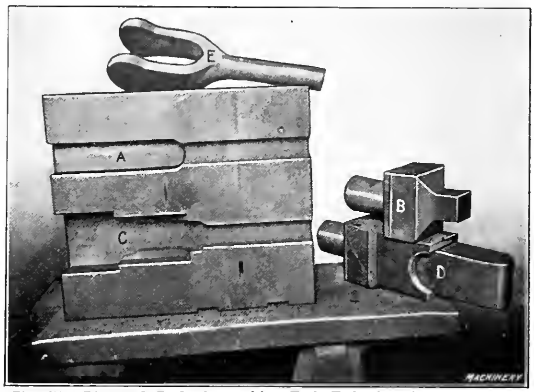

Fig. 76. Dies and Tools for making Fork End of Main Driver-brake Pull Rod shown at D in Fig. 70 in a Forging Machine

Still another type of spring hanger which is completed in the forging machine is shown at *C* in Fig. 70. This is made from a rectangular bar of wrought iron which is first lapped over and then welded, after which the eye end is formed to shape on the forging machine. The square hole is rough-formed by the vertical press of the universal forging machine shown in Fig. 71, and is then finished in the upper impression in the dies held in the horizontal part of the forging machine. No material is removed to form the square hole, the metal simply being expanded, increasing the width of the bar.

Dies and Tools for making Fork End of Main Driver-brake Pull Rod

The fork end of the main driver-brake pull rod shown at *D* in Fig. 70 is made from a $2\frac{1}{4}$-inch bar of round wrought iron which is first squeezed down flat on one end until the flattened end is 3 inches wide by 14 inches long. This operation is handled in the vertical head of the machine shown in Fig. 71. A piece of $\frac{1}{2}$ by 3 by 14-inch wrought iron is laid on the flattened portion of the bar (both pieces, of course, being heated) so that they can be stuck together by the dies held in the vertical head of the universal forging machine, thus holding them while the welding heat is being taken. The next step in the production of this fork is to increase the diameter of the rod from $2\frac{1}{2}$ to 3 inches square. This opera-

tion is accomplished in the upper grooves A of the dies shown in Fig. 76, using the plunger B for upsetting. The 3-inch squared end is now split for about 9 inches of its length with suitable tools held in the vertical head of the machine, and at the same time is opened up slightly. The piece is then taken

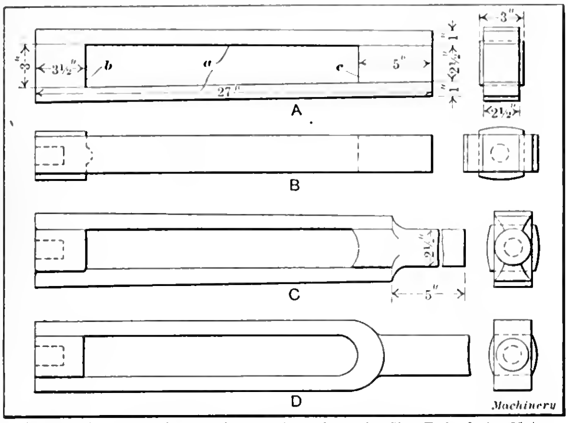

Fig. 77. Sequence of Operations performed on the Slot End of the Main Driver-brake Pull Rod shown at E in Fig. 70

to the furnace and heated, after which it is placed in the lower grooves C of the dies, and with one blow of plunger D is brought to the final shape as shown at E.

Dies and Tools for making Slot End of Main Driver-brake Pull Rod

The slot end of the main driver-brake pull rod shown at E in Fig. 70 is made as shown in Fig. 77 from two pieces a of

Fig. 78. Butt-welding Bottom Connecting-rods in an Ajax Forging Machine in the Collinwood Shops of the L. S. & M. S. Railway

1 by 2½-inch flat bar iron 27 inches long, one piece b of 3-inch square iron 3½ inches long, and one piece c of 2½-inch square iron 5 inches long. The two pieces a are clamped by a pair of tongs on the end where the block c is located and a welding heat is taken on the other end. The work is then removed from the furnace by the tongs and quickly placed in the top groove of the dies. The machine is operated and as the plunger, which has a punch on its front end, advances, it punches a hole in the work and displaces the stock, forming a boss on each side as indicated at B. The position of the tongs on the work is then reversed and the other end of the forging is heated, after which it is swaged to 2½ inches in diameter for a distance of 5 inches on this end to the shape shown at C. This operation is handled by the gripping dies which are provided with circular grooves located between the upper and lower impressions. The forging is again heated and placed in the lower impressions of the dies, the round part entering the plunger. The machine is then operated, forming the forging to the shape shown at D.

Butt-welding Bottom Connecting-rods

In the fifth installment of this article, which appeared in the September number of MACHINERY, it was mentioned that butt-welding is seldom accomplished on forging machines, owing to the difficulty generally experienced in successfully making this type of weld. The bottom connecting-rods shown in Fig. 78 and also at F in Fig. 79, are produced satisfactorily by butt-welding in the Collinwood Shops of the L. S. & M. S. Railway, so that a description of the method used in handling will no doubt be appreciated. The stock for the forked ends A, Fig. 79, is sheared off from a bar of 2½ by ¾-inch wrought iron and bent to a U-shape in the bulldozer. The center portion of this connecting-rod is made from 1¾-inch round wrought-iron bars which are also sheared to the required length before coming to the forging machine.

The U-shaped pieces A and bars B are now placed in the furnace G, Fig. 78, where they are heated to a welding temperature. The operator then removes a rod and also a U-shaped piece and butts them together as indicated in the illustration; he then places the pieces which are stuck together in the impressions in the gripping dies C and D, Fig. 79, and operates

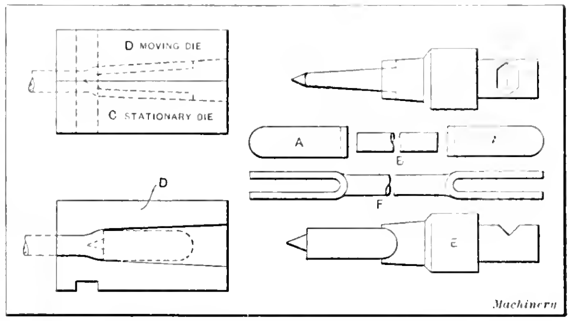

Fig. 79. Illustrations showing Sequence of Operations in the Butt-welding of Bottom Connecting-rods, shown in Fig. 78

the machine. Now as plunger E, which has a pointed end, advances it forces itself through the fork into the round stock, thus intermingling the grain of the material and insuring a solid weld. To prevent scale from forming on the pieces to be welded, a small jet of compressed air is made to play on them just before and while the machine is operating.

After welding, the work is removed from the gripping dies and placed between suitably shaped forming dies held in the side shear H, Fig. 78. The machine is then operated, forming the U-shaped end to the proper shape, after which the piece is thrown down in the sand to cool off (see I, Fig. 78). After all the rods have been completed in this manner, the other or straight end is placed in the furnace and the procedure followed that was previously described. The completed bottom connecting-rods are shown at F in Figs. 78 and 79, respectively. To prove that this type of weld was satisfactory, numerous tests were made to break it at the welded joints.

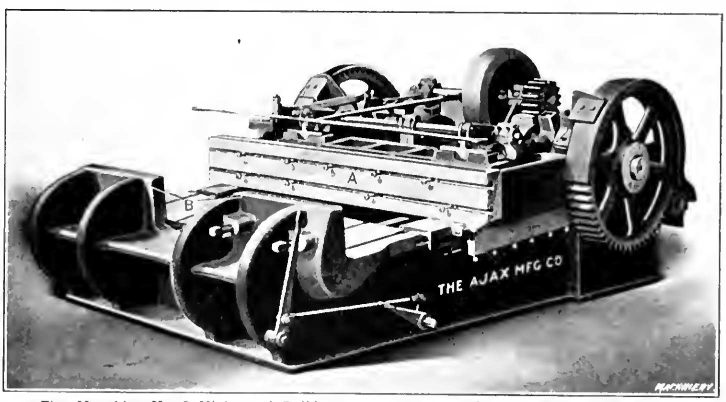

Fig. 80. Ajax No. 7 High-speed Bulldozer—an Important Adjunct to the Forging Machine

This was not accomplished until the testing machine registered a pull of 74,000 pounds, which is equivalent to a tensile stress of approximately 30,000 pounds per square inch. As the tensile strength of wrought iron seldom exceeds 48,000 pounds

per square inch, it will readily be seen that this type of weld would be satisfactory for the general run of forged work.

Bulldozer as an Auxiliary to the Upsetting and Forging Machine

Considering that so many parts completed on the forging machine can be handled successfully only when partially formed by the bulldozer it may not be out of place to include a short description of this type of machine. Fig. 80 shows the type of bending and punching machine known as the bulldozer, which is used so extensively as an auxiliary to the forging machine in the manufacture of many forgings.

The construction of this type of machine is simple, consisting primarily of a moving crosshead A which carries one member of the forming dies, the other member of the forming dies being held against the toes B of the machine. The operations are accomplished by the forward travel of the crosshead, the work as a general rule being completed in one travel of the head. Of course while the machine is fairly simple in construction and operation, many types of interesting forming tools are used. However, it will be impossible to go into this subject fully in this article, as it is necessary to confine our attention more particularly to the forging machine rather than to its auxiliaries.

The forming tools for the bulldozer can generally be made cheaper and more conveniently from cast iron, especially when they are provided with hardened steel plates where any friction takes place—that is, those parts of the tool which actually do the forming or shaping should, as a general rule, be reinforced with hardened steel plates. This enables the tools to be renewed very cheaply, as the plates when worn out can be replaced by new blocks of steel. The roller type of tool which is carried and operated by the crosshead is the best for saving material and power when it is possible to use this type. However, the type of tool to use depends largely on the shape to be formed and other requirements. In all cases where hot punching or cutting is done, high-speed self-hardening steel should be used for the working members of the tool.

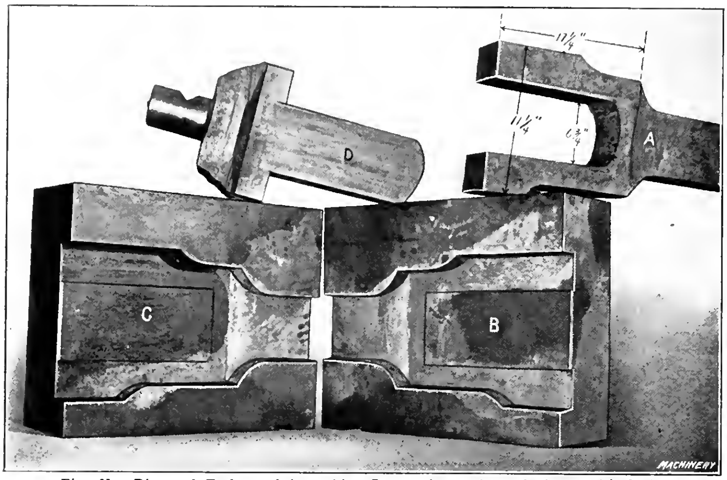

Fig. 81. Dies and Tools used in making Locomotive Main Rods in the 6-inch Ajax Universal Forging Machine

Tools for making Engine Main and Side Rods in the Forging Machine

The locomotive main rod shown at A in Fig. 81 is the largest piece of work ever handled in a forging machine in the Chicago shops of the C. & N. W. Railway. The main rod is first roughed out under a steam hammer and the end split before it is brought to the forging machine shown in Fig. 71. The roughing out of the slot and the finish-forming in the forging machine are done in one heat. In the forging machine the work is gripped by the dies B and C and is upset and formed to shape by the plunger D.

Another good example of heavy forging accomplished in the Ajax 6-inch universal forging machine is the locomotive side rod shown at A in Fig. 82. This side rod is made from square stock drawn down to the required size under the steam hammer, and is upset and formed on each end in the forging machine shown in Fig. 71. The gripping dies, only one of which is shown at B in Fig. 82, are used for forming the end C of the rod. It requires two operations to complete this end. The first operation is performed in the lower groove D of the dies and consists in rough-forming the slot with the plunger E. The work is then placed in the upper groove F and completely formed to shape by means of plunger G.

The other end H of the side rod is upset and formed to shape by another set of dies—only one of which is shown at I. The rod, which is heated to a welding temperature, is placed in the impressions in the gripping dies and is upset and formed to the required shape by means of the plunger J. These two examples of machine forging illustrate very well the adaptability of the forging machine to locomotive manufacture.

HANDLING A LARGE TURRET LATHE JOB

At the shops of the United States Light & Heating Co., Niagara Falls, N. Y., some very interesting turret lathe work is handled on Warner & Swasey machines. One of these jobs in particular is unusual because of the extreme size of the work, and the number of tools in the set-up. The tool set-up is shown in Fig. 1, and the piece in question is illustrated in Fig. 2 which shows the work in section and the chuck in side elevation. This is an aluminum casting, being a mounting frame for an electric starter for automobiles. The casting is 18 inches in diameter over-all, and is machined on ten surfaces. These surfaces are finished with eight tools, all of which cut simultaneously.

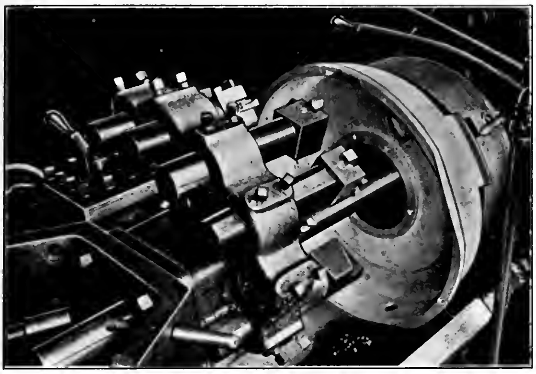

Fig. 1. A Turret Lathe Job and the Special Tools employed

The entire machining is accomplished without indexing the turret so that the operation is very simple after the tools have once been set up. Referring to Fig. 1, it may be seen that five of the tools are supported from the special turret bracket, which is, in turn, bolted to one of the turret faces. The sixth tool is mounted on a boring-bar that is supported from the turret, and the seventh and eighth tools are held in the front carriage of the turret lathe. On account of the size and thinness of the walls of the casting, it is somewhat difficult to support it, and the gripping is done from the inside of the central hole, as shown in Fig. 2.

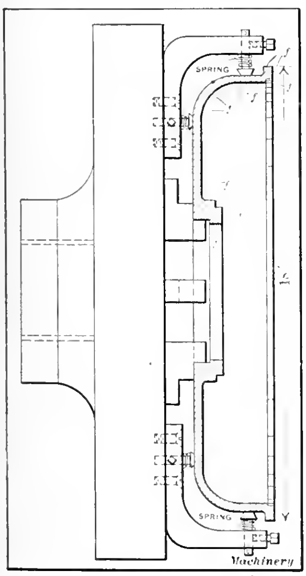

Fig. 2. How the Piece was held to eliminate Vibration

The machining of a casting or shell with thin walls is always productive of chatter. As chatter is one of the chief causes of the dulling of tools, it is important to reduce it to a minimum. This is done by providing spring pins that extend from four brackets supported from the chuck body and spaced equidistantly around the casting. From each of the brackets two pins extend, one against the back and the other against the side of the casting. After the piece has been chucked, allowing the pins to bear against the work, setscrews are tightened, thus backing up the work securely and supporting it while being turned. These pins serve to obviate the vibration which would otherwise occur. Two of the sets of spring pins and brackets are illustrated in Fig. 2, but do not appear in Fig. 1. For a cutting lubricant "Magic" compound is used with excellent results.

The work was formerly performed upon a large engine lathe, and the output was but ten pieces per day when done in this manner. On the Warner & Swasey 3-A machine, however, the output is seventy-five pieces per day, and the production is more accurate. C. L. L.

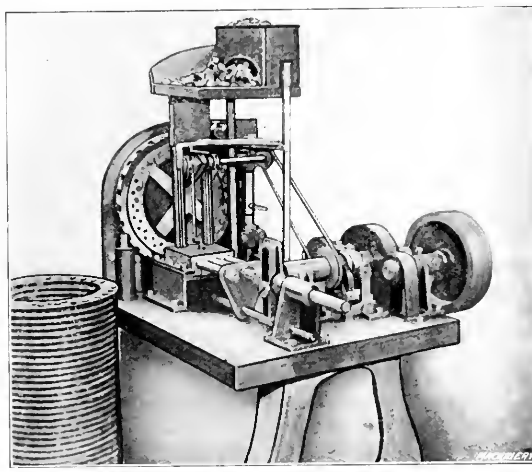
INSERTING CORKS IN CLUTCHES

BY H. F. HINES*

The illustration shows a semi-automatic machine for inserting corks in the steel disks of multiple automobile clutches. These disks have fifty-six holes 7/16 inch in diameter, the holes being staggered as shown in the partially filled disk mounted in the machine. The corks used for these clutches are 11/16 inch in diameter before they are compressed to be forced into the disk.

The operation of the machine may be briefly described as follows: The disk is placed on the revolving head of the machine and located by two small plungers, after which it is securely clamped in position. The locating plungers enter holes on opposite sides of the disk and when the corks are inserted in these holes they push the plungers back. The head which carries the disk is automatically indexed by means of a lever and pawl. This index mechanism is actuated by a cam on the crankshaft, the head being indexed after each stroke of the plungers which press the corks into the disk.

The corks are placed in a hopper at the top of the machine which delivers them to two feeding chutes, small wire brushes being provided to force the corks through the chutes into the slides in which the plungers operate. As the corks drop in front of these plungers on their forward stroke, they are driven through tapered bushings which reduce their diameter from 11/16 to 7/16 inch—the size of the holes in the disk. As the fit of the corks in these bushings becomes tight, it causes the slide to be pushed up against the disk, and as the plungers continue their forward stroke, they force the corks into place. As soon as the plungers start on their return stroke, a small catch pulls the slide off the ends of the corks which project from the disk and thus allows the disk to be indexed by the time the plungers have reached the end of their return stroke and are ready for the next operation.



Special Machine for inserting Corks in Automobile Disk Clutches

It will be seen from the illustration that the crosshead which carries the plungers is operated by a crank on the end of the main driving shaft, the action of the machine being controlled by a foot treadle which operates a clutch on the driving shaft. The machine will continue to run as long as the treadle is held down, but stops at the end of the first return stroke which is made after the treadle has been released. The machine runs at about forty strokes per minute, and as two corks are inserted at a time a disk is completely filled in about forty seconds. The efficiency of the machine is indicated by the fact that it has made a record of filling four hundred disks in 9 hours 20 minutes, requiring the insertion of 22,400 corks.

Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit contributions from practical men on subjects pertaining to machine shop practice and machine design. All contributed matter published exclusively in MACHINERY is paid for at our regular space rates unless other terms are agreed on.

OCTOBER, 1913

NET CIRCULATION FOR SEPTEMBER, 1913, 26,285 COPIES

THE DUTIES OF A FOREMAN

Just exactly what the duties of a foreman are depends, of course, largely upon the conditions in various shops. In some, he may be selected largely because of his mechanical knowledge and of his ability to direct the work from a mechanical point of view. In others, the work may be of such a nature that his mechanical qualifications are of minor importance, but his general executive ability is of greater value. It is certain, however, that the foreman should not be selected because of his ability as a clerk; and yet in many shops a large proportion of his time is occupied by work that is purely clerical: making out reports, keeping records, filling in and signing stock orders, etc. In fact, he does work which could and should be done by men who do not possess his qualifications for mechanical training or executive ability, leaving him free to devote himself to the greater task of managing his department.

It is in line with good management, whether it be "scientific" or otherwise, to relieve superintendents and foremen of their clerical work and permit them to devote their time and energy to running their departments and to obtaining the highest efficiency. It is poor policy to save the pay of an ordinary clerk at the expense of having the whole department, where scores of men are employed, run in a haphazard way. There are too many cases where this condition exists, and there are even so-called "well managed" shops that require their foremen to spend nearly half of their time in doing work that a clerk receiving one-third the pay could do with equal efficiency.

PANAMA-PACIFIC INTERNATIONAL EXPOSITION

The Panama-Pacific Exposition to be held in San Francisco in 1915 promises to be an event of unusual international importance, notwithstanding the fact that Great Britain and Germany have refused to participate. It will mark the beginning of a new period in the world's commerce. The diversion of ocean trade through the Panama Canal will undoubtedly have a profound effect on the commerce of the world in general and that of the United States in particular.

World's fairs have been promoted freely during the past twenty years and such enterprises have undoubtedly been overdone in Europe, but it should be remembered that none of those held during the past five years has had the international significance of the event to occur in 1915. This exposition will bring the East and the West closer together, open new avenues of trade and broaden those already open. The liberal policy of the exposition management with regard to small exhibitors in permitting a number to club together and exhibit in one space with all the rights and privileges of independent exhibitors should encourage many to show their products, who under the ordinary conditions of exhibition at world's fairs would not or could not do so.

The exhibition will be on a vast scale. The machinery building alone will have nearly eight acres of floor space. All parts of the building will be served by adequate crane facilities, and electric current both alternating and direct, and gas and water will be available in all parts of the building. Compressed air and steam will be provided adjacent to the gas and fuel section, and general illumination will be provided by the exposition company. Eastern manufacturers interested in developing trade in the Pacific coast states will largely embrace the opportunity to make their products known and at the same time become personally acquainted with the conditions of Western and Oriental business.

A GERMAN VIEW OF SCIENTIFIC MANAGEMENT

It has been said that one must go to Germany to see American systems of factory management carried out to their full possibilities and logical conclusion. It has also been said that when the Germans begin to adopt the scientific management system developed in America they will organize their factories along these lines much more rapidly and efficiently. The reason given for this is that the German people, on account of their temperament and training—their military services and consequent habits of obedience to superiors—would fit into a system of scientific management much more readily than would Americans. While no doubt there is considerable truth in these assumptions, prominent Germans themselves do not believe that the "millennium" of scientific management will arrive very quickly. Prof. Schlesinger, who presented a paper on this subject at the joint meeting of the Society of German Engineers and the American Society of Mechanical Engineers at Leipzig the past summer, dwelt on the point that no matter how well adapted a people may be to work under this system, the great difficulty of securing properly trained managers for installing the new system and operating factories under it will always exist. He pointed out that a system of management properly carried out along the lines laid down by Taylor requires managers and engineers of unusual ability. Not only must they be well trained, both in the theory and practice of their line of business, but they must, in addition, be exceptional students of human nature and keen observers of human traits. This is a point of great importance and one which is often overlooked. People speak of scientific management as though it were something that could be bought and sold in the market, that can be accepted or left alone, as they please, but it is not so. Scientific management can be logically and properly installed and carried on only by men of exceptional qualifications; and it is not a system which anyone can adopt and install at will. This is probably the reason for the many alleged failures of this type of management reported; and also for the misunderstanding and misconception of the system itself.

Scientific management is by no means an entirely new development, although it was worked out in more minute details and given more prominence, as well as a name, by Mr. Taylor and others who have taken up his work; but the principles of scientific management have been applied in many of the well managed factories in this and other countries for years, and the extent to which these attempts in the past were successful as systems of management depended on the personal factor—on the manager. And so it will continue in the future. Men with the peculiar capacity for leading other men along definite, well-thought-out and systematic lines will succeed with scientific management, while those who have not this ability will fail, and will have to be satisfied with getting along in the conventional way.

PRICE-CUTTING VS. PRICE-MAINTENANCE

The recent decision of the U. S. Supreme Court, that selling a patented article for less than the specified retail price does not constitute an infringement of the patent, removed a bulwark behind which much of the fixed-price business of the country was established. The decision is one viewed with satisfaction by those who realized that the use of the patent privilege to fix prices was a serious, if not a dangerous, abuse of the law. But the price-cutting likely to result in retail trades from the removal of the means for holding retailers to fixed prices may work much injury. Louis D. Brandeis, the well-known lawyer, active in progressive legislation, has published a protest against price-cutting and a plea for the maintenance of the fixed-price principle when not coupled with monopoly. An extract from his statement which follows is of general interest:

> There is no improper restraint of trade when an independent manufacturer in a competitive business settles the price at which the article he makes shall be sold to the consumer. There is dangerous restraint of trade when prices are fixed on a common article of trade by a monopoly or combination of manufacturers.
>
> The independent manufacturer may not arbitrarily establish the price at which his article is to sold to the consumer. If he would succeed he must adjust it to active and potential competition and various other influences that are beyond his control. There is no danger of profits being too large as long as the field or competition is kept open; as long as the incentive to effort is preserved; and the opportunity of individual development is kept untrammeled. And in any branch of trade in which such competitive conditions exist we may safely allow a manufacturer to maintain the price at which his article may be sold to the consumer. Competition is encouraged, not suppressed, by permitting each of a dozen manufacturers of safety razors or breakfast foods to maintain the price at which his article is to be sold to the consumer.
>
> By permitting price-maintenance each maker is enabled to pursue his business under conditions deemed by him most favorable for the widest distribution of his product at a fair price. He may open up a new sphere of merchandising which would have been impossible without price protection. The whole world can be drawn into the field. Every dealer, every small stationer, every small druggist, every small hardware man can be made a purveyor of the article, and it becomes available to the public in the shortest time and the easiest manner.
>
> Price-cutting of the one-priced trademark article is frequently used as a puller-in to tempt customers who may buy other goods of unfamiliar value at high prices. It tends to eliminate the small dealer who is a necessary and convenient factor for the widest distribution; and ultimately, by discrediting the sale of the article at a fair price, it ruins the market for it.

Price-cutting is one of the most efficient means of establishing monopoly in retail trade. The dealer who offers to sell a well-advertised fixed-price article at or below the wholesale price does so for an ulterior purpose. The sale of the advertised article is limited and the constant effort is to induce customers to buy other and "just-as-good" articles yielding a larger profit. Competition having been destroyed by price-cutting methods, the field is open for high prices and the abuses that invariably follow the establishment of a private monopoly.

* * *

Machine contractors who bid on work for the government find that the law requiring that all government work done under contract must be carried through by men working on the eight-hour day basis necessitates their placing much higher bids upon the work. Two years ago the successful bidder on a lot of 5000 3-inch cast-iron shells was awarded the contract on a bid of eighty cents each, his men being employed on the ten-hour day basis. Recently when bids were received for a similar lot of 5000 of these shells to be made to the same specifications, the lowest bid was one dollar and forty cents each, and it is claimed that the increased figure of the last bid was largely due to the fact that the work must be done on the eight-hour day basis.

POINTS ON BROACH-MAKING

BY FRANKLIN D. JONES*

Broaches have a series of teeth that successively cut the work to the required form, and naturally the proportioning of these teeth is one of the most important features of broach design. While the design of a broach, aside from its general shape or form, depends largely upon its intended use, there are certain features which apply to broach-making in general. One of the first things to determine is the pitch of the teeth, or the distance from one tooth to the next.

Pitch of Broach Teeth

As a general rule, the pitch P (see Fig. 1) should increase as the length of the hole increases to provide sufficient space between the teeth for the chips. The pitch of the teeth

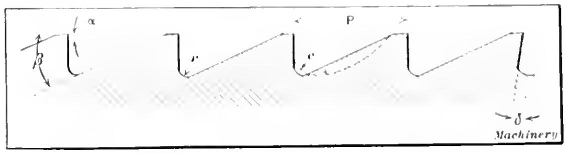

Fig. 1. Diagram illustrating Pitch, Clearance Rake and Filleting

for broaching under *average* conditions can be determined by the following formula, in which P = pitch of teeth and L = length of hole to be broached:

$$P = \sqrt{L \times 0.35}$$

This formula expressed as a rule would be: *The pitch of the teeth equals the square root of the length of the hole multiplied by the constant 0.35.* For example, if a broach is required for a square hole 3 inches long, the pitch of the teeth would equal $\sqrt{3 \times 0.35} = 0.6$ inch, approximately.

Of course a given pitch will cover quite a range of lengths, the maximum being the length in which the chip space will be completely filled. The constant given in the preceding formula may be as low as 0.3 for some broaches and as high as 0.4 for others, although the pitch obtained with the value 0.35 corresponds closely to average practice. When a broach is quite large in diameter, thus permitting deep chip spaces in front of the teeth, the pitch might be decreased in order to reduce the total length of the broach. On the other hand, if the work is very hard and tough, a coarser pitch might be advisable in order to reduce the power required to force the broach through the hole. If the pitch is too fine in proportion to the size of the broach, there may be difficulty in hardening, owing to the fact that the fine teeth will cool much more rapidly than the broach body, thus

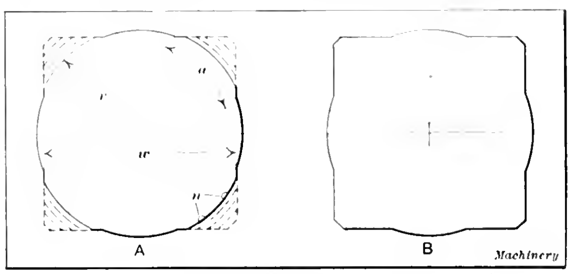

Fig. 2. Diagram illustrating Distribution of Tooth Cuts in broaching a Square Hole

producing severe strains which tend to crack the teeth, especially at the corners. If the teeth are too closely spaced, so much power may be required for drawing the broach through the work that there is danger of pulling the broach apart. In general, the pitch should be as coarse as possible without weakening the broach too much, but at least *two teeth should be in contact* when broaching work of minimum length.

Depth of Cut per Tooth

The amount of metal that the successive teeth of a broach should remove, or the increase in size per tooth, depends largely upon the hardness or toughness of the material to be broached. The size of the hole in proportion to its length

* Associate Editor of MACHINERY.

also affects the depth of cut, so that it is impossible to give more than a general idea of the increase in size per tooth. Medium-sized broaches for round or square holes usually have an increase of from 0.001 to 0.003 inch per tooth for broaching steel, and approximately double these amounts for soft cast iron or brass. Large broaches up to 2 or 3 inches may have an increase of from 0.005 to 0.010 inch per tooth Obviously, the depth of cut is governed almost entirely by the nature of the work. For example, a small broach for use on brass or other soft material might have a larger increase per tooth than a much larger broach for cutting steel. If the amount of metal to be removed is comparatively small and the broach is used principally for finishing, the increase per tooth may not be over 0.001 inch even for large broaches.

The diagrams *A* and *B*, Fig. 2, show a common method of broaching square holes in the hubs of automobile transmission gears, etc. Prior to broaching a hole is drilled slightly larger in diameter than the square width. The first tooth on the broach is rounded considerably and cuts a long circular chip, as indicated at *a*, and the following teeth form the square corners by removing successive chips (as shown by the dotted lines) until the square is finished as at *B*. As will be seen, the first tooth has the widest cut, the chip width *a* greatly decreasing toward the finishing end of the broach. Hence, if this hole were finished with a single broach, it would be advisable to vary the sizes of the teeth so that the depth of cut gradually increases as width *a* decreases. It is good practice to nick some of the wide teeth as indicated at *n*, in order to break up the chips, as a broad curved chip does not bend or curl easily. In case two or more broaches are required, the first broach of the set may have a uniform variation in the radii *r* of different teeth, but the depth of cut should be less than for the following broaches which remove comparatively narrow chips from the corners of the square. Several end teeth, especially on the last broach of a set, are made to the finish size. This feature, which is common to broaches in general, aids the broach in retaining its size and tends to produce a more accurately finished hole.

Testing Uniformity of Teeth

When testing a broach to determine if all the teeth cut equally, first use a test piece not longer than 2 × pitch of teeth. Pull the broach through and note the amount of chips removed by each tooth; then "stone down" the high teeth and test by drawing through a longer piece, and, finally, through the full length required. If a broach is warped much, or is otherwise inaccurate, some teeth may take such deep cuts that the broach would break if an attempt were made to pull it through a long hole on the first trial.

Clearance Angles for Broach Teeth

The clearance angle *a* (Fig. 1) for the teeth of broaches is usually very small, and some broaches are made with practically no clearance. Ordinarily there should be a clearance angle varying from 1 to 3 degrees, 2 degrees being a fair average. A common method of providing the necessary clearance is as follows: All the lands of the hardened broach are first ground parallel and then they are "backed off" slightly by means of an oilstone. Just back of the narrow land (which may not be over 1/32 inch wide) there is a clearance of 2 or 3 degrees, machined prior to hardening.

The clearance space required for the chips depends upon the length of the hole and the depth of the cut. When the cut is light, and especially if the material to be broached is tough, thus making it necessary to use as strong a broach as possible, the clearance space should be proportionately small. The fillet at the base of each tooth should have as large a radius *r* (Fig. 1) as practicable and the grooves between the teeth should be smooth so that the chips will curl easily. A curved clearance space, similar to that indicated by the dotted line *c*. is superior to the straight slope, although not so easily machined. The front faces of the teeth are sometimes given a rake δ of from 5 to 8 degrees so that the broach will cut more easily and require less pressure to force it through the holes.

Steel for Broaches

Three kinds of steel are used for making broaches: namely, alloy steel, carbon steel and, to some extent, casehardened machine steel. Carbon-vanadium tool steel is especially adapted for broaches. This steel differs from the high-speed steels in which vanadium is also used in that it does not contain tungsten or chromium, but is simply a high-grade carbon steel containing a certain percentage of vanadium. The addition of vanadium to carbon steel imparts certain qualities, the most important of which are, first, the higher temperature to which the steel can be heated without coarsening the grain (thus permitting a greater range in temperature for hardening without spoiling the tool), and second, the tough core which makes the broach stronger and more durable than one made of regular high-carbon steel. The makers recommend hardening carbon-vanadium steel at a temperature varying from 1350 to 1425 degrees F., the temperature depending somewhat upon the size of the tool. The steel is then drawn to suit conditions, the drawing temperature generally being about 460 degrees F. This particular brand of steel will not harden in oil.

Regular carbon steel that is used for broaches should have from 1.00 to 1.10 per cent carbon. To prevent the steel from warping excessively, the broach should be annealed after the teeth have been roughed out. A successful method of hardening to prevent excessive warping is as follows: After machining the broach and before hardening, heat to a dark red and allow the broach to cool while lying on a flat plate, then heat to the hardening temperature and harden in the usual manner. This method, which is applicable to all tool steels, reduces warping to a minimum and is of especial value when hardening slender broaches.

Straightening Hardened Broaches

Broaches that have been warped by hardening can be straightened at the time the temper is drawn. Place the broach on two wooden blocks on the table of a drill press equipped with a lever feed, and insert a wooden block in the end of the drill press spindle. Heat the broach with a Bunsen burner until the hand can barely touch it; then apply pressure to the "high" side. Continue heating (as uniformly as possible) and bending until the broach is straight, but complete the straightening operation before the broach has reached a temperature of about 350 degrees F., so that the drawing temperature will not be exceeded. With this method the heat required for straightening is also used for drawing the temper, the broach being removed and quenched as soon as the tempering temperature is reached. The temperature is judged by brightening some of the teeth throughout the length of the broach and watching the color-changes as the temperature increases.

THE COUNTRY BLACKSMITH AND THE AUTOMOBILE

The rapid increase of automobile users in the agricultural districts has brought to the country blacksmiths a class of repair work which many are poorly fitted to handle. The ordinary horseshoer has little conception of the proper procedure to follow when called upon to straighten a bent channel section frame, for example, and much time and hammering are expended in accomplishing what proper heating and a few successful blows would otherwise quickly perform. The result is high cost for unsatisfactory repair work.

The country blacksmith should become familiar with the peculiarities of beam sections generally and with the construction of gas engines, frames, wheels, crankshafts, clutches, springs, etc. He should, in short, become an all-around mechanic of good judgment and quick action if he is to embrace the opportunity offered to the shops in good locations. The opportunity for the progressive man in many localities is golden. He must equip his shop with a few machines and apparatus not required for horseshoeing and repair of farm machinery, but the returns will amply reward him for the investment.

INSPECTION TESTS FOR CINCINNATI GEAR-CUTTING MACHINES

METHODS OF TESTING ALIGNMENT OF DIFFERENT PARTS WHILE GEAR-CUTTING MACHINES ARE BEING ASSEMBLED

The accuracy required for gearing necessitates a very close inspection of gear-cutting machines when erecting and of the machining operations of various parts. In most cases where gears are found to be defective, the fault lies in the imperfect machining of the gear blank rather than in the machine itself. As it is difficult to turn a gear blank so that it will run absolutely true after it has been removed from the mandrel and put back again in a reversed position, it is not strange that imperfect gears are commonly due to inaccurate blanks or improper mounting on the gear-cutting machine. When the blanks are accurately machined and properly mounted so as to avoid springing while being cut, gears can be finished very accurately in a properly built machine.

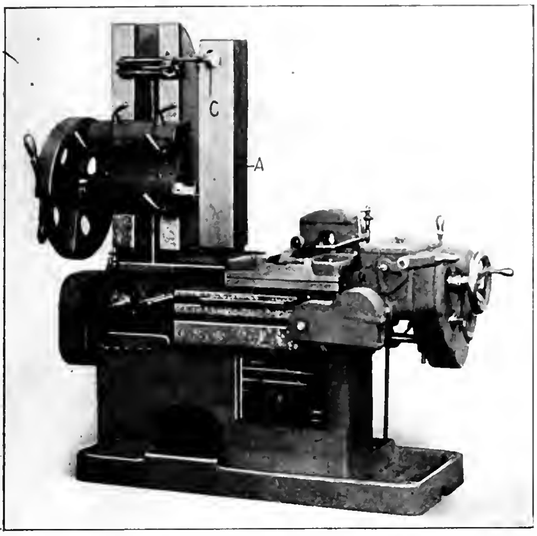

Fig. 1. Testing Position of Spindle-head Column relative to Base

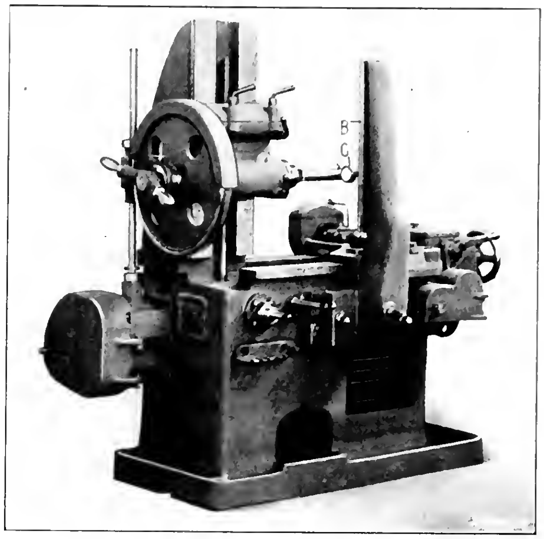

Fig. 2. Testing Parellelism of Faces of Outer Support and Housing

The illustrations shown herewith indicate the methods employed by the Cincinnati Gear Cutting Machine Co. Cincinnati, for testing the alignment of different parts while the gear-cutter is being assembled. The top of the machine bed is used as the foundation from which the tests are started. Upon this accurate surface a square column A is placed, as illustrated in Fig. 1. The sides of this column are parallel and perpendicular to the broad base which rests upon the ways. By turning this column and using its different sides, it is possible to determine accurately whether the face of the housing is perpendicular to the bed, the dial indicator C being placed upon the housing both at the top and bottom. When the housing is found to be perpendicular, the next inspection (shown in Fig. 2) is to determine the parallelism of the face of the outer support B with the housing face. The indicator C is attached to the spindle and the test is made by traversing the spindle-head vertically and noting any variation as indicated by the dial gage.

The hole in the work-spindle is next tested, as shown in Fig. 3, to determine whether it is concentric with the outside of the spindle and also whether its axis is parallel with the bed. The accuracy of the hole is determined by inserting the test-bar D in the spindle and revolving the latter while the dial gage is in contact with the bar. On the bottom of the indicator stand there is a block which comes against the inside edge of the bed, so that by placing the indicator in different positions along the top of the bed the parallelism of the spindle (as shown by test-bar D) can be determined.

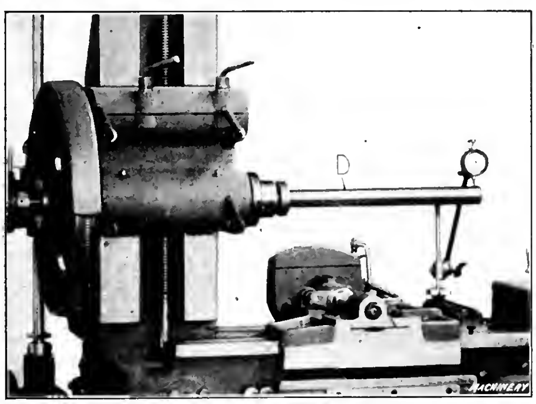

Fig. 3. Testing Concentricity of Hole in Work-spindle

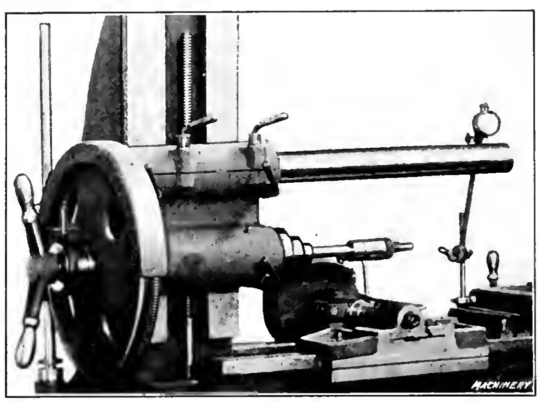

Fig. 4. Testing Alignment of Over-arm

The tests for the over-arm and centers that are used when cutting small gears are indicated in Figs. 4 and 5. These tests are similar to that employed for the work-spindle and are self-explanatory. After the truth of the work-spindle is determined, it is used as a tram, as shown in Fig. 6, to see if the ways of the cutter-spindle slide are at right angles to the work-spindle. A special angular surface-plate E is inserted in the dovetail ways and the indicator C is attached to an arbor and is swung from one side to the other by turning the spindle, thus bringing it into contact with op-

posite ends of the surface plate. The cutter-arbor is tested as shown in Fig. 7 to determine whether it is parallel with the top of the bed and also whether it runs concentric with the cutter spindle. In making this test, the indicator base rests upon the top of the bed, as shown.

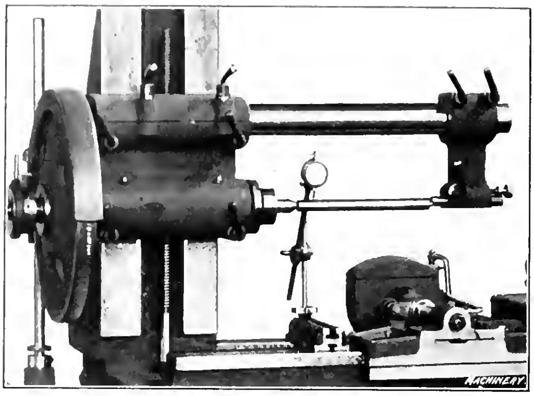

Fig. 5. Testing Centers used when cutting Small Gears

The test of the elevating screw is illustrated in Fig. 8. This is effected by using different blocks of a known length and comparing these blocks with the readings on the dial of the machine. The test indicator is first brought into contact with one of the blocks B and its dial is set at zero. The

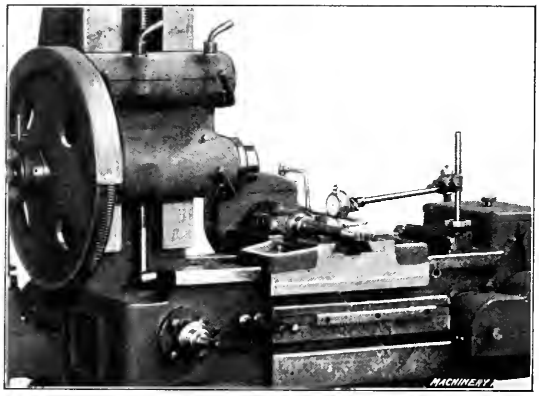

Fig. 7. Testing Accuracy of Cutter-arbor with Spindle and Bed

spindle-head is then elevated a distance equal to the difference between the length of block B and the next one to be used. The longer block is then placed under the test indicator and any variation of the pointer from zero shows the error in the elevating screw. The outer supporting arm for the

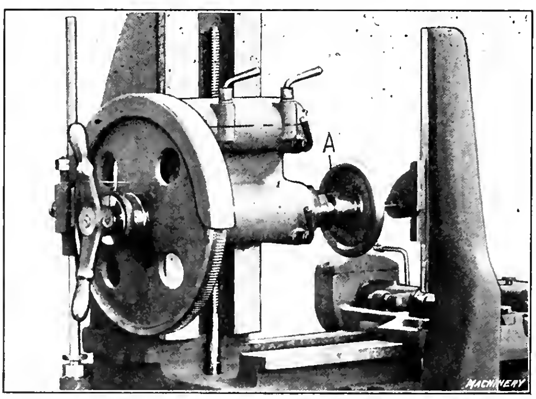

Fig. 9. Finish-boring Outer Supporting Arm in Alignment with Spindle

work-arbor is rough-bored prior to erection, but the finish-boring is done as shown in Fig. 9. The work-spindle and boring-bar are revolved by a small motor (not shown) belted to the index wormwheel which is temporarily converted into a pulley by placing a rim over it. The feed of the cutter-bar is effected by holding wheel A stationary. The truth of the bored hole is tested as illustrated in Fig. 10.

The method of testing the accuracy of the index wormwheel is shown in Fig. 11. Two disks D and D_1 are placed

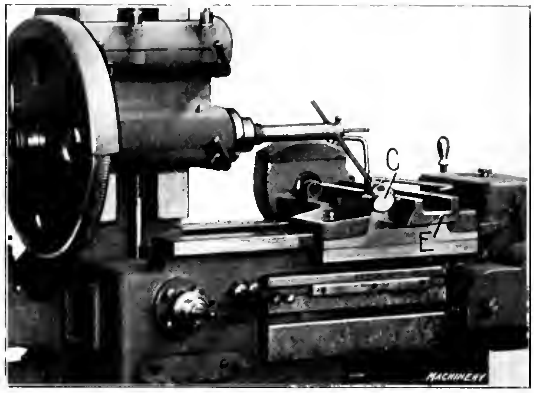

Fig. 6. Determining if Cutter-spindle Slide is at Right Angles to Spindle

side by side on a "floating" arbor. This floating arbor compensates for any slight error in the periphery of the disks, and by means of a knife-edge scriber fine lines are scratched across these two disks. This is done with the machine belted for use, and the operation is practically the same as if a

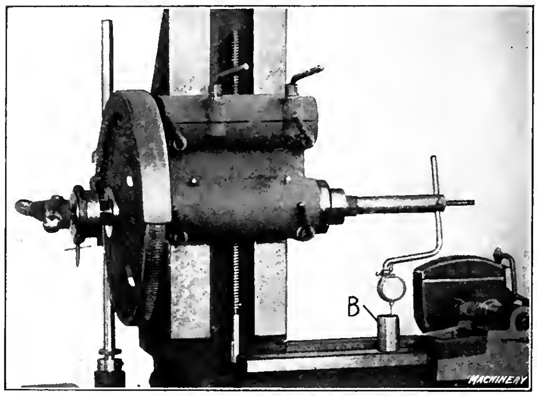

Fig. 8. Testing Accuracy of Elevating Screw

gear were being cut. After the disks have made a complete revolution, one of them is revolved half a turn in order to double any indexing error that may exist. As these disks are 18 inches in diameter, the error found in this way would be the same as though a 36-inch solid disk were used. After

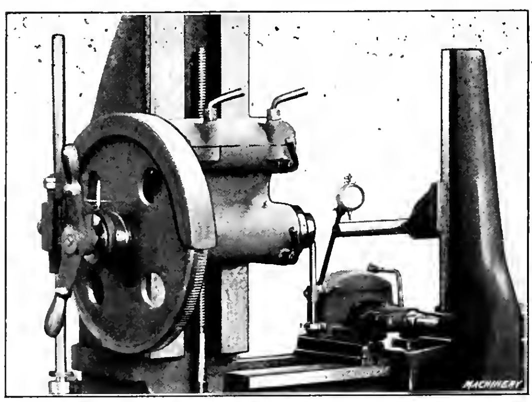

Fig. 10. Testing Bored Hole in Outer Supporting Arm

one disk is turned a half revolution, a comparison is made with the lines on the stationary disk by the aid of a microscope and a thin strip of metal upon which there are a thousand lines to the inch. Under the microscope, the thou-

sandth inch appears almost like one-sixteenth inch, so that very slight errors are easily observed.

An accurate means of setting the cutter centering device is shown in Fig. 12. A disk D having an included angle of 60 degrees is placed on the cutter-arbor and another disk D_1, notched to a corresponding angle, is placed on the work-arbor.

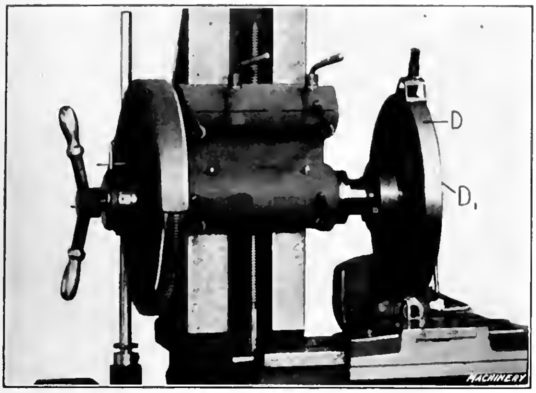

Fig. 11. Testing Accuracy of Indexing Wormwheel

The disk on the cutter-arbor is adjusted to such a position that all light is excluded between it and disk D_1 on the work-arbor; then the latter is reversed and if the light is still excluded this indicates that the disk on the cutter-arbor is central with the work-arbor and it is then used for setting the center gage. F. D. J.

Engineers who have returned from Spitzbergen after constructing the Norwegian Government's wireless station express the view that the natural resources on the islands are much more valuable than is generally supposed.

RATCHET WHEELS FOR FEED ROLLS

BY SIDNEY C. CARPENTER*

When selecting ratchet wheels for the feed rolls of power presses, the diameters of the rolls on the machine and the feed of the stock which is required are usually known, and the problem is to select a suitable wheel from the assortment in stock and then to determine the number of teeth on this wheel which corresponds with the required feed. For this purpose, the writer has compiled the diagrams shown herewith and has found that they save a considerable amount of time when a problem of this sort comes up. A complete list of the wheels that can be used for a given feed may be quickly obtained by following the vertical line corresponding with the required feed. As an example, let us suppose that a feed of 1.4 inch is required with feed rolls $2\frac{1}{2}$ inches in diameter.

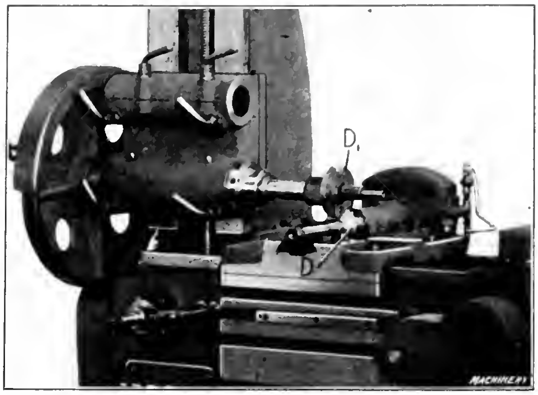

Fig. 12. Accurate Method of setting Cutter-centering Device

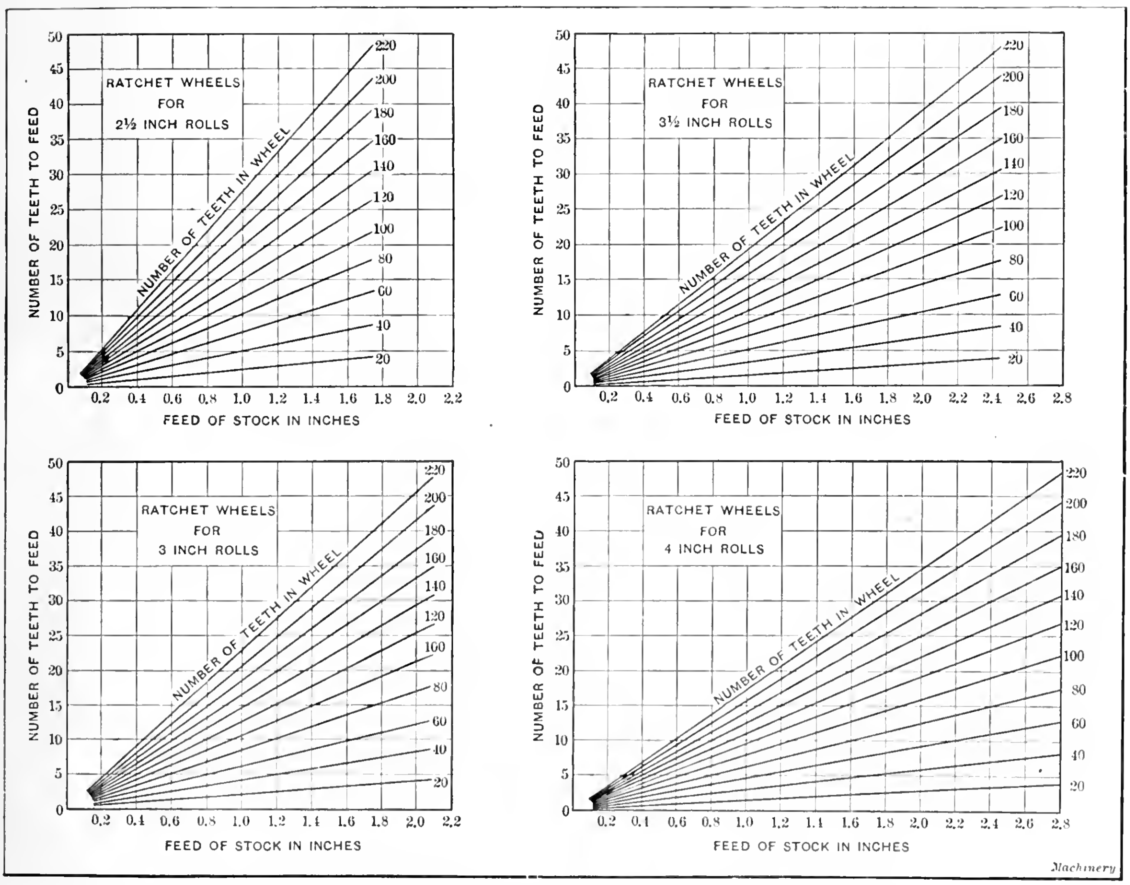

Diagrams showing Ratchet Wheels for a Given Feed with Rolls of the Size indicated

* Address: 49 Oakland Terrace, Hartford, Conn.

Following the vertical line from 1.4 on the diagram for $2\frac{1}{2}$ inch rolls—referring at each diagonal to the "number of teeth to feed" column at the left-hand side of the diagram—the following list of wheels is quickly obtained:

Wheel	Feed
40	7 teeth
80	14 "
120	21 "
160	28 "
200	35 "
220	39 "

If double pawls are used, half teeth can be read directly from the diagram.

A leading press manufacturer gives the practical limit for the feed of the stock as 0.7 of the diameter of the roll, which figures out about 0.22 of the number of teeth in the ratchet wheel. The limit for the different wheels in the diagrams is based upon this proportion. If a larger feed is required, gearing may be interposed between the ratchet and the rolls to give the required result. The diagrams give the principal relation between the feed of the stock in inches, the number of teeth in the wheel, and the number of teeth to feed for feed rolls of $2\frac{1}{2}$, 3, $3\frac{1}{2}$, and 4 inches in diameter. They are figured from the following formulas:

$$F = \frac{tC}{T} \qquad T = \frac{tC}{F} \qquad t = \frac{TF}{C} \qquad C = \frac{TF}{t}$$

in which C = circumference of feed roll;
T = number of teeth in ratchet wheel;
t = number of teeth to feed;
F = feed of stock in inches.

Similar diagrams for other sizes of feed rolls can be easily figured from these formulas.

SHOP PROBLEMS INVOLVING THE USE OF THE PRONY BRAKE FORMULA*†

BY J. H. CARVER‡

A convenient form of the prony brake formula is:

$$\text{H. P.} = 0.000016\ TN$$

where H. P. = horsepower transmitted;
T = twisting moment $(P \times R)$;
N = number of revolutions per minute.

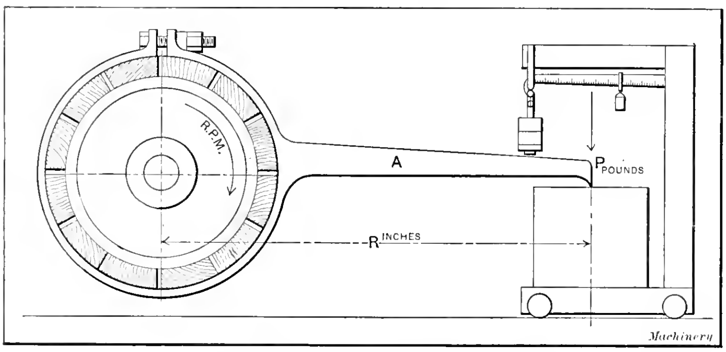

Diagram used in deriving Prony Brake Formulas

It is derived from the accompanying illustration, where it will be evident that if arm A makes N revolutions per minute, then a point R inches from the center travels $\frac{2\pi RN}{12}$ feet per minute. If P pounds are registered on the scale beam, the amount of power being developed is:

$$\frac{2\pi RN}{12} \times P = 0.5236\ PRN \text{ foot-pounds per minute.}$$

Therefore, as 33,000 pounds acting through a distance of one foot in one minute means one horsepower, then the horsepower transmitted is:

$$\text{H. P.} = \frac{0.5236\ PRN}{33{,}000} = 0.000016\ PRN \qquad (1)$$

Where it is convenient to use the twisting moment, $T = PR$, then:

$$\text{H. P.} = 0.000016\ TN \qquad (2)$$

In many instances, problems arise where the following formulas may be used to good advantage.

$$T = \frac{63{,}000 \text{ H. P.}}{N} \quad (3) \qquad N = \frac{63{,}000 \text{ H. P.}}{T} \quad (4)$$

$$P = \frac{63{,}000 \text{ H. P.}}{RN} \qquad (5)$$

These are derived from the equations:

$$\text{H. P.} = \frac{0.5236\ PRN}{33{,}000}$$

$$PR = T = \frac{33{,}000 \text{ H. P.}}{0.5236\ N} = \frac{63{,}025 \text{ H. P.}}{N}$$

(Neglecting 25 in the numerator.)

The following examples explain the use of the diagrams presented in the current Data Sheet Supplement.

$$\text{H. P.} = 0.000016\ PRN \qquad (1)$$

$$\text{H. P.} = 0.000016\ TN \qquad (2)$$

A hand-operated geared crane has a crank on each end of its driving shaft. Two men each exert a pressure of 50 pounds at a distance of 24 inches from the center of this shaft and turn it at 70 R. P. M. for a short period. If operated by a motor, what horsepower is necessary? T = twisting moment or torque of motor = 100 × 24 = 2400 inch-pounds.

Then H. P. = 0.000016 × 2400 × 70 = 2.68 H. P.

Using Diagram No. 1 and starting downward from 70 R. P. M. to the 100-pound diagonal and then moving to the right, stopping at the 24-inch line, and then downward gives 2.7 H. P. Therefore, allowing a possible 50 per cent overload on the 2.7 H. P. shows that a 4 H. P. motor is necessary, 5 being the nearest probable commercial rating obtainable.

$$T = \frac{63{,}000 \text{ H. P.}}{N} \qquad (3)$$

A motor pulley 20 inches in diameter is running at 500 R. P. M. Find the torque of motor when it is delivering 20 H. P. Using Diagram No. 2, start at 20 H. P. upward to the 10-inch diagonal; then move to the left, intersecting the vertical coming down from 500 R. P. M. at a point on the 250-pound diagonal. This point of intersection shows 250 pounds pressure on a 10-inch radius or a torque of 2500 inch-pounds.

$$N = \frac{63{,}000 \text{ H. P.}}{T} \qquad (4)$$

What speed is necessary for a shaft having a twisting moment of 16,000 pounds to give 70 H. P. (20 × 800 gives T, the twisting moment.) Start from 70 H. P. at the bottom of Diagram No. 3 and stop at the 20-inch diagonal; then moving to the left to the 800-pound line and upward shows 275 R. P. M. as speed necessary. (Figures show 275.6 R. P. M.)

$$P = \frac{63{,}000 \text{ H. P.}}{RN} \qquad (5)$$

It is required to find the tooth load on a 35 H. P. motor pinion running at 600 R. P. M. where the pitch diameter of the pinion is 12 inches. On Diagram No. 3, starting upward from 35 H. P. to the 6-inch diagonal, then moving to the left, intersecting the vertical downward from 600 R. P. M. shows approximately 610 pounds load. (Figures give 612.5 pounds.)

A scale used in connection with a prony brake registers 200 pounds. The lever arm is 5 feet long and the speed of the gas engine being tested is 600 R. P. M. What horsepower is being transmitted? Using Diagram No. 4 and starting downward from 600 R. P. M., stopping at the 200-pound diagonal, then moving to the right to the 60-inch line and downward again, gives 115 horsepower.

HARDENING AND TEMPERING STEEL

A REVIEW OF THE GENERAL REQUIREMENTS AND CHARACTERISTICS OF QUENCHING AND TEMPERING BATHS

While there have been many articles published regarding the hardening and tempering of steel and the furnaces used, there is but little detailed information available regarding the baths used for these operations. The time has long since passed when each hardener had his own carefully guarded secrets regarding the composition of quenching baths. On the other hand, the time has also passed when it was a common belief that to harden a piece of steel it was only necessary to cool it off more or less rapidly in almost any kind of cooling medium; it has been found that the cooling mediums for hardening and the heating mediums or baths for tempering do, after all, play quite an important part both as regards economy and the efficiency of the tools treated. It is the intention in this article to outline the methods which have proved most successful, and to give the compositions of baths which from long experience in connection with hardening operations have proved to give the best all around results and to be the most economical; in many cases they have not been the cheapest in initial cost, but nevertheless are most economical because of the better results obtained with the tools treated and the greater length of time that the baths could be used before deteriorating. A description of such receptacles—cooling tanks and tempering furnaces—for the treatment of steel as have proved to be the best for all around purposes has also been included.

For the sake of convenience the subject will be divided into four distinct parts as follows: (1) Baths used for cooling (quenching). (2) Baths used for tempering (drawing the temper after hardening). (3) Some tests and analysis of baths referred to under (1) and (2). (4) Receptacles and furnaces used in quenching and tempering.

Characteristics of Quenching Baths

No matter what the composition of a quenching bath, to insure uniform hardening the temperature of the bath must

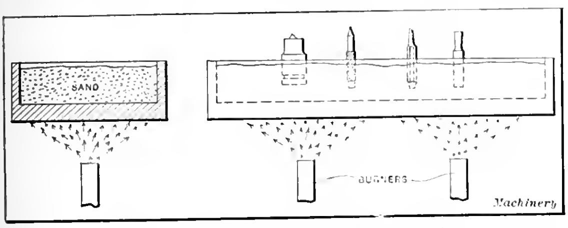

Fig. 1. Arrangement used for Sand Tempering

be kept constant, so that successive pieces of steel or tools quenched will be acted upon by baths of the same heat. The necessity of a uniform temperature for a quenching bath will be readily understood by reference to ordinary water for a cooling bath; everyone having any knowledge of the subject knows that a tool quenched in such a bath at room temperature will come out much harder than if quenched when the water is at the boiling point. In fact, it is well known that one way of partially annealing steel is by plunging it at a red heat into hot water. The same difference in hardness will result when using any quenching bath at different temperatures, and hence no actual and dependable data can be obtained unless means are taken for keeping these baths at a uniform heat.

When using quenching baths of different composition the tools quenched will vary in hardness. This is due mainly to the difference in heat-dissipating power of the different baths. Thus a tool hardened at the same temperature in water and brine will come out harder when quenched in brine; the greater the conductivity of the bath the quicker the cooling. The general opinion, today, is that the composition of a quenching bath is of small importance as long as the bath cools the pieces rapidly. Those who have made a study of the subject have found different opinions regarding the same quenching bath by different users, and a good many quenching fluids have been condemned owing to improper heating and in many cases to improperly built furnances. As an example may be cited an oven furnace with which the user once had trouble. Owing to faulty construction of this furnace, more air was let into the heating chamber of the furnace than could be taken care of by the fuel oil; after having condemned first the steel and then the quenching bath, and then trying one quenching bath after another with the same results, it was suggested that the "heating" did not look just right, and an expert was called in to find out what the trouble was. After much experimenting with

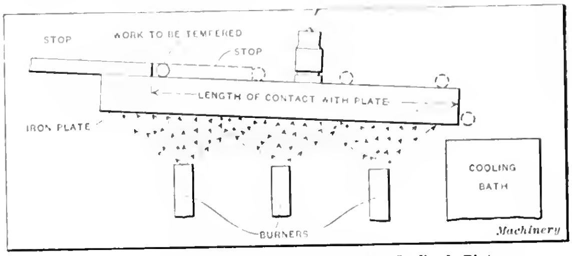

Fig. 2. Tempering Arrangement utilizing an Inclined Plate on which the Objects roll down

the burners and the furnace itself good results were finally obtained. The difficulty seemed to be that the oxygen of the air attacked the steel and formed oxide of iron on the surface of the tools, which consequently had a soft scale on the outside.

Those who are skeptical as to there being any difference in the effect on steel of cooling baths of different composition will readily admit that it is advantageous to use baths free from oxygen and from ingredients that tend to oxidize. Quenching baths should be uniform; good tool steels of high carbon are very sensitive to differences in both water and oils. Water for hardening tool steel should be soft; entirely different and very unsatisfactory results will be obtained when using hard water. While different quenching oils show less difference in the results obtained, vegetable and animal oils will give somewhat different degrees of hardness depending upon the sources from which they are obtained. One cannot be too careful in the selection of water, as it is likely to contain many impurities. If it contains greasy matters, it may not harden steel at all, whereas if it contains certain acids, it will be likely to make the tools quenched in it brittle and even crack them.

List of Quenching Baths

(1) Water—soft—preferably distilled; good tool steel should require no mixture added to pure water. (2) Salt added to water; will produce a harder "scale" than if quenched in plain water. (3) Sea (salt) water—the keenest natural water for hardening. (4) Water as under (1), containing soap. (5) Sweet milk.* (6) Mercury.* (7) Carbonate of lime.* (8) Wax.* (9) Tallow.* (10) Air—mostly used for high-speed steel; mere exposure, however, is in many cases and on many steels not sufficient to produce hardness and an air blast is necessary, as this furnishes cool air in rapid motion. (11) Oils† such as cottonseed, linseed, whale, fish, lard, lard and paraffine mixed, special quenching oils, etc.

The following list of oils and names of firms supplying them is given for the sake of convenience. The firms mentioned are reliable and their oils have been thoroughly tried out in comparison with other makes and have proved to be superior; opinions may, of course, differ in this respect and no doubt there are many oils that have not been tried that may be as good.

Cottonseed oil—Union Oil Co., Providence, R. I.; Underhay Oil Co., Boston, Mass.

* Generally used for special purposes only.
† A small quantity of sal-ammoniac added to the oil bath has a tendency to make the tools come out clean from the bath.

Linseed oil—Spencer Kellogg & Sons, Inc., Buffalo, N. Y.

Whale oil—no difference found between two different kinds.

Fish oil—only one kind tried.

Lard oil—W. B. Bleecker, Albany, N. Y.; E. F. Houghton & Co., Pittsburg, Pa.

Paraffine oil—Underhay Oil Co., Boston, Mass.

Special quenching oil—E. F. Houghton & Co., Pittsburg, Pa. Very good and cheap. While this may possibly deteriorate somewhat faster than some of the others mentioned it will prove very economical.

The order of the intensity with which various cooling baths will harden steel of about 0.90 to 1.00 per cent carbon is as follows: Mercury, carbonate of lime, pure water, water containing soap, sweet milk, different kinds of oils, tallow and wax. In all cases, except possibly the oils, tallow and wax, it must be remembered that the tools become harder as the temperature of the bath becomes lower.

Baths used for Tempering

The object of tempering is to reduce the hardness and to remove internal strains caused by sudden cooling in quenching. The composition of a tempering bath is of little importance compared with that of a quenching bath when considering the effect upon the pieces treated. Aside from the operator's convenience and possible bad effects upon his health, the different baths used for this operation must be considered with regard to initial cost, lasting quality, effects on finish, etc.

While oil is the most widely used medium for tempering tools in quantities, other means and methods are employed, especially by those who have tools in small quantities to temper, when the expense of installing and running an oil tempering furnace would not be warranted. Of these methods we first find the one used by the old-style tool hardener of only partly cooling the tool when quenching it, then quickly withdrawing it, polishing off the working surface, and then letting the heat which remains in the tool produce the required temper as judged by the color. If the tool has a shank, it is good practice to heat part of the shank also and quench the working part of the tool only, in which case this part can be cooled off thoroughly; the heat remaining in the body or shank of the tool will do the tempering, which also in this case must be judged by the color.

The sand bath is another frequently used medium for tempering, the sand being deposited on an iron plate and heated; by the use of this method a piece to be tempered can be given different tempers throughout its length, as, for example, rivet hole punches; these are placed endwise—bottom down—in the sand about two-thirds projecting outside the sand into the air (see Fig. 1). It is readily seen that the nearer the bottom of the sand bath, the higher the heat, and the punch so placed, when tempered right, will have the bottom soft—a deep dark blue—the neck a very dark straw, and the working part of the punch on top a light straw color; thus there is a gradual increase in hardness from the bottom up. Pieces so drawn must previously have been polished, and the temper is judged by the color. When the pieces have attained the right color they are, of course, cooled off, generally in water or oil. A plate without sand similarly heated can also be used, but it is not as satisfactory.

A plate arranged as shown in Fig. 2 will be found very convenient when drawing small, round pieces. The pieces are rolled on the inclined plate which is heated as indicated. The length of time the work is in contact with the plate can be regulated by adjusting the amount of the incline, as well as the location of the "stop." This arrangement can also be used for such work as punches, etc., in which case the plate, of course, should stand level and not in an inclined position.

Another frequently used tempering medium is hot air, the temper in this case also being judged by the color. For this method of tempering special furnaces should be employed in order to get uniform results. This method is used more especially for small and light work in quantities and where the color has to be bright and clear. While all of these methods have the advantage of enabling one to actually see the temper given to tools treated, the oil tempering bath is the one mostly used owing to its economy.

The two main points to be considered when using an oil tempering furnace are: first, to have the heat uniform throughout (not hotter where the burners or flames are in contact with the walls of the furnace); and second, to leave the pieces to be tempered in the oil long enough to have attained the heat of the oil throughout when taken out. The first point can be taken care of, as far as possible, by proper construction of the furnace; the second can best be taken care of by immersing the pieces to be tempered in the oil before starting to heat, and letting the pieces remain in the oil and be heated with it to the temperature required. In such a case, one should, of course, have more than one furnace, or else after each operation take the hot oil out and refill the tank with cold. The method described is very much better than the one frequently used of immersing the pieces in a bath which already has the required temperature and then letting them remain long enough to attain the heat of the bath throughout, as a furnace yet has to be designed which will maintain a uniform heat for even as short a time as is required for this operation. Furthermore, it is not necessary that a piece to be tempered be held in the bath a certain length of time at the required temperature; the temperature desired need only be maintained long enough to insure that the piece has been evenly heated throughout.

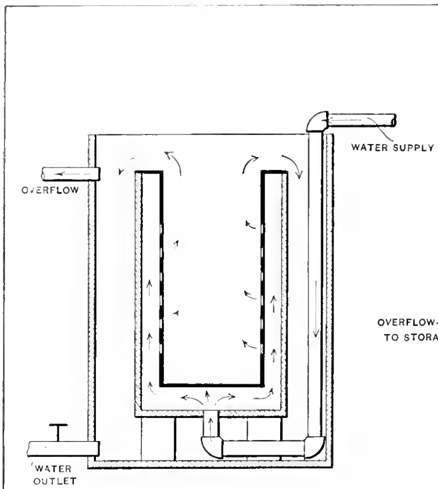

Fig. 3. Water or Brine Tank for Quenching Baths

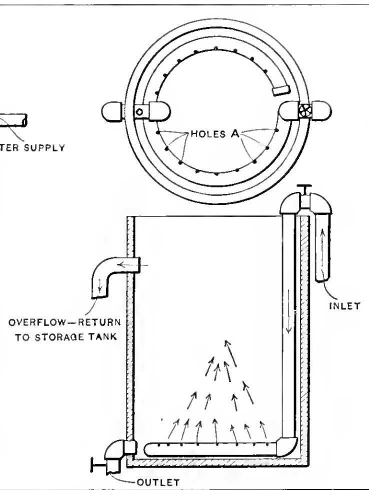

Fig. 4. Another Type of Water or Brine Tank

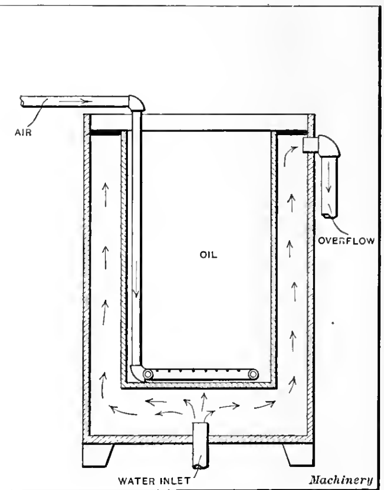

Fig. 5. Oil-quenching Tank with Water circulated in an Outer Tank

When tempering to high heats, or, rather, when tempering to higher heats than the flash point of any tempering oils (650 to 700 degrees F.*) some other tempering fluid than oil must be used. Lead is the one usually employed. As it is impossible when using lead to let the pieces to be tempered be heated up with the lead, they must be immersed at the predetermined temperature and kept there until heated evenly throughout to the same temperature as the lead. It is claimed by many that it is easier to maintain a uniform heat in a lead bath than in an oil bath, but it has been found that,

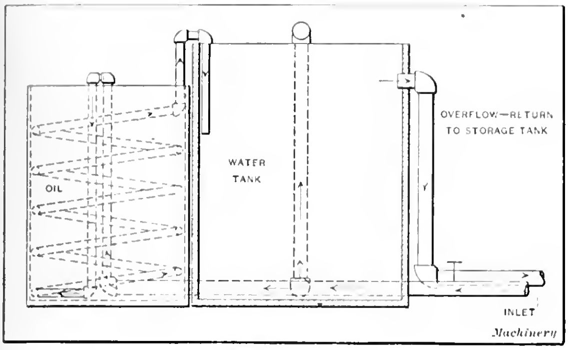

Fig. 6. Water and Oil Tank Combined

owing to the lead not circulating as readily, the temperature may vary considerably in different parts of the bath, and hence it is not very reliable.

Salt is another medium frequently employed for tempering heats between 575 and 875 degrees F. Salt fuses at 575 degrees F., but when immersing the pieces to be tempered the salt will immediately solidify around the cold pieces. When these are heated to 575 degrees, the salt will melt and the pieces should be withdrawn. This is not reliable, however, as the pieces, especially if large, will not have had time to be heated through before the salt melts. If a higher temper

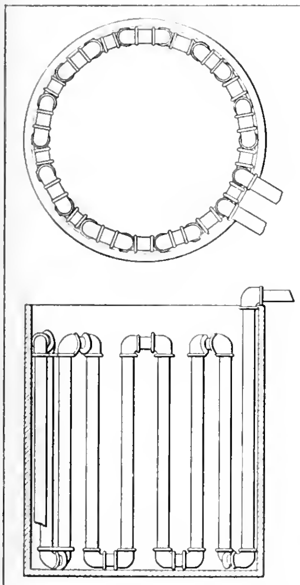

Fig. 7. Ordinary Type of Quenching Tank

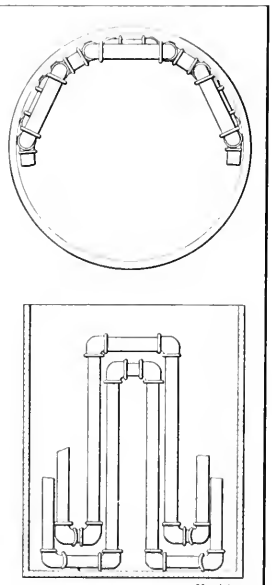

Fig. 8. Oil-quenching Tank with Water and Steam Coils

is required, it is, of course, only necessary to let the pieces remain in the bath and get the readings of the heat from a pyrometer. In all these methods, it is questionable if it is good practice to suddenly immerse cold pieces to be drawn into baths of such high temperatures. When a lower temper is required, and an oil tempering bath or furnace is not available, alloys of lead and tin can be used for as low heats as 400 degrees and of lead and antimony for 500 degrees. However, this involves the inconvenience of keeping a large number of different alloys on hand, if it is desired to vary the temper heats. The following table for different alloys which melt at the temperatures given was compiled by Mr. O. M. Becker.

Lead	Tin	Melting Temperature, Degrees F.	Lead	Tin	Melting Temperature, Degrees F.
14	8	420	24	8	480
15	8	430	28	8	490
16	8	440	38	8	510
17	8	450	60	8	530
18.5	8	460	96	8	550
20	8	470	200	8	560

The oils for tempering baths specified below are given for the sake of convenience only; the statements are based upon the findings of thorough experiments. There may, of course, be many other oils just as good that have not been tried.

(1) Walter A. Wood, Boston, Mass., XXX tempering oil; as cheap in initial expense as any; good lasting qualities.

(2) Frankfort tempering oil, Strong, Carlisle & Hammond Co., Cleveland, Ohio.

(3) Fish oil, cottonseed or linseed oil may also be used; in many cases these are mixed with high fire and flash test mineralized oils.

Tests and Analysis

The analysis and test results of oils when new (not used) as compared with those of oils which have been used such a

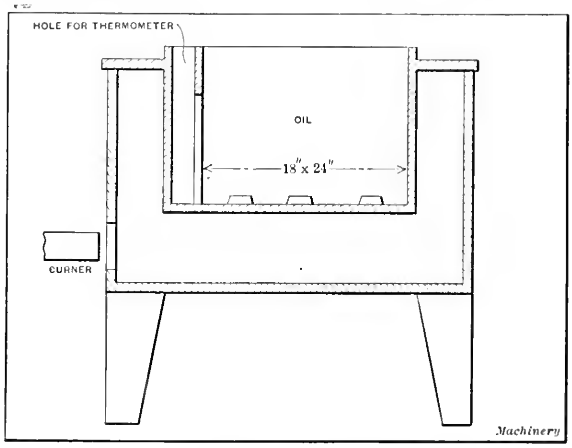

Fig. 9. Ordinary Type of Tempering Furnace

length of time as to render them practically valueless will be found interesting.

	W. A. Wood Tempering Oil		Lard and paraffine oil mixed (half and half) used for quenching	
	New	Old (thick)	New	Old (thick)
Flash point	550	475	400	380
Fire test	625	550	475	450
Mineral oil, per cent	94	30	25	10
Saponifiable oil, per cent	6	70	75	90
Specific gravity	0.920	0.950	0.912	0.925

Houghton tempering oil: flash point, 595 degrees; fire test, 685 degrees; specific gravity, 0.900.

Frankfort tempering oil: fire test, 670 degrees.

Frankfort quenching oil: fire test, 500 degrees.

Paraffine oil (Underhay): fire test, 450; specific gravity, 0.912.

Lard oil (Bleecker): fire test, - - ; specific gravity, 0.920.

The great difference in tests and analysis between new and used oils should be noted; oils used constantly at high heats will gradually lose the "mineral" part of the oil, the more so the higher the heat used. A tempering bath can therefore be prolonged in life by adding to it now and then new mineral oil. To lengthen the life of the bath high heats should be avoided as much as possible.

Receptacles and Furnaces used in Quenching and Tempering

The main point to be considered in a quenching bath is, as mentioned, to keep it at a uniform temperature so that suc-

* There are tempering oils on the market claimed to have a flash test of 750 degrees, but it is doubtful if they ever have been found to stand this test. Heavy black cylinder oil has been found to stand a flash test of 725 degrees.

cessive pieces quenched will be subjected to the same heat. The next consideration is to keep the bath agitated, so that it will not be of different temperatures in different places; if thoroughly agitated and kept in motion, as is the case with the bath shown in Fig. 3, it is not even necessary to keep the pieces in motion in the bath, as steam will not be likely to form around the pieces quenched. Experience has proved that if a piece is held still in a thoroughly agitated bath, it will come out much straighter than if it has been moved around in an unagitated bath. This is an important consideration, especially when hardening long pieces. It is, besides, no easy matter to keep heavy and long pieces in motion unless it be done by mechanical means.

In Fig. 3 is shown a water or brine tank for quenching baths. Water is forced by a pump or other means through the supply pipe into the intermediate space between the outer and inner tank. From the intermediate space it is forced into the inner tank through holes as indicated. The water returns to the storage tank by overflowing from the inner tank into the outer one and then through the overflow pipe as indicated. In Fig. 4 is shown another water or brine tank of a more common type. In this case the water or brine is pumped from the storage tank and continuously returned to it. If the storage tank contains a large volume of water, there is no need of a special means for cooling. Otherwise, arrangements must be made for cooling the water after it has passed through the tank. The bath is agitated by the force with which the water is pumped into it. The holes at A are drilled on an angle, so as to throw the water toward the center of the tank. In Fig. 5 is shown an oil quenching tank in which water is circulated in an outer surrounding tank for keeping the oil bath cool. Air is forced into the oil bath to keep it agitated.

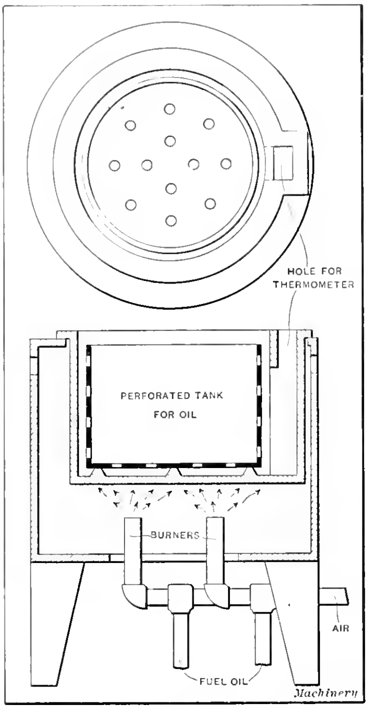

Fig. 10. Special Tempering Furnace with Perforated Oil Tank

Fig. 6 shows a water and oil tank combined. The oil is kept cool by a coil passing through it in which water is circulated, which later passes into the water tank. The water and oil bath in this case is not agitated.

Fig. 7 shows the ordinary type of quenching tank cooled by water forced through a coil of pipe. This can be used for either oil, water or brine. Fig. 8 shows a similar type of quenching tank, but with two coils of pipe. Water flows through one of these and steam through the other. By this means it is possible to keep the bath at a constant temperature.

Tempering Furnaces

In tempering furnaces the only really important consideration is to insure that the furnace is so built as to heat the bath uniformly throughout. It is doubtful if there can be found a tempering furnace on the market that will fill this requirement entirely, although many give good results in general. It is never safe, however, to let any tools being tempered rest against the bottom or sides of the tank, as no matter how scientifically the furnace may be built these parts are, in most cases, hotter than the fluid itself. It is, of course, just as important not to let the thermometer rest against any of these parts in order to insure correct readings. After the pieces tempered are taken out of the oil bath, they should immediately be dipped in a tank of caustic soda (not registering over 8 or 9), and after that in a tank of hot water. This will remove all oil which might adhere to the tools.

Fig. 9 shows an ordinary type of tempering furnace. In this the flame does not strike the walls of the tank directly. The tools to be tempered are laid in a basket which is immersed in the oil. In Fig. 10 is shown a tempering furnace in which means are provided for preventing the tools to be tempered from coming in contact with the walls or bottom of the furnace proper. The basket holding the tools is immersed in the inner perforated oil tank. This same arrangement can, of course, be applied to the furnace shown in Fig. 9.

ARE IRON AND STEEL CHIPS COMBUSTIBLE?

"Pig iron under water" has been described as a typically safe insurance risk, and to most persons iron or steel in any shape is equally free from liability to catch fire and burn up. Nevertheless, a recent experience of the Rushmore Dynamo Works in Plainfield, N. J., with a big pile of steel chips which actually caught fire from a blazing rubbish heap near by shows that finely divided iron or steel may sometimes oxidize faster than it can get rid of its heat, and hence may exhibit all the phenomena of combustion. The story is vouched for by Mr. S. W. Rushmore in the following words:

"Out in our yard we have a big heap of steel chips from the automatic turret and screw machines, which we sell from time to time in lots of several car loads. Steel being generally considered a non-combustible, this heap is quite close to the box lumber pile. Saturday afternoon, August 2, the pile stood eight feet high and contained several car loads, when the yard gang piled up alongside of it a lot of old barrels and rubbish and set fire to the latter. Of course, the steel pile got warm. On going my rounds, to see that everything was in shape before going home, I discovered smoke and flame issuing from the supposedly fireproof heap, which at several points at the bottom glowed white hot. The heat rapidly increased until it threatened to fire the lumber, so the watchman got out the hose and played a one-inch stream on the pile. The flame went down and I supposed the fire would soon go out, so I went home. Three hours later the night watchman 'phoned me that in spite of the hose the fire was getting worse, so I called the fire department, which found a lively little volcano at work. They worked on that pile of chips for just an hour with two powerful streams, and after many explosions of steam and gas, and after the whole yard had been flooded, declared the fire out and went home. At 10 o'clock Sunday morning the day watchman 'phoned me in a hurry that the fire had started again, and sure enough I found that darned pile a seething mass, making a weird and threatening hissing sound, but with little smoke and only thin yellowish flames. The department was again called, and after a couple of hours the pile was cooled down and dug into until apparently dead.

"The chips are put through a centrifugal separator, and the small amount of oil remaining had nothing to do with the fire. It was a plain case of burning iron. The metal was so finely divided, and presented so much surface to the oxygen in proportion to the radiating surface of the pile, that, once started by the heat from the rubbish pile, the combustion proceeded exactly as in a pile of coal, only apparently at a more rapid rate. I had never seen an iron fire before, and had never considered iron chips a fire risk, but anyone having seen that fire would never think of storing a large quantity inside any building. I was surprised to find that the metal had not melted. Where the fire had been hottest the chips were a dark blue. The pile sank about a third in height, and a lot of metal must have been oxidized to create so much heat. Next time I shall almost expect to see the concrete walls blaze up."

* * *

We talk lightly of high vacua, or even of a perfect vacuum, says the *Scientific American*. It is instructive to calculate the number of molecules contained in a cubic millimeter of gas at the lowest pressure on record. W. Gaede has recently succeeded in exhausting a vessel to a pressure of two ten-millionths of a millimeter of mercury (four one-thousand-millionths of a pound per square inch). At this pressure one cubic millimeter of gas would still contain about eight-and-a-half million molecules.

AN ITALIAN MILLING MACHINE

A MACHINE IN WHICH BOTH SPEED AND FEED CHANGES ARE DERIVED FROM THE SAME GEAR BOX

BY JOSEPH HORNER*

An unusual design of milling machine, manufactured by Officine Dubosc, Societa Anonima, machine tool builders of Turin, Italy, is shown in Fig. 1. The most interesting feature

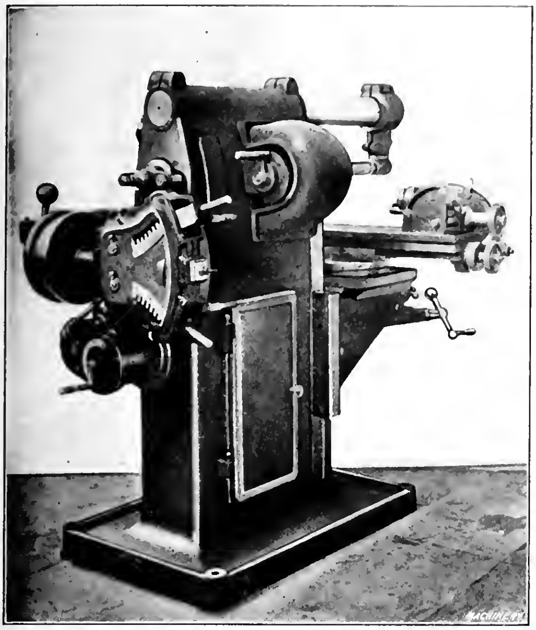

Fig. 1. Italian Milling Machine with Combined Speed- and Feed-changing Mechanism

of this machine is the mechanism by means of which the speed and feed changes are obtained. The power is derived from a single belt pulley which transmits motion through a cluster of bevel gears enclosed in a box at the rear of the column. The main spindle is driven through a sliding gear meshing with one side of the central cone of gears, and the

with a brass bushing. The belt pulley is engaged or disengaged by means of these friction disks which are located on each side, as shown. The disks are operated by a lever attached to part B, the lever being weighted with a knobbed handle, as shown in Fig. 1. When the machine is not in use, the friction disks are kept out of contact with the pulley by a coiled spring located in recesses formed at the inner ends of the disk hubs. Part B has a threaded extension which screws into a bushing in bearing bracket C. When the ball-handle attached to B is turned to the right, the adjustable screw E and part B move axially and cause disk D to grip the driving pulley. The amount of this axial movement is slight, being just enough to make and break frictional contact with the pulley.

The pulley shaft G is mounted in three bearings and is equipped with a ball end-thrust bearing, having provision for adjustment by means of lock-nuts. On the right end of this shaft, through which power is transmitted to the spindle and feeding mechanism, a cone of seven bevel gears is keyed permanently. The sliding gears H and F, which are feather-keyed on the diagonal shafts seen above and below, can be engaged with any one of the cone of gears on shaft G. The speed changes are obtained by shifting lever N and gear H, and the feed changes by lever O and gear F. These levers have two movements; that is, they swing vertically about pivots at the inner ends, to bring the sliding gears into mesh with large or small gears of the cone, and the handles and sliding gears also have an axial movement. As will be seen, the gears are carried in bosses at the ends of the handles, in which they are secured by circular nuts. The axial movement is provided for by splines extending along the pivoted shafts.

In the diagram Fig. 4, the locations of the centers of the pitch cones for different positions of the movable gears are shown by the small circles. The apices of the pitch cones of any movable and fixed gear that may be in mesh intersect on the center line of the central cone of gears. The speed- and feed-change levers are properly located and locked in each position by a series of notches with which suitable locking pins engage. Adjacent to each notch the speeds and

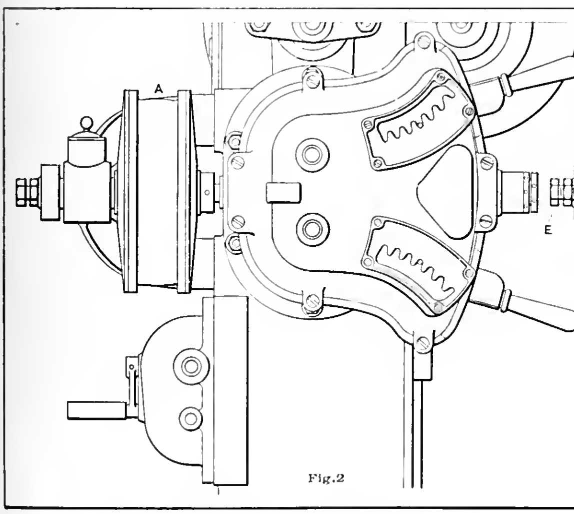

Fig. 2. Rear View of Speed and Feed Box

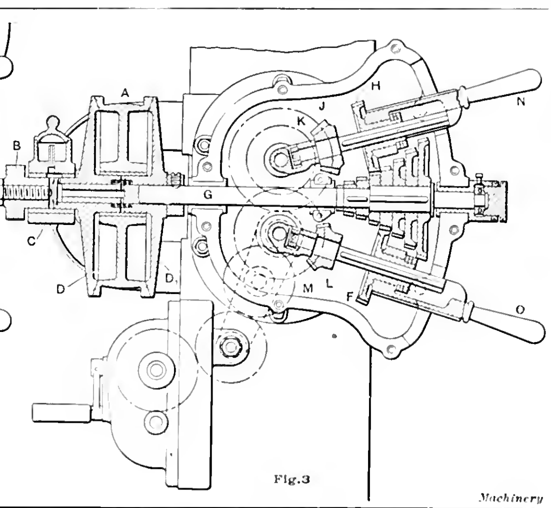

Fig. 3. Sectional View of Speed and Feed Box

feed mechanism is driven through a sliding gear on the opposite side of the central cone.

Fig. 2 is a rear elevation showing the outside of the gear box, and Fig. 3 is a sectional view showing the nest of cone gears and their relation to the driving pulley. This pulley A is driven at 320 revolutions per minute. Normally, it runs loosely on the hubs of friction disks D and D_1 and is provided

* Address: 45 Sydney Bldgs., Bath, England.

feeds which correspond to that particular position are stamped.

The speed and feed motions are transmitted through the sliding bevel gears H and F upward and downward, respectively. Motion to the spindle is transmitted through fixed pinion J, which engages with gear K (see Figs. 3 and 5). Gear K, in turn, is keyed to a horizontal shaft N, Fig. 5, having at its opposite end a gear O. The latter is constantly

in mesh with gear *P*, which, with gear *S*, runs loosely on the main spindle *Q* of the headstock. On this spindle a larger gear *R* is keyed. By means of these gears, and the spring pins *B*, the spindle can be driven either direct or through the back-gearing. This change is effected by operating a forked lever engaging with collar *T* and actuated by the

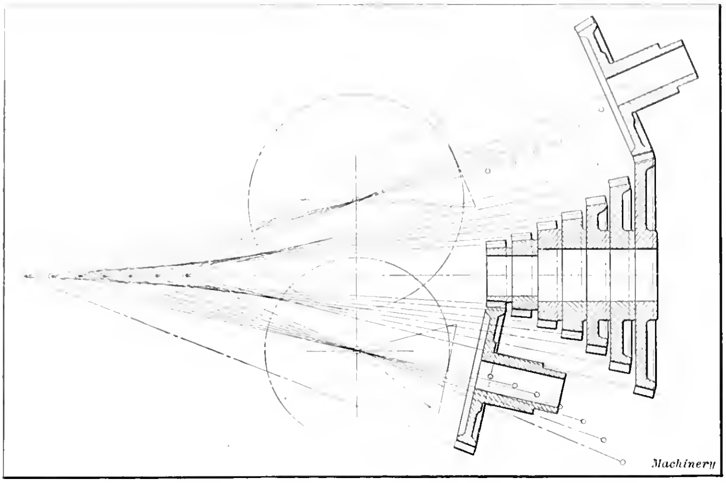

Fig. 4. Diagram showing Relative Positions of Fixed and Sliding Gears

handle seen at the rear of the housing, in Fig. 1. When the spindle is driven direct, gears *P* and *R* are locked together by pins *B*, at which time the back-gears are disengaged. The movement of the lever for shifting collar *T* also controls the position of the back-gears, so that when the spindle is to be driven direct the back-gears are automatically disengaged.

The speed-changing mechanism gives the following revolutions of the cutter spindle per minute:

With the back-gears in mesh....	14	17	22	27	34	42	54
When driving direct.............	63	84	108	132	164	203	260

The feed motion is derived from fixed pinion *L* which meshes with gear *M* (Figs. 3 and 5). The latter is keyed to shaft *W*, which, through gears *X*, transmits motion to feed box *Y* at the rear of the machine. At this point two changes of feed can be obtained by shifting the handle seen attached to the box in Fig. 1. The feeding movement is transmitted to the front of the machine through a telescopic shaft in the usual manner. Gear *Z*, through a shaft and gear meshing with gear *A*, drives the cross-feed shaft which engages nut *C*. This nut has an adjustable section for taking up the back-lash due to wear of the threads. The shaft driven by gear *Z* carries the miter gear *D* which meshes with another miter gear on the vertical shaft (not shown) from which pinion *E* is driven. The latter, in turn, transmits motion to miter gear *F*, which actuates the longitudinal feed-screw; the latter is provided with the usual reverse clutch. The vertical adjustments of the knee are effected by a ball-handle having a shaft set diagonally and connecting with the telescopic screw through a pinion meshing with bevel gear *J*. The main spindle bearings are fitted with split boxes which are fitted in bored conical seats. Axial adjustment is provided for taking up wear.

REDUCING SHOP COSTS

The efficiency expert or systematizer who tries to accomplish a reduction of manufacturing costs by reducing wages is attacking the problem at the wrong end, and he generally comes to speedy grief. The storekeeper who tries to get more trade by reducing prices is in the same class. The storekeeper is likely to go into bankruptcy soon after having demoralized his trade and prices. Both the efficiency expert and the storekeeper fail to realize that the secret of success is service. The systematizer's real business is to train the employes to produce more with the same effort and thus to earn more for themselves and the concern employing them. To cause them to earn less for themselves will almost inevitably result in earning less for their employers. The storekeeper who cuts prices voluntarily reduces his own wages, which means that he must eventually render poorer service. What he should do is to study how he can serve the public better. If he can render better service and thus attract larger trade at standard prices, he may then be able to reduce prices because he is producing more per employe, and all are earning more. Service should be the motto—not merely reduction of costs. More service means lower costs, and this applies to goods and wages alike.

* * *

CYANIDE FOR CLEANING HARDENED STEEL

A method of treating taps and other tools in hardening which leaves them free from scale and with a silvery surface is to use a layer of potassium cyanide on top of a lead heating bath. A tap or other tool immersed in the lead receives a coating of cyanide which cleans off all scale or rather prevents its formation. When dipped in the hardening bath the cyanide dissolves instantly, leaving the work in condition for rapid polishing. Of course an exhaust hood must be provided over the pot to draw off the deadly cyanide fumes

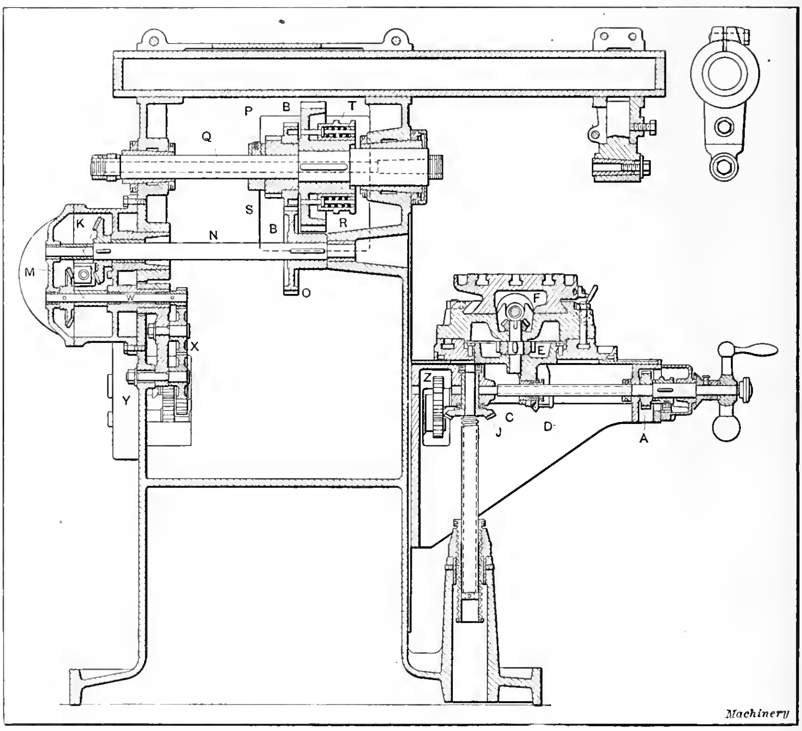

Fig. 5. Sectional View of Italian Milling Machine

RESISTANCE OF STEELS TO WEAR IN RELATION TO HARDNESS AND STRENGTH*

The increasing speeds and heavy duty of machinery and motive power, with resultant shortening of the length of service of parts through rapid wear, makes the study of wear resisting qualities of metals, especially steel, one of increasing importance. In the railway field, the increasing wear of tires and rails due to increased loads and speeds is a serious matter. Not only is it desirable to have high resistance to wear, but it is necessary to have other qualifications, such as strength and toughness, to insure against failure or breakage. The tests described in this article were undertaken with the object of studying the relations, if any, between the wear resistance of various steels and the various physical properties of elastic limit, tensile strength, and hardness. Owing to several protracted interruptions, only a relatively small proportion of these tests have so far been completed.

Machinery

Note—Under the heading Treatment, 825—600 degrees C, for example, indicates that the specimen was oil-quenched from 825 degrees and drawn back at 600 degrees C.

There are three classes of wear: (1) Abrasion—such as grinding, crushing and excavating machinery is subjected to. (2) Lubricated sliding or rolling friction, such as that experienced by machine parts, axles and shafting. (3) Dry rolling friction of the kind existing between wheels and rails. The first class, wear by abrasion, is in many ways less important than the other two. It has, however, been utilized frequently as a means of comparing the wearing qualities of metals for all three classes. The machines used for this purpose are some form of grinding machines and the specimens are ground or abraded under a constant pressure for a certain length of time. The amount of metal removed under these conditions determines the relative wearing value. The most extensive investigations along this line were made by F. Robin and published in the 1910 proceedings of the British Iron and Steel Institute.

Investigations of wear by lubricated friction have been in the past largely confined to bearing metals rather than steel. This undoubtedly has been due to the fact that steel is usually worked against soft bearing metals or bronzes which wear much faster. The investigation of the wear resistance of steel and iron under lubricated friction, however, is growing more important with the increasing severity of the requirements of service. Probably the most satisfactory machine for testing wear under lubricated sliding friction is the Derihon machine consisting of a hard steel disk revolving in oil, against the edge of which is pressed the test specimen. E. Nusbaumer, engineer of the Derihon Steel Works, describes this machine and some tests made with it in the proceedings of the fifth congress of the International Association for Testing Materials, 1909.

The third class, wear by dry rolling friction, is the most important; especially when we consider the vast tonnage of steel in service in the form of rails, wheels and tires. A machine for investigating wear under dry rolling friction was described by E. H. Saniter in 1908 British Iron and Steel Institute and consists essentially of a revolving test specimen which drives by friction the inner ring of a ball bearing, the outer ring of which is stationary and loaded. At the sixth congress of the International Association for Testing Materials, Mr. Saniter presented a report on hardness testing and resistance to mechanical wear and gave a summary of the results obtained by Robin, Nusbaumer and himself of the investigation of each of the three classes of wear. The general conclusions of Mr. Saniter were "that while metal with a high Brinell number may be expected to give better wear, there are so many exceptions that the use of a hardness test for the purpose of indicating wearing properties is unreliable as far as the methods of wear testing reviewed are concerned."

The investigations of the author have been confined so far to the third class of wear *i. e.*, dry rolling friction. The machine used is a modification of Dr. Stanton's fatigue-testing machine described by him in a paper before the British Iron and Steel Institute, 1908. Details of the machine are shown in the illustration. It consists essentially of three casehardened rollers 3½ inches in diameter. The two lower rollers are driven by gears, while the third or upper roller is driven by friction. The upper roller is carried in the lever by which the load is applied to the test specimen. A load of 1000 pounds on the specimen is possible with this machine. The rollers each have a groove in the middle, ¼ inch wide, to take the corresponding band on the test specimen and keep it from lateral motion. If the rollers all revolved at a uniform speed the amount of wear on the test specimen would be very slight, practically nil, as there would be no slippage of the test specimen. In order to accelerate the wear and approximate as nearly as possible the actual wearing conditions of wheels and rails, the two lower

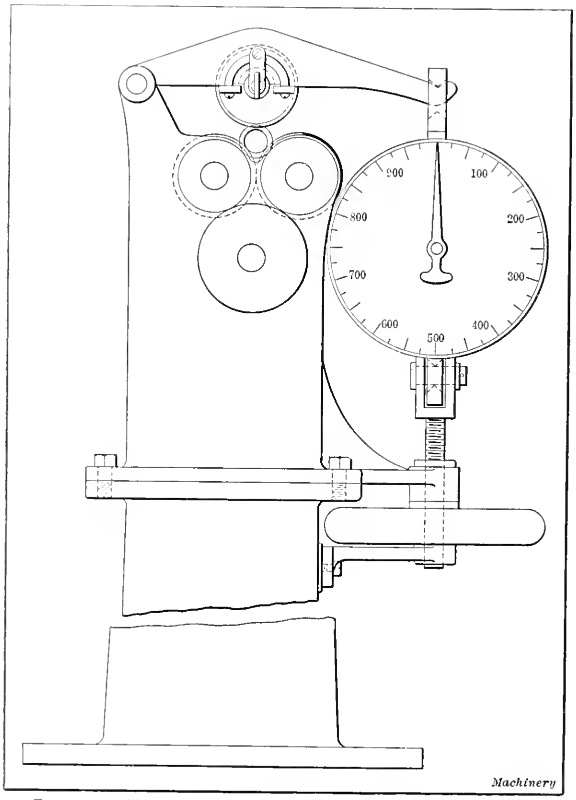
Machinery

*Abstract of a paper read by George L. Norris before the sixteenth annual meeting of the American Society for Testing Materials.

rollers are driven at different speeds to produce slippage of the specimen. This is accomplished by having three less teeth in one of the driving gears.

The test specimens are 2 inches long by 7/8 inch in diameter; and the guide band is 1/8 inch larger in diameter and a scant 1/4 inch wide. They weigh about 160 grams and can be accurately weighed on a chemical balance to 1/10 milligram. The diameter of the specimens which this machine will accommodate can vary from 5/8 inch to 1½ inch as may be required. The driving speed of the machine is 1000 revolutions per minute, and the speed of the test specimen is about 5000 revolutions per minute. The usual run before weighing is 100,000 revolutions of one of the driving rollers, corresponding to practically 500,000 revolutions of the test piece. In the following tests the applied load was 224 pounds, or 100 kilograms. Excepting in the cases noted in Table I, the specimens were all turned from rolled bars 1⅛ inch in diameter. While the tests show a general decrease in the amount of wear, as the hardness and strength increase, the progression is very irregular, and there are several instances where softer steels show less wear than the harder ones, as, for example, 12 and E-1; C-1 and F-1.

It is evident that the composition of the steel influences the resistance to wear to a very considerable degree. Robin,



Type of Machine used for testing Resistance to Dry Rolling Friction

in his investigations, found that nickel, chromium and vanadium each increased the resistance of the steel to wear. The tests made by Nusbaumer showed remarkable resistance to wear in low carbon steel with manganese about 1.5 per cent. Saniter, on the contrary, did not find increased resistance to wear in the case of the few alloy steels he reported, excepting for a high manganese steel of the Hadfield type. His chrome-vanadium anad nickel-chrome steels gave greater wear with greater hardness than simple carbon steels of about 0.70 per cent carbon and 0.60 per cent manganese.

The tests made by the writer confirm the conclusions of both Robin and Nüsbaumer, and also those of actual experience that manganese, nickel, chromium and vanadium have a marked effect on the wearing quality of steels. Manganese apparently has a greater effect than either nickel or chromium. Vanadium, however, evidently has a much greater effect than either of these three elements, as it only requires a very small percentage to produce a marked increase in resistance to wear. This is very apparent in steels E-1 and F-1, and C-1 and D-1, each of which pairs is practically alike, excepting for vanadium. As stated in the beginning of this article, these tests are only a small proportion of those planned, and it is the intention to cover not only a considerable range in composition and heat-treatment, but also to study the effect of rollers of different composition and hardness on the rate of wear of the various steels.

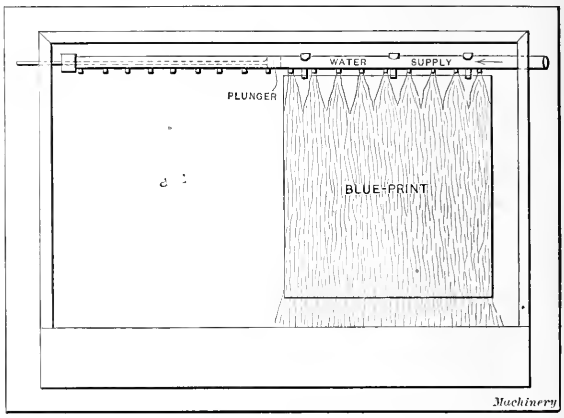
A BLUEPRINT WASHER

A little kink in washing blueprints that is in use in the drafting-room of the George P. Clark Co., Windsor Locks, Conn., seems worthy of description. The principal feature of this washing arrangement is that it takes care of small prints as well as large ones without waste of water. Above the washing sink there is an upright board, slightly inclined, along the top of which runs the water supply pipe, as shown in the accompanying illustration. The blueprint is hung over the top of this pipe by means of clips and the water emerges from small openings closely spaced in the bottom of the pipe. Within the supply pipe there is a plunger which may be moved to any desired position by means of a rod which extends through the blind end of the pipe. This plunger serves to cut off the water supply at any desired point, and limits the stream to passing through the openings at the right of the



A Blueprint Washer

plunger, bringing the full force of the water upon the print and nowhere else. Thus, when a small print is being washed, it is hung at the right-hand side of the washing tank and the plunger moved, so as to limit the progress of the water to the section of the tank occupied by the blueprint. This prevents waste of water and confines that in use to the space occupied by the blueprint, resulting in quicker and better washing.

* * *

The press agent of the New York, New Haven & Hartford Railroad has great faith in the new steel passenger cars. In describing the Merchants' Limited Express train, "the most gorgeous train in America," he says: "These new trains are practically indestructible. Made of steel, they could go through a stone wall without being scratched. Reinforced underneath with two immense steel girders running the length of the car and attached at the end to a solid cast-steel U-frame, forming the vestibule, no impact, however great, could telescope them. A rear end collision might tilt them up on end a bit, but that would be all. So far as resisting powers go they are built like battleships."

Speed at the expense of quality is easy, because it is sliding down hill.

ELECTRIC FURNACE HEAT-TREATMENT OF STEEL*

ARRANGEMENT OF THE ELECTRIC FURNACE—EFFECT OF DIFFERENT ELEMENTS ABSORBED BY HEATED STEEL

BY E. F. LAKE†

The use of electric furnaces for hardening and tempering steel, has passed through the experimental stage and there are several types now on the market that have been made commercial successes. It is now about three years since the electric furnace was placed on the market that uses a molten salt bath in which to heat the steel to any of the hardening temperatures used for carbon, alloyed or high-speed steels. This electric salt-bath furnace is also used for any drawing temperature above the flash points of oil, while an oil bath type is used to heat steel to drawing temperatures below this flash point. In the salt-bath furnaces, the electric current is sent directly through the salt by placing electrodes inside of the bath on opposite sides, while in the oil bath furnaces the oil tank is heated from the outside.

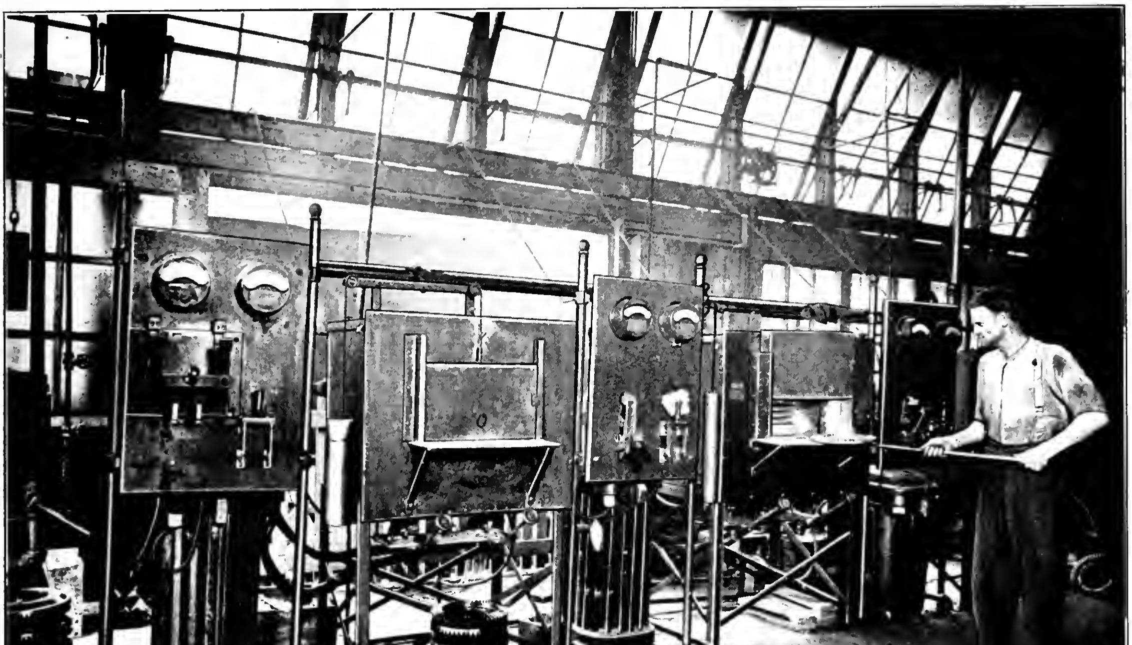

Fig. 1. Battery of Hoskins Electric Hardening Furnaces

Since the introduction of the salt-bath furnace, the oven type of electric furnace has been perfected and installed by several manufacturers for commercial work. Small furnaces of this type have long been in use for laboratory and experimental work, but the principle used for heating, namely, sending the current through coiled resistance wires inside of the heating chamber, is too expensive for the larger furnaces used for commercial work, and the high temperatures required for high-speed steel cannot be reached without burning out the resistance wires. They are very successful, however, for small furnaces that are used at temperatures below 1800 degrees F.

One of the largest installations of this kind is the battery of electric hardening furnaces that are in daily use at the Timken-Detroit Axle Co's. plant, as shown in Fig. 1. These were manufactured and installed by the Hoskins Mfg. Co. of Detroit, Mich. Each separate unit consists of a furnace, switchboard and transformer, which stands back of the switchboard. On the board is placed the line switch for turning on and off the current; a circuit breaker, adjusted to open the circuit automatically in case of an excessive flow of current; an ammeter to show the amount of current being used; and a pyrometer to indicate the temperature inside of the furnace. No rheostat is required, as the furnace can be adjusted to regulate the amount of current that is necessary to produce any given degree of temperature.

Heating Gears in Electric Furnace

The bulk of the work heated in these furnaces consists of the gears that enter into the construction of rear axles used on automobiles. In Fig. 2 is shown the method employed to heat the driving gears to the hardening temperature. It was difficult to harden these large ring gears uniformly at accurate predetermined temperatures, without warpage, before the electric furnaces were installed, but now most of the difficulties have been overcome and good results are obtained. The gears are first preheated to about 1200 degrees F. in another kind of furnace, the corner of which is shown to the right in the halftone. Four gears are then placed on the thick iron disk *A* and heated to the correct temperature for quenching to harden. The disk *A* is slowly revolved automatically, by mechanical means, to insure obtaining a uniform temperature around the entire circumference of the gears. To re-heat four carbon-steel gears, 11¼ inches in diameter, from the 1200 degrees of the preheating furnace, to the 1500 degrees required to harden the gears, takes about twenty minutes. Prolonged heating does not harm the gears as the furnace is maintained at the correct hardening temperature and they will not be overheated, while the atmo-

* For additional information on electric furnaces see the following articles previously published in MACHINERY: "Improvements in Electric Furnaces," July, 1912; "Heat-Treatment of Steel by the Electric Furnace," June, 1912; "Electric Hardening Furnaces," December, 1908; "Hardening Steel by Electricity," February, 1907.

† Address: 1453 Waterloo St., Detroit, Mich.

sphere is reducing and thus prevents the formation of any scale. If not left in long enough, however, they will not attain the temperature of the furnace and therefore the quenching will not give them the desired hardness.

Adjustment and Arrangement of the Electric Furnace

To keep the furnace at the desired temperature, handwheels *B* are turned either to the right or left. This either raises or lowers the electrodes and squeezes together or allows gaps between the carbon plates that form the sides of the interior walls of the furnace. The carbon plates on one side can be seen at *C*. Squeezing the carbon plates together, causes more current to flow and hence more heat to be generated, while allowing them to separate, reduces the flow of current and also the heat inside the furnace. By watching the ammeter, any desired temperature can be produced when one knows what ammeter reading corresponds to this temperature. The operation can be more plainly seen by referring to Fig. 3, which is a sectional view through the center of the furnace. *J* is the heating chamber and *I* the outer shell, which is filled with firebrick. The screws *G* are operated by handwheels *B* to raise and lower electrodes *F*. The latter, in turn, press against graphite blocks *E*, to squeeze together or allow gaps to occur between the carbon plates *C* that form two sides of the interior of the furnace. *D* is the carbon top plate, or roof, and *H* the cement bottom of the heating chamber. The current enters and leaves the furnace at *K*.

Action of Carbon in Heated Steel

It is a well known fact that steels absorb various elements which they come in contact with, when the conditions are conducive. As is well known, this is the principle of the carbonizing process. Many impurities which injure some of the good qualities possessed by the metal, are absorbed under certain conditions, and several elements that better some qualities are absorbed under other conditions. Some of these conditions are known and can be controlled, while many others are unknown or partially known.

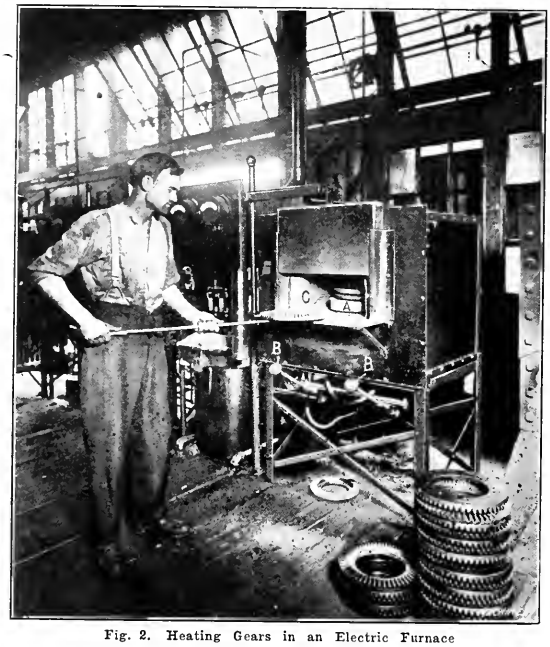

Fig. 2. Heating Gears in an Electric Furnace

Some beneficial elements, of which chromium is an example, can be injected into steel. Carbon flows through steel in a somewhat similar manner to the flow of electricity, although very much slower. If a piece of high-carbon steel and a piece of low-carbon steel are bound closely together and allowed to stand a long enough time, they will both have the same percentage of carbon. This would take many years at atmospheric temperatures, but if the steel is heated, each degree of temperature increase accelerates the flow of the carbon. When the molten stage is reached, minutes will produce, in the equalization of the carbon content, what it might take centuries to produce at atmospheric temperatures.

The principle here involved is that carbon flows to the body or element which has the greatest attraction for carbon. In carbonizing steel, a carbonaceous gas is produced, but the steel has a greater attraction for the carbon than the atmosphere in the carbonizing retort and hence it enters into a combination with the steel. Likewise, with two pieces of steel, the one low in carbon has a greater attraction than the piece high in carbon and draws this element away until the attractive force in each piece has been equalized. In manufacturing steel, the carbon is put into the molten metal and as the iron has a greater affinity for carbon than any of the elements in the slag, it combines with the iron and stays in the steel thus produced; hence, the correct percentage is found in the finished product.

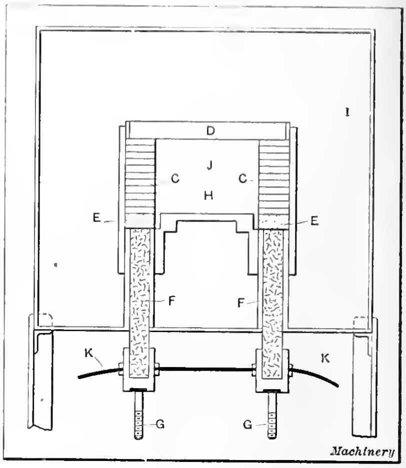

Fig. 3. Diagram showing Arrangement of Electric Furnace

In some furnaces, we often find decarbonized spots in steel that has been heated for hardening. A condition has here been produced whereby some element has entered the heating chamber that has a greater attraction than iron for the carbon; hence enough carbon flowed out of the steel to satisfy this attraction for the time this condition prevailed. Time and temperature seem to be the two factors that control the rate of flow of the carbon. Salt and lead-bath furnaces may produce these decarbonized spots. Sometimes a pitting of the surface occurs, which means that some element is present that has a great attraction for iron and has eaten it away.

In the electric furnaces previously referred to, no such elements seem to be present, as pitted and decarbonized surfaces are not found in the steels heat-treated in them. This applies to the carbon steels, which are heated to hardening temperatures as low as 1300 degrees F., and also to the high-speed steels that require a temperature as high as 2200 or 2300 degrees. Nearly all of the temperatures between these points are utilized, as the correct hardening temperature for some of the carbon steels is as high as 1500 degrees, while the alloyed steels require from 1500 to 1700 degrees and some high-speed steels need a temperature as low as 1750 degrees. The elimination of pitting and decarbonizing is doubtless due to the fact that the oxygen in the air is not required to perfect combustion and none of the products of combustion are present to attack the metal. As the steel leaves the furnace, no scale can be seen and scale always comes from an excess of oxygen. Even when the heated steel is held in the air, the formation of scale starts very slowly; neither is there any of the deposit that is sometimes produced by the products of combustion.

Effect of Oxygen on Iron and Steel

Under certain conditions oxygen has a great affinity for iron and penetrates steel much more rapidly in a moist atmosphere, or one that has been heated. If steel is left in a damp place, it is only a question of time when it will be reduced to an iron oxide in a powdered form, the degree of dampness being the factor that governs the speed of this reduction. This is due to the fact that oxygen forms only one-fifth of the air, whereas it forms eight-ninths of water, by weight.

Thus, if steel is immersed in water it decomposes much more rapidly than when left in the air. Salt water reduces the time of this decomposition as the salt aids the oxygen in forming its combination with iron. Without the aid of moisture, any increase in the temperature of steel increases the ability of oxygen to unite with the iron. When the boiling point is reached, the metal is saturated with oxygen and other gases, but the bulk of these are expelled when the steel solidifies. Enough is often left, however, to considerably weaken its various physical properties.

In furnaces that depend on combustion, or flames, for obtaining the necessary heat, a scale is liable to form on steel at the temperatures required for hardening, unless all of the oxygen is utilized to form the combustion and passes out of the vent as carbon dioxide (CO_2). This scale injures the piece being hardened, as it reduces its size and makes the surface uneven. This formation of scale proves that oxygen combines with steel at temperatures way below the melting point; hence the valves of such furnaces must be carefully adjusted so as not to deliver an excessive supply of air.

In addition to the formation of scale, oxygen injures steel in other ways. When the steel is heated to the higher temperatures, oxygen may enter the open pores to form microscopic bubbles and thus reduce the cohesive force that binds the molecules of the mass together. It may take the form of occluded gas in combination with other gases, or it may form a ferrous oxide with the iron. In any of these forms, oxygen reduces the strength, wearing qualities and resistance to fatigue or torsion stresses. Steels containing oxides also rust more quickly than those that are practically free from them. It is not so much the oxygen itself that is injurious, as it is the oxides that it forms with other elements. The percentage of oxygen has heretofore been considered to be too small to be taken into account, but it is now known that 0.05 per cent of oxygen is equal to 0.22 per cent of ferrous oxides and this is sufficient to materially reduce the physical properties. As oxygen is a gas, it was long difficult to analyze steels for this element, but with the new methods that have been devised, it has been found to be present in steel in larger quantities than was supposed, and efforts are now being made to reduce this impurity in all steels. That the pores of steel are opened by heat and allow the gases to enter or leave, has been proved by a number of experiments where both cast and rolled steel have been heated in a vacuum. Under this condition, the gases began to leave the steel at temperatures between 300 and 600 degrees F. The volume reached a maximum at temperatures between 900 and 1000 degrees, and then reduced to a minimum volume at about 1300 degrees. Another maximum point was reached at about 1450 degrees; then again reduced and again increased at higher temperatures. The greatest evolution of gas seemed to take place at the transformation point of the metal. That gases travel into the steel under atmospheric pressure, instead of out when in the vacuum, is shown by the fact that oxygen combines with iron and raises blisters or scale and also that nitrogen penetrates steel that has been raised to temperatures around 2200 degrees.

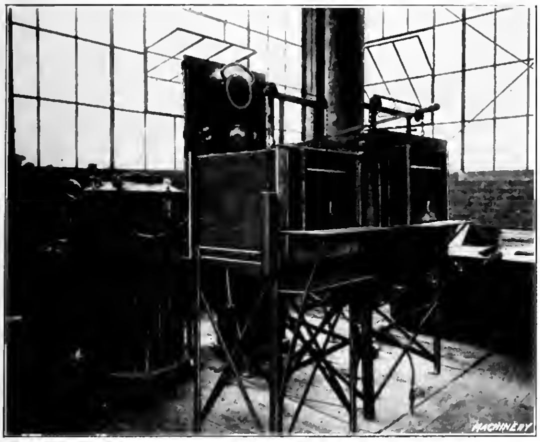

Fig. 4. Low- and High-temperature Electric Furnaces used in Pairs

Effect of Nitrogen on Steel

Nitrogen is just beginning to be recognized as an injurious element in steel. It now occupies practically the same position that sulphur and phosphorus did but a short time ago, when the chemist first proved that they were very injurious elements to the physical properties and means should be devised to keep them as low as possible. Then the practical steel makers scoffed at the chemists for saying that such small percentages of any element could weaken the steel and if it did their ancestors would have made it known. One does not have to be very old to remember the time when such talk was prevalent in the steel mills. It has been proved, however, that nitrogen is as liable to cause brittleness and "cold shortness" as does phosphorus and is as injurious.

The better grades of steel contain 0.005 to 0.025 per cent of nitrogen, while the cheaper grades contain between 0.010 and 0.065 per cent. Each increase in the percentage causes the elongation to diminish rapidly and the ductility to reduce. At first, only a slight decrease occurs in the toughness, but the decrease becomes more rapid as the percentage of nitrogen increases. When the carbon content of steel is high, 0.035 per cent of nitrogen will cause the elongation and contraction to become practically nil, while in medium carbon steel it may take a nitrogen content of 0.050 per cent to accomplish this, and 0.065 per cent in low-carbon steels. Steels made in the resistance type of electric furnace contain only traces of nitrogen, but those made in the presence of basic slag in the arc type may contain an injurious amount.

As four-fifths of the air is composed of nitrogen, by volume, consuming the oxygen with a flame would leave much of the nitrogen free to enter the pores of steel that is heated to the hardening temperatures in ordinary oven furnaces; especially when the steel is heated to the 2200, or more, degrees F. required for hardening some brands of high-speed steel. Decarbonization is doubtless due to the nitrogen that may be occluded in steel combining with the carbon to form methane, which escapes when the metal is heated. Hydrogen being the lightest of the gases, if any of this is present in the steel, it will escape when the metal is heated. This will cause the proportion of nitrogen to carbon to increase and thus enhance the tendency toward decarbonization. As the resistance type of electric furnaces do not consume any of the oxygen in the air, none of the nitrogen is set free. Thus a condition that allows the nitrogen to penetrate the steel is not created, even though it be heated and the pores open. As steel pieces do not warp as much in this type of electric furnaces, as in coal-, oil-, or gas-fired furnaces, it may be because the metal is more dense owing to its not absorbing any gases. The absorption of nitrogen, followed by the formation of iron nitrides, keeps molecules of their own kind further apart by preventing the iron molecules and iron-carbide molecules from coalescing. This causes a greater contraction of the metal, and, consequently, a lower temperature, before the like molecules are brought sufficiently near together for the molecular attractive force to effect a change; hence there is a greater tendency for the piece to warp.

The combustion type of furnace, especially when using coal as fuel, gives off many elements as products of combustion which may be injurious to steel. Among these may be mentioned such hydrocarbons as anthracine, naphthalene, toluene, benzine, methane, ethane, etc., while acetylene, benzole and sulphur are other products. With a large amount of hydrocarbons present in a furnace, it is almost impossible to prevent carbonization in the steels as the gases that are commonly present, other than nitrogen, have no other effect on steels. Thus, some parts of the piece being hardened would be carbonized more than others and cause a variation in the hardness. To prevent this, the muffle type of furnace should be used. The instruction given with all high-grade steels is to heat in a muffle furnace so the products of combustion, or the flame, cannot attack the metal. The construction of the electric furnace, however, is such that it forms its own

muffle and the expense of renewing muffles is done away with. In the neutral atmosphere inside the electric or muffle furnace, the oxygen holds the nitrogen and the nitrogen holds the oxygen. Neither are active and they do not attack the steel. This is plainly seen, as far as the oxygen is concerned, by watching the steel that is being heated. No matter how long it is subjected to the temperature of the furnace, no scale forms on the steel while in this neutral atmosphere. Oxygen always attacks the exposed surfaces first and causes blisters or scale to form on them; therefore, its action is visible. When no scale forms, the elements in the air must be inactive. When the hot steel is exposed to the air, other forces cause the oxygen to become active, and scale forms rapidly until the steel has cooled to comparatively low temperatures.

In Fig. 4 is shown two electric furnaces that are in use in the Sprang & Chalfant Co.'s plant in Pittsburg, Pa. The furnace to the left is heated by resistance wires and is of the type that is commonly used for laboratory work. It is here used for hardening all steels that do not require a hardening temperature of more than 1800 degrees F., and for preheating high-speed steels which require a greater temperature for hardening. As the wires would burn out if the temperature were raised to about 2000 degrees, its practical working temperature should be kept below this; thus, 1800 degrees is a good maximum to establish. After preheating in this furnace, which is the cheapest in fuel consumption, high-speed steels are heated to the hardening temperature in the furnace on the right-hand side. This furnace is capable of withstanding a temperature of 2400 degrees continuously. It is the same type as shown in Figs. 1, 2 and 3.

Current Consumption and Operating Cost

The carbon resistance furnace to the right, with a heating chamber 12 inches wide, 18 inches deep and 8 inches high, can be brought up to the higher temperatures required for high-speed steel, with 30 kilowatts, in one hour and fifteen minutes, and then be maintained at this temperature with about one-half of this current. With an average amount of steel to heat, it can be operated during a ten-hour day with about 145 kilowatts. The wire resistance furnace on the left-hand side, with a heating chamber 12 inches wide, 26 inches long and 8 inches high, can be raised to its working temperatures for carbon steels in one hour and 30 minutes, with 15 kilowatts and then be held at this temperature with less than one-half of this current. The heat insulation is so effective that furnaces have been closed after turning off the current, and at the end of twelve hours the temperature had only dropped to between 700 and 800 degrees. Smaller furnaces with a heating chamber 7 inches wide, 12 inches deep and 5 inches high, only use one-half as much current.

The current cost for an electric furnace is undoubtedly higher than the fuel cost for a gas-, oil- or coal-fired furnace of the same size, but when all other things have been taken into consideration, this current cost is minimized and the electric furnace can be made to compete commercially with other kinds. This is especially true when quality is a factor in the work heat-treated. The ease with which the temperature can be controlled and accurately maintained; the absence of scale or pitting; the decrease in warpage; the cleanliness of the work due to the absence of deposits of any kind; the overcoming of decarbonized spots; the lowering of the penetration of gases or other injurious elements, such as sulphur; and the uniformity in the hardness or temper of the steel, are all things which should be figured against the cost of fuel. In addition to this, the electric furnace can be so heat-insulated that the hand can be held on the outer shell or case without burning. This lowers the temperature of the hardening room and makes the working conditions so much better that operators are enabled to turn out more work. One company cites a case where they heat-treated three tons of cold-rolled steel per week, in the shape of razor blades, in six electrically heated furnaces with two operators; whereas, before their installation, it required fifteen men and sixty-five machines, that used gas and blast, for the hardening operations on the same tonnage. While this might be a case where the work was particularly adapted to electric furnaces, many others can doubtless be found, where a saving could be effected when all of the factors are figured into the cost.

[Since the foregoing article was written, a report has been received from the Timken-Detroit Axle Co. to the effect that the four furnaces mentioned have been in operation three months, and that each hour of the ten-hour work day averages 75 pounds of steel gears heated to the hardening temperature in each furnace. The average current consumption is 13 K. W. per hour for each furnace, costing 1¼ cent per K. W. The average cost per pound of steel hardened is a trifle more than 0.2 cent.—E. F. L.]

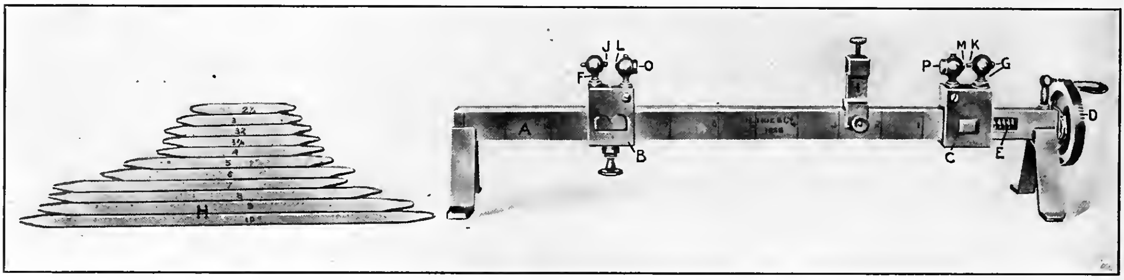
AN OLD BEAM MICROMETER CALIPER

The measuring machine shown in the accompanying illustration was found by the writer in the shops of R. Hoe & Co., New York City, manufacturers of printing presses. This interesting measuring device which is virtually a bench beam micrometer caliper was made by F. Corwin in 1858, who at the time was employed as a first-class toolmaker. The caliper is considered to be one of the first of its type ever developed. The beam *A* is laid off in twelve one-inch divisions, and the graduation lines and figures on the beam were all hand engraved. The adjustable jaw *B* is set on the line by the aid of a magnifying glass, while the other jaw *C* which is screw adjusted is set at division 1, the dial *D* being set at zero. The screw *E* is a square thread of ten pitch, and the dial *D* has 100 divisions, thus providing for readings of 0.001 inch.



An Old Measuring Device originated in the Shops of R. Hoe & Co. Fifty-five Years ago

When first made the caliper jaws were set on the inch mark by the aid of a magnifying glass, and fractional readings between the inch divisions were read off on the dial *D*. An addition was made to the machine so that it could be used for outside as well as inside measurements. This was accomplished by putting additional studs *F* and *G* in the jaws *B* and *C*. Hardened steel pins were inserted in these studs and acted as contact points between which the standard length gages shown at *H* were placed. These standards having square bodies were held in a support *I* clamped to the beam. To set the machine at a required dimension a standard length gage of the required length was placed between the measuring points and the dial set at zero. Then both outside and inside measurements could be taken, as the continued points of the measuring surfaces *L* and *M* (which have since been cut off) were in exact alignment with the points *J* and *K*. The machine was further remodeled by dispensing with the standards and using the additional measuring surfaces *O* and *P* in connection with the graduations on the dial. The jaws were set by standard plug gages and then by means of the graduations on the dial, readings exceeding the setting by one inch could be obtained. D. T. H.

ARBORS FOR SECOND-OPERATION WORK

VARIOUS TYPES USED FOR TURNING, BORING AND GRINDING, WITH EXAMPLES ILLUSTRATING APPLICATION

BY ALBERT A DOWD*

Cylindrical work which cannot be completely machined in one setting and which requires concentricity of the various surfaces obviously makes necessary some method of holding

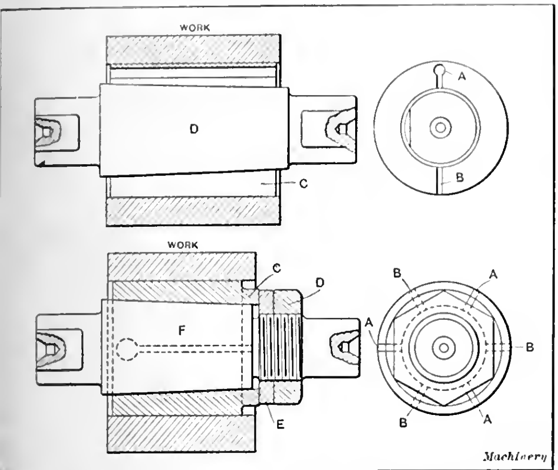


Fig. 1. Two Types of Expansion Arbors with Split Sleeves

it for the second operation which utilizes a previously machined surface for securing the proper location. When this surface is external, the use of soft jaws, a step-chuck or collet jaws is feasible, but when an internal surface is the locating

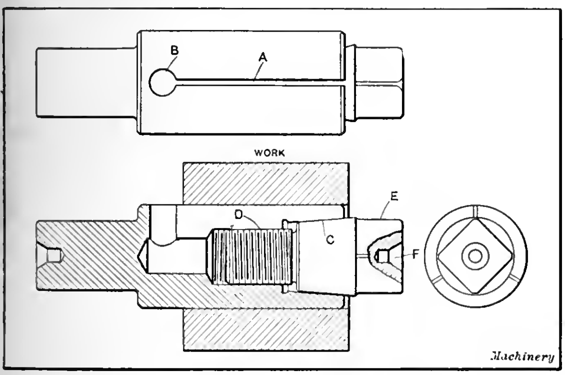

Fig. 2. Arbor expanded by Internal Taper Plug

point the most efficient method is conceded to be some form of arbor. This arbor may be either a plain stud made to fit the hole in question, or it may be so designed as to be susceptible of a certain amount of expansion and contraction in order to take care of slight variations in the finished hole. The degree of accuracy required in the finished product determines the form of arbor which should be used. If a variation of 0.002 to 0.003 inch in concentricity is permissible, a plain arbor with some method of driving the work will answer the purpose very well. When very accurate work is required, however, greater care must be used in the design, and the expanding type of arbor is commonly used.

Important Points in Design of Arbors

The fundamental features which tend to make an arbor thoroughly efficient are as follows: Expansion must be uniform along the entire periphery; release must be quick and easy; ample driving facilities must be provided; clamping the work must be effected without chance of distortion.

* Address: 84 Washington Terrace, Bridgeport, Conn.

As an additional refinement, provision may be made for truing up the arbor so that it will run accurately with the center line of the spindle.

Lathe Arbors

Let us first consider the arbors designed for use in the engine lathe, adapted to be held between centers and driven by means of a dog on one end. The arbor shown in the upper part of Fig. 1 is the simplest of all those which have a split sleeve or bushing capable of expansion or contraction. The mandrel *D* is slightly tapered and is flattened on each end to receive the dog for driving. The sleeve *C* is correspondingly tapered and is drilled entirely through at *A*, after which it is saw-cut at *B* to allow for expansion. This arbor is the poorest of all the expanding types in that the expansion is not uniform, being in two directions only, and it cannot be depended upon to give results which are absolutely accurate.

A much better arbor is shown in the lower part of the same illustration. It will be noted that the mandrel *F*, in addition to being tapered, is threaded on one end to receive the hexagon nut *D*. This does away with the necessity of

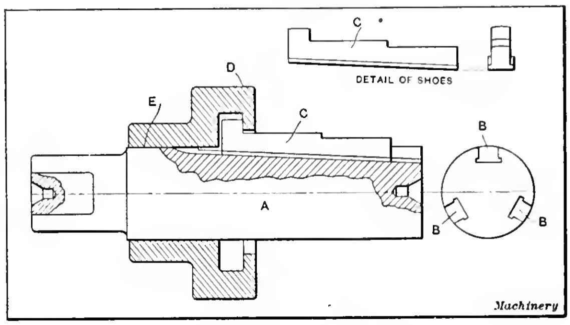

Fig. 3. Expanding Arbor of Sliding-shoe Type

using the arbor press to expand the sleeve. The collar *E* is interposed between the nut and the split bushing. This bushing *C* is saw-cut at *A* from one end and at *B* from the other, thus allowing a uniform expansion along its entire periphery. In this connection, it is well to note that the ends of the saw-cuts should be left tied together until after the sleeve has been hardened and ground; they can then be cut apart readily with a thin emery wheel. An arbor of this kind is mechanically correct and, if carefully made, should give results which leave nothing to be desired as far as accuracy is concerned.

Fig. 2 shows an arbor of a very different type, which might be called a solid expanding arbor. Three holes *B* are drilled 120 degrees apart and the saw-cuts *A* are milled as shown.

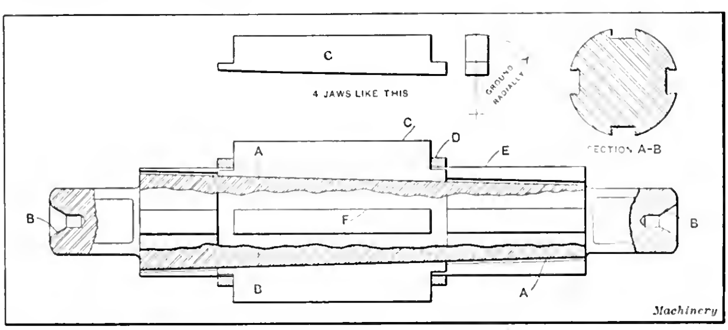

Fig. 4. Expanding Arbor with Sliding Shoes retained in Slotted Sleeve

The special screw *E* is tapered at *C* and threaded at *D* in the body of the arbor. The end of this screw is squared and contains the center *F*. When made as shown there is nothing

in this arbor to commend it. In the first place, the expansion takes place at one end only and is not at all uniform, and, in the second place, the center F in the end of the screw cannot be depended upon to remain true for any length of time, even assuming that it may have been made reasonably true to start with, which, in itself, is a difficult machining proposition.

The arbor shown in Fig. 3 was at one time manufactured commercially by G. E. Le Count, South Norwalk, Conn., but the writer is unable to state whether it is on the market at the present time or not. It consists of the body A in which are milled the tapered slots B. The shoes C (also shown in detail in the upper part of the illustration) have a narrow rib running along each side and this rib engages with the grooves in the sides of the slots B, thus preventing the shoes from falling out. The collar D controls the action of the shoes and is ground to a sliding fit on the cylindrical portion E of the arbor. It may be noted that the shoes have two shoulders, thus increasing the range of the arbor. By providing shoes of various diameters the range can be increased considerably.

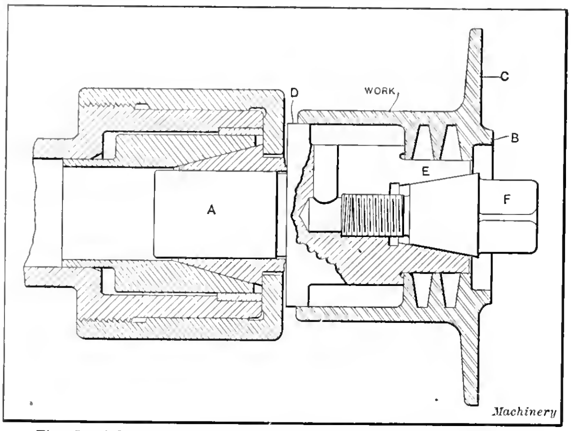

Fig. 5. Arbor held in Collet and expanded by Internal Taper Plug

W. H. Nicholson & Co., Wilkesbarre, Pa., manufacture the expanding arbor shown in Fig. 4 in various sizes and to suit various conditions. The body A is made of tool steel, hardened and ground to a cylindrical form. The centers are exceptionally large and are carefully rounded and lead-lapped after hardening. There are four slots in the body (shown in the section A–B), and these slots are relieved at each corner to prevent any interference by dirt. After hardening, the slots are also ground to insure truth. The jaws C (also shown in detail) are made of special steel and carefully ground to the same taper as the slots. After assembling, they are also ground radially on their own arbor. The sleeve D acts as a retainer for the jaws and is a running fit on the cylindrical portion E of the arbor. Four slots are cut through the sleeve and the jaws are held in position by them. These arbors are too well known to need further comment, as they are in general use throughout the country.

Turret Lathe Arbors

We will now go a step further and take up the type of arbors adapted for use in the horizontal turret lathe. It is well to bear in mind that arbors of this sort should be so designed that the work may be easily and quickly put on and taken off without the assistance of anything more than a wrench or spanner. Every precaution must also be used in clamping and driving the work, so that no chance for distortion is possible.

The arbor shown in Fig. 5 is somewhat similar in construction to that in Fig. 2, except that it is adapted to be held in collet jaws instead of on centers, as in the former instance. This arbor gave satisfactory results on the work for which it was used, the surfaces B and C being faced within the required limits of accuracy. The work was a push fit on the cylindrical portion D, the expansion taking place at E, controlled by the tapered screw F. In this case, the nature of the work permitted a slight margin of error and

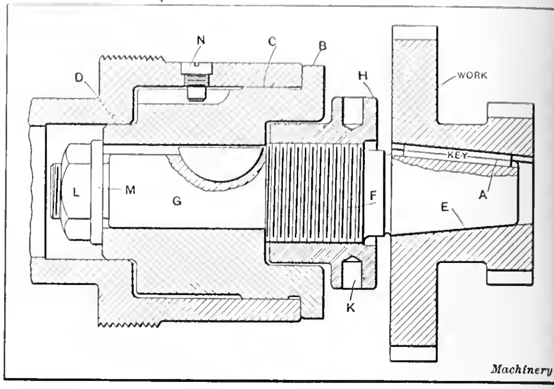

Fig. 6. Taper Arbor mounted in Spindle and equipped with Nut for removing Work

the expansion was only necessary to prevent chatter and act as a driver. The shank A is held in the collet jaws.

The arbor shown in Fig. 6 was made for the transmission gear which is shown in position. After the taper hole had been "chucked" in the work (which was done in a previous setting), the keyway A was cut for assistance in driving. The arbor body B is of cast iron, ground to fit the spindle at C and D. The stem G is of steel, hardened and ground to fit the body, into which it is keyed to resist the torsion of the cut. It is held in position and drawn back by the nut and collar L and M. The forward end is ground to the correct taper E, and the key is inserted at A. The portion F is threaded with a six-pitch Acme thread, right-hand, and the nut H is used to remove the piece after the work is finished, a piece of drill rod being used in the spanner hole K to turn the nut. The screw N prevents the body from turning in the spindle. This arbor has given very satisfactory results.

A somewhat extraordinary condition is shown in Fig. 7, which illustrates a steel automobile hub and arbor. In this case, the bearing seats at A and B were required to be absolutely concentric. In order to assist in machining, the portion C was bored to size in the first setting, although no finish was required at this point. The body of the arbor D is of tool steel, hardened and ground at all important points. The small end is slotted in three places as shown at F and

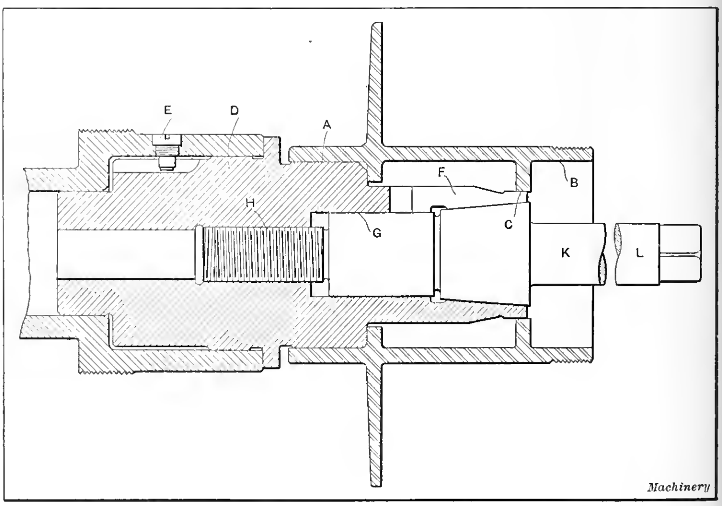

Fig. 7. Arbor with Split Expanding End and Pilot for steadying Tools

is spring tempered at this end. The operating rod K has a very free thread at H and is ground to a snug running fit in the cylindrical portion G to insure a true running pilot L, regardless of the condition of the threaded part. All the tools used on surface B of the work were piloted by the stem L, thus securing absolute truth and concentricity of the ends A and B.

There are several important points to be noted in the construction of this arbor. First, the method of obtaining a true running stem L by means of the long cylindrical bearing at G; second, the use of the stem as a pilot for tools, thereby obtaining concentricity in the two ends of the work A and B; third, the positive location of one end at A, while using an expansion principle at the other end to insure rigidity and freedom from chatter. This arbor was very satisfactory, the two ends being within the extremely narrow limits of concentricity required.

An entirely different type is illustrated in Fig. 8. This is used for two different sizes of bronze bearing retainers, the use of adapters making this feasible. In the construction of this arbor, the body A is screwed directly onto the spindle nose, bringing up snugly against the end of the spindle at B. The body itself is of steel and is tapped out at C to receive the operating screw E. As in Fig. 7, the thread is a free fit, while the cylindrical portion D is ground to a snug running fit to insure concentricity. The bushing F is saw-cut in six places, three cuts from one end running nearly through, and the other three in like manner, in order to allow uniform expansion of the bushing. Both the bushing and the operating screw are tapered correspondingly at G. The adapter H slips onto the body of the arbor and is located from shoulder M and secured in place by three screws N. A pin driver L in the adapter relieves the bushing of excessive strain. The larger retainer O (shown in detail) is also handled on this same arbor by using the adapter K. The results obtained with this arbor were perfectly satisfactory.

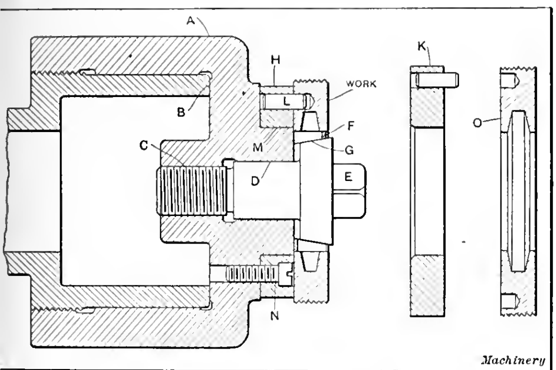

Fig. 8. Arbor having Taper Plug which expands Split Bushing

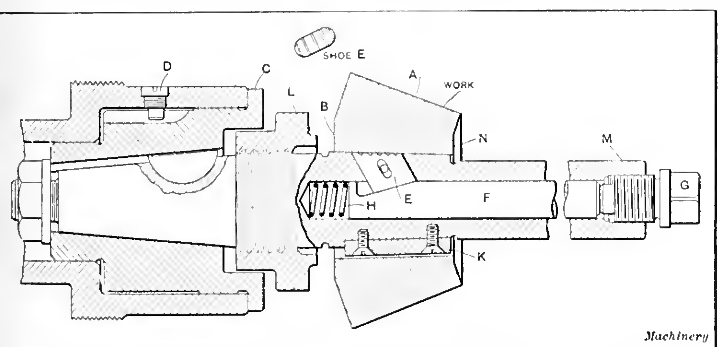

Fig. 10. Arbor having Adjustable Shoe E which bears against Taper Bore of Pinion Blank

In Fig. 9 the principles of expansion and contraction are both used in handling steel rifle part A. The permissible limits of error on this work were very close, so that extremely careful workmanship was necessary. This operation was the final one on the piece, after it had been machined all over, leaving 0.015 inch at C for truing to insure absolute concentricity between surfaces B and C.

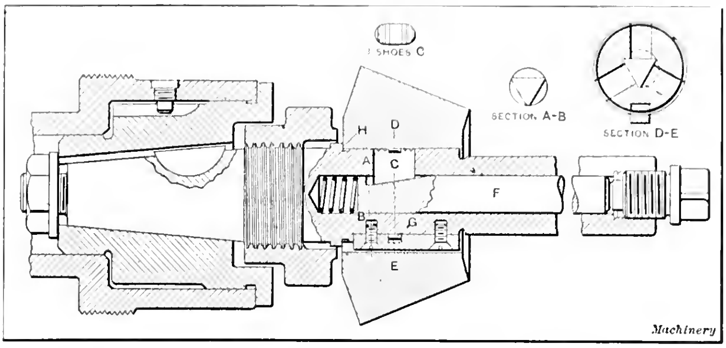

Fig. 11. Arbor for Pinion Blanks, equipped with Three Expanding Shoes

The machine to which this fixture was applied was equipped with collet mechanism, part of which was used in the operation. The body of the fixture E is of cast iron and is screwed onto the spindle nose, being secured against turning by the teat-screw F. The sides of the fixture were left open to enable the operator to reach in and grasp the work, in order to guide it onto the locating bushing B. The operating rod G was milled at an angle on the forward end H, in order to force the pin K outward and thus insure rigidity at this point. The collet operating sleeve M is secured to the rod by pin N, so that the collet closing mechanism can be used to operate the rod. At the forward end of the fixture, the split bushing O is used to center the work which is gripped on the finished cylindrical surface D. The bushing is knurled at Q and is contracted by the action of the hollow set-screw P. All important surfaces were ground to an accurate fit and parts subject to wear were hardened. No trouble was experienced with this fixture and the work was machined within the limits of accuracy required.

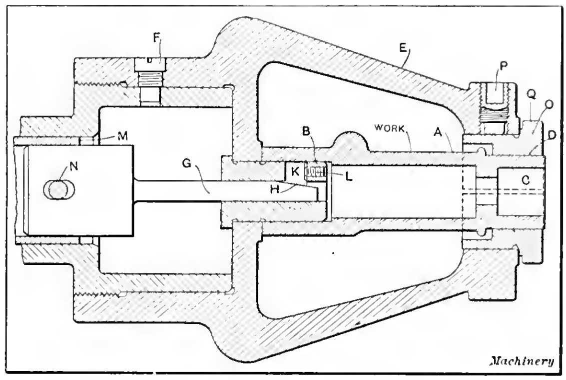

Fig. 9. A Fixture which holds Work by Expansion and Contraction

The steel pinion blank shown at A in Fig. 10 has been previously faced at B and the taper hole carefully bored, leaving the remainder of the work to be accomplished at the setting shown. The body C, in this instance, is of cast iron and is held in position by the teat-screw D. The arbor is of tool steel, carefully hardened and ground. The shoe E is shaped as shown in the detail above. The operating rod F is forced inward by screw G, and its release is effected by spring H which bears against its inner end. It should be noted that the action of shoe E is both outward and backward; therefore it has a tendency to force the work back

onto the tapered portion. Obviously key K acts as a driver. In order to avoid any chance of springing the arbor out of true a small, special wrench is used for turning screw G, so that too much pressure cannot be applied. The nut L is threaded on the arbor with a coarse-pitch Acme thread and is of hexagon shape at the forward end. This nut is used to start the work off the arbor when the piece is finished. The stem of arbor M enters a bushing in the turret and acts as a support while the beveled surface of the work is being turned. This stem is also used as a pilot for the face mills which form the end of the pinion at N. This arbor while used for producing work of the best quality was somewhat fragile and required careful handling.

The pinion blank shown in Fig. 11 has a straight hole instead of a taper one, and the arbor for holding it, while somewhat similar in construction to that shown in Fig. 10, differs as regards a number of points. There are three shoes C, 120 degrees apart, controlled, as to their outward movement, by the operating rod F. These shoes are retained in their positions by the thin circular spring G. The shoulder H on the arbor acts as a positive longitudinal stop for the work. The various sectional views give a good idea of the construction. This arbor is also of tool steel and all important surfaces are hardened and ground. It gave very satisfactory results, but the rather delicate construction necessitated careful handling.

Arbors for Vertical Boring Mill and Vertical Turret Lathe Work

We now come to a class of work of larger size, which can be more conveniently handled in the vertical boring mill or the vertical turret lathe. Arbors for comparatively large work frequently develop into combination locating and holding devices, so that they are more nearly related to locating fixtures in the truest sense of the word. It is well to remember that in all fixtures of large size some efficient means

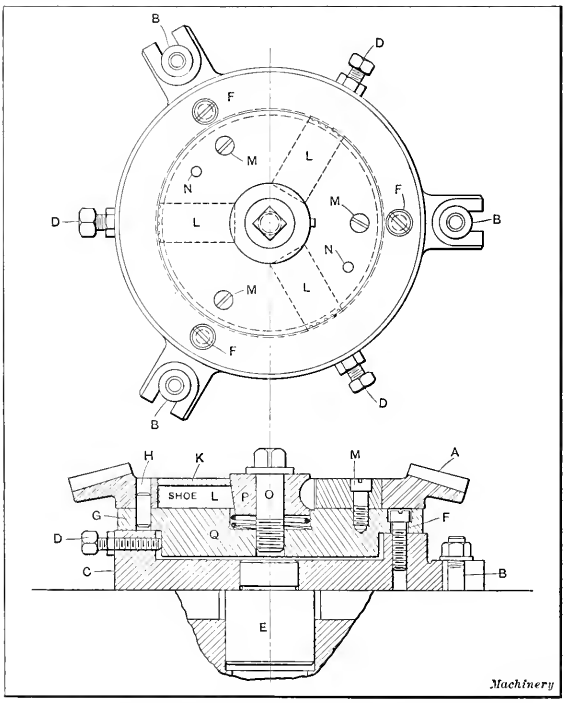

Fig. 12. Vertical Boring Mill Fixture for holding Bevel Gear—The Three Shoes L are forced outward by Plug in Center

of driving the work must be provided, for the thrust of the tool, incident to the cutting action, is much greater on work of large diameter; furthermore, the amount of stock to be removed is usually considerably more than on smaller work. The fixtures themselves should also be of exceptional strength and rigidly secured to the table to prevent movement or breakage.

The large automobile bevel driving gear shown in Fig. 12 is of alloy steel, and it has been previously bored and faced on the rear side; the screw holes were also drilled in a jig before placing the gear on the fixture shown. This fixture was rather expensive, being made entirely of steel (except the base, which is of cast iron), and all working parts were hardened and ground or lapped to a perfect fit. The base is located in the center of the table by means of the locating stud E, and is securely fastened down by the three T-bolts B which enter T-slots in the table. The adjustable part G is held onto the base by the three screws F. It will

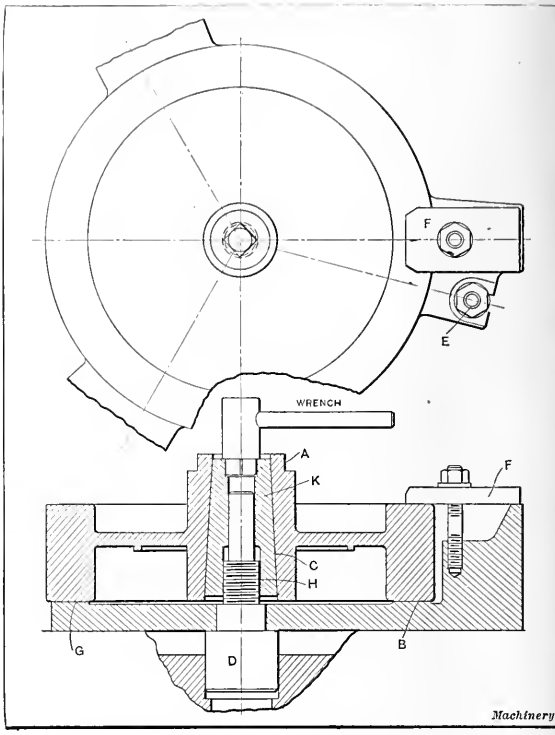

Fig. 13. Flywheel Centering Plug having Vertical Adjustment to compensate for Slight Variation between Bore and Rim Face

be noted that the screw holes have a certain amount of clearance over the body of the screw to permit adjustments to be made. The screws and check-nuts at D are for the purpose of conveniently adjusting the fixture. A pin-driver H engages one of the jig-drilled holes in the work. The upper plate K is square slotted at three points L to receive the shoes L. The screws M and the dowels N hold this plate in its proper position. The collar-head screw O forces down the plunger P on which three angular flat spots are milled. These angular surfaces control the action of the shoes L and force them out, uniformly, against the work, thus centering it. The spring Q simply aids in releasing the shoes.

This fixture is an exceptionally good one, for in its construction every care is taken to insure a true-running arbor and one which can readily be indicated for truth and brought into perfect concentricity by means of the adjusting screws. Its action was satisfactory in every respect.

Fig. 13 shows an automobile flywheel which has a finished taper hole and has been turned, bored and faced in a previous setting. It was essential that the surface A should be concentric with the taper hole. As it was practically impossible to machine the face of the flywheel B and the taper hole C so that they would always come in exactly the same relation to each other, it was necessary to make the taper plug adjustable in a vertical plane. The base of this fixture is of cast iron and is located centrally by means of plug D which accurately fits into the hole in the table. The base is clamped in position by three T-bolts E (see plan view) engaging the table T-slots. Three clamps F are used to clamp the work down on the annular rim G of the fixture. The plug D not only locates the fixture base, but extends above the latter and is threaded at H, while above

this portion it is cylindrical and is carefully ground to a running fit in the taper bushing K. The threaded portion mentioned is a very free fit, so as to permit the cylindrical part to do all the centralizing. In using the fixture, the bushing K is screwed down and the flywheel placed in position, after which, by the aid of the wrench, the bushing is raised until it bears in the taper hole. After this, the clamps F are swung around and tightened. This is a simple fixture, rather inexpensive, and one which was thoroughly dependable.

Fig. 14 shows a cast-iron double-bevel gear used on harvesting machinery, the gear rings A and B having cast teeth. These were not machined, thus leaving a rough surface by which to clamp the work, as some support was needed in order to properly machine the annular ring C. The cylindrical hole D and the end E were machined at a previous setting.

The cast-iron base of the fixture is centered by the stud F which fits the center hole in the table. This stud extends up through the fixture and is tapered at its upper end to receive the spit bushing G. This bushing is saw-cut in six places—three from each end—and is shouldered at its upper end so that the vertical movement can be controlled by the operating screw H. The collar K was pinned in place after the bushing was slipped over the screw. It will be noted that the vertical movement of the bushing is entirely mechanical, no springs being used to effect its release, as in previous instances. The positive locating point of the fixture is at E, but as it was necessary to have some support at B the four spring pins L were used; these bear against the rough surface of the casting and are prevented from being pushed down by the screws shown. The flat spot against

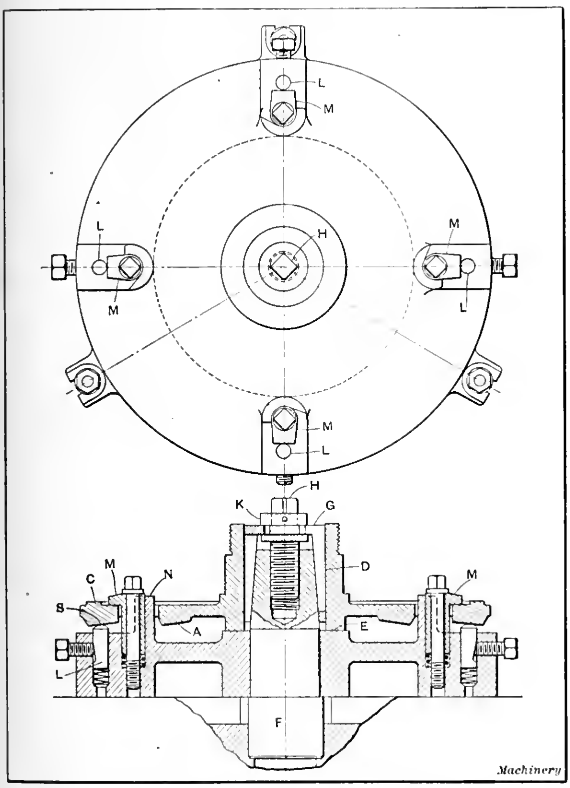

Fig. 14. Vertical Boring Mill Fixture for Special Design of Bevel Gear

which the screws bear is milled back at an angle of ten degrees. The rim of the gear has four cored holes and hook-bolts were necessary for holding and driving. These are shown at M in the illustration. In this connection, it is well to note that these hook-bolts are well backed up by a portion of the fixture N, for a hook-bolt which is not backed up in some way is worse than useless. This fixture was capable of rapid manipulation and the results obtained by its use were within the necessary limits of accuracy.

An Expanding Arbor for the Vertical Milling Machine

In one of the large automobile factories, considerable trouble was experienced in the manufacture of eccentric piston rings by the breaking of the rings as they were being cut off on an automatic machine. A new method was therefore devised by which the "ring pots" were bored and turned eccentric and then taken to a vertical milling machine where they were placed on the arbor shown in Fig. 15. The fixture of which the arbor forms a part is located in

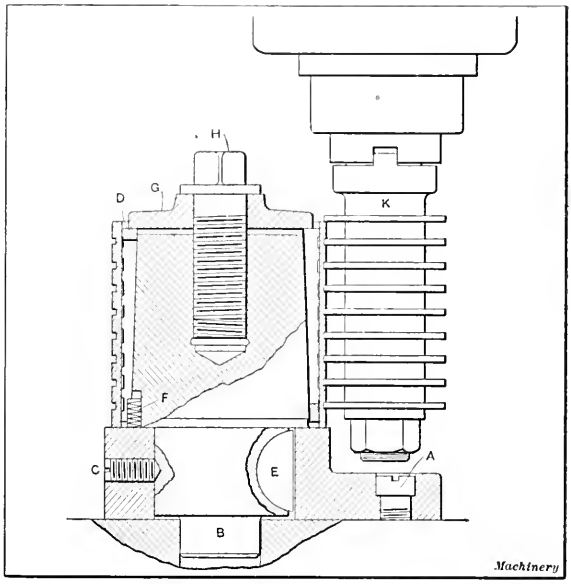

Fig. 15. Expanding Arbor for holding Casting while Gang-sawing Packing Rings

the center of a circular milling table by the stud B, and is secured to the table by means of the three screws A in the T-slots. The stud is tapered at its upper end to receive the split bushing D, and is secured by the pointed screw C and prevented from turning by the key E. The bushing was saw-cut in six places to permit expansion, and was also counterbored in three places at its lower end to make a pocket for the coil springs F. These springs tend to make the releasing of the split bushing easy after the work has been done. The collar G bears on the upper portion of the split bushing D and is operated by the screw H which is threaded into the body of the arbor.

A special arbor K in the spindle of the vertical milling machine was arranged with a gang of saw cutters properly spaced for the correct width of ring. As the table is revolved by power feed, the gang of cutters produce a set of nine clean and unbroken rings. It may be noted that the split bushing is relieved on its periphery at the points where the cutters pass through the work, in order to avoid dulling the cutting edges on the hardened surface. This fixture was made up very carefully and proved very satisfactory. To the best of the writer's knowledge, it is still in use although made over six years ago.

A Grinding Arbor for Piston Rings

The right-hand view, Fig. 16, shows an eccentric piston ring for a gas engine which has been bored, turned eccentric, ground parallel on the sides and split apart at the point A. The arbor shown to the left in the same illustration was used for grinding the periphery to make it perfectly cylindrical after it had been split and closed up at A. The body of the arbor B is of tool steel with generous centers in each end. These centers were lead-lapped after hardening and before grinding the cylindrical portion. The faces C and D are also carefully ground. The locating collar E is of tool steel, hardened and ground to a very close running fit on the arbor and at the point H where the rings fit. The portion F is knurled to give a good gripping surface for the hand when pulling back the sleeve. The spring detent G serves to hold the sleeve in position when it is pulled back

out of the way for grinding. The hole K is an air hole and is very essential, for as the parts are all very closely fitted the suction is so great that it is almost impossible to pull back the sleeve unless this relief hole is drilled. A longitudinal groove along the arbor would answer the same purpose, but is more likely to catch dirt and thus cause trouble. The nut N is of tool steel, has a coarse pitch thread and is made hexagon at the small end. The faces which bear against the rings are ground parallel with the thread. When in use, the nut is slipped back out of the way and the two rings M are sprung into place inside the locating collar, after which the nut N is brought up against the rings and tightened. The locating collar is then pushed back out of the way, until the detent snaps into place, and the work is then ready for the grinding operation on the periphery. Arbors of this type are in daily use in nearly all of the automobile factories in this country.

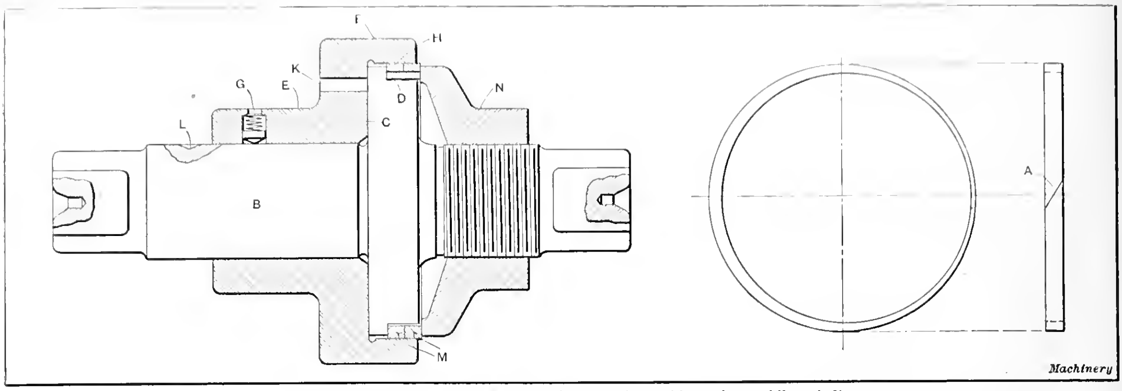

Fig. 16. Arbor for compressing and holding Split Packing Rings while grinding

The various types of arbors and fixtures illustrated and described in this article cover representative work of nearly all kinds, and may be modified to suit almost all possible conditions whether they affect the work part, the machine, or both.

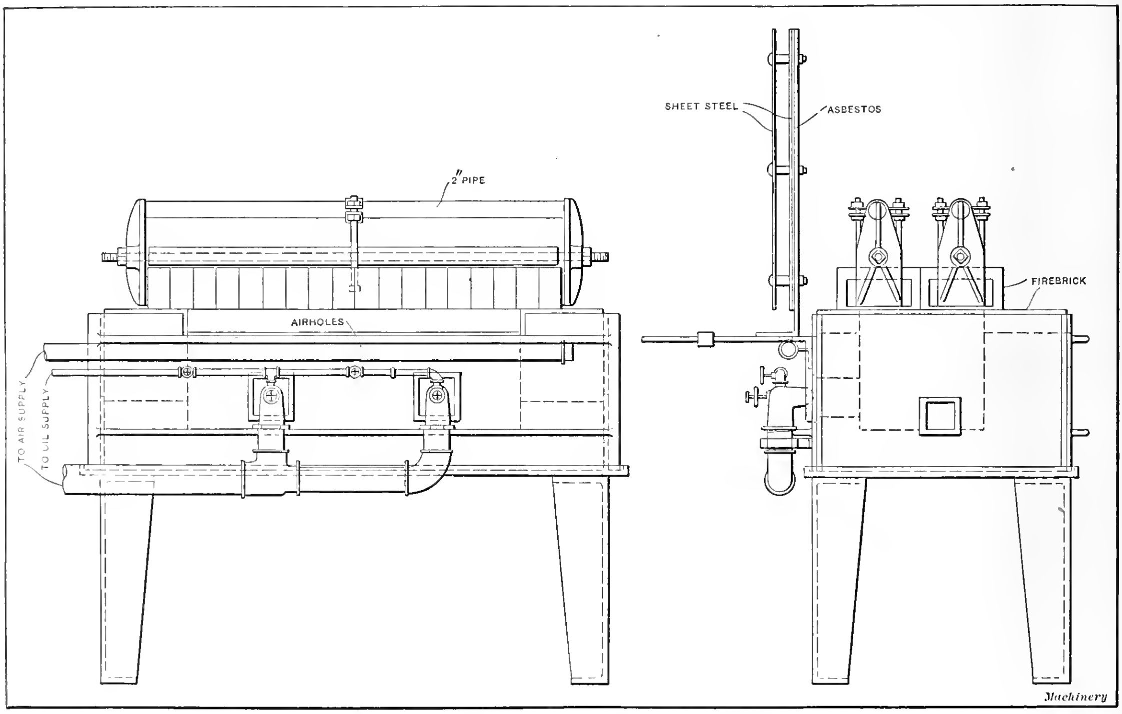
It is better to have a customer kick at the price than at the quality.

OIL FORGE FOR MACHINE BLACKSMITHING

BY M. W. W.

The oil forge illustrated herewith was built and tried out in a large shop which produces many varieties of forgings, and it was found to be so well suited for this class of work that two more similar forges were made. The distinctive feature of this forge lies in the bridge construction which is made of two rows of firebricks held together by the clamping mechanism shown in the illustration. It will be seen that this clamping mechanism consists of two clamp members which bear against the end bricks of the bridge construction. These clamps are carried by pieces of 2-inch pipe and are tightened by a bolt provided with a nut at each end. When these nuts are tightened, the firebricks are firmly held without requiring the use of fireclay or cement of any kind. It will be seen from the illustration that two rows of bricks are secured in this way to form the bridge of the forge, the bridge itself being held in place by gravity. With this form of construction, it is a very easy matter to renew the bridge work when the bricks have become so badly burned that replacement is necessary. The convenience of this construction will be evident to all who have maintained furnaces.



Bridge Construction for Oil Forge which is easily Renewable

SOLVING THE FUEL PROBLEM FOR THE MOTOR TRUCK

CHARACTERISTICS OF KEROSENE AS A FUEL FOR INTERNAL COMBUSTION ENGINES

BY HAROLD WHITING SLAUSON*

No sooner has the gasoline motor been well-nigh perfected, than the automobile designers and drivers find themselves face to face with another problem. Methods of carburetion, lubrication, and ignition have all been successfully developed, and the driver now looks for little trouble from these sources; but the success of the designers in eliminating these troubles has, in a sense, defeated its own purpose, for when the low price, reliability, and compactness of the gasoline engine began to solve so many power-producing problems, the demand for what had once been the "useless by-product" of the refineries increased to such an extent that gasoline is now a valuable fuel. A fifty per cent increase in price in a few months is not so important in itself, but when it is taken as an indication of further increases the problem assumes a serious aspect—serious for the motor truck owner, at least, if not for the driver of a pleasure car.

The reason for the slow acceptance of substitutes for gasoline is psychological as well as chemical and mechanical. The owner of a pleasure car is not as disturbed over the few cents increase in the cost of gasoline as might be expected; he argues that gasoline is a tested fuel that has given satisfaction, and he understands its characteristics perfectly. A small or even a large amount, spilled when filling the tank, causes no damage or annoyance, for the evaporation is rapid and no residue is left to collect dust. The heavier oils, such as kerosene, however, are slow to disappear by evaporation. The owner of a motor truck, however, has invested in the machine because he is convinced it will represent a dollars-and-cents saving over his former delivery or hauling system, and any device which will contribute toward economical operation will be given due consideration; furthermore, the fuel consumption of a motor truck is much higher than that of a pleasure car. A gallon of gasoline that will drive the latter twelve or fifteen miles will serve only for one-third or one-fourth that distance in a two- or three-ton business vehicle.

Kerosene as a Fuel for Internal Combustion Engines

In the search for new fuels that has been in progress since it has been evident that the supply of gasoline could not hold

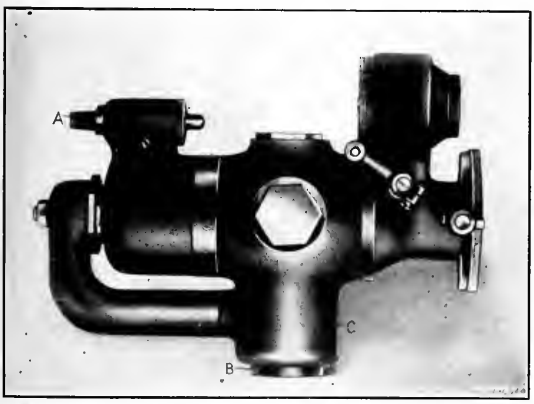


Fig. 1. Kerosene Carbureter in which the Primary Air is admitted Cold and the Exhaust Heat is used only around the Float Chamber

out, kerosene has stood foremost. This is logically due to several reasons, the chief of which is probably the fact that no change whatsoever need be made in the design of the gasoline engine in order to adopt it to the use of kerosene. In addition, kerosene is but one group lower than gasoline in the great hydrocarbon family of which petroleum is the parent, and the motor car driver therefore feels that he is not dealing with an absolutely new and unknown fuel; but of course, kerosene would not be regarded as a satisfactory solution of the fuel problem were it not present in large quantities in all grades of petroleum. The most valuable petroleum is the Pennsylvania crude, but even in this, gasoline is not present to a greater extent than three or four per cent, and in the poorer qualities, it is so scarce that no effort is made to distill it. Kerosene, on the other hand, is present

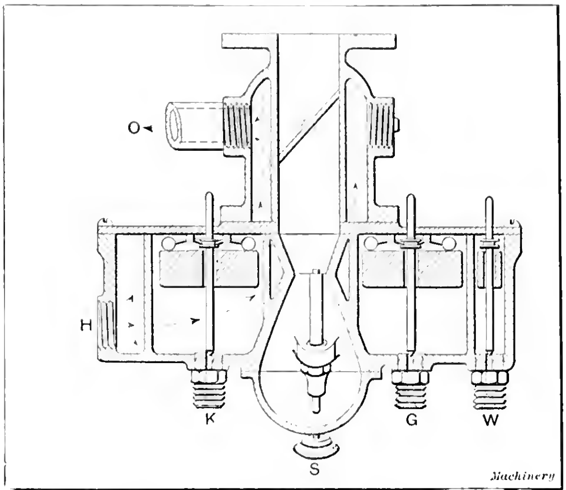

Fig. 2. Kerosene Carbureter having Part of Intake Pipe and Throttle Chamber jacketed for heating, as well as the Float Chamber

in varying quantities in practically every quality of petroleum and in some grades comprises as much as thirty or forty per cent of the total. Hence the supply of kerosene would seem to answer the fuel requirements of the internal combustion engines for years to come—or at least until the engines manufactured and in use today are worn out and the condition of the alcohol market has been so changed that the production of alcohol-burning motors becomes profitable.

When we say that the specific gravity of present-day gasoline on the Baume scale is approximately 62 and that of kerosene 45 or 48, we do not express the only difference that exists between the two liquids. Kerosene has a higher specific gravity and is therefore heavier and less volatile than gasoline, but it is by no means a poor substitute. The carbon content is different, and therefore kerosene in a gaseous state is as dissimilar from gasoline as when in a liquid form. Both before and after evaporation, the two fuels must be treated differently. The fact that kerosene is not volatile at ordinary atmospheric temperatures was the first problem to be met by the designers. It must be borne in mind that it is the *vapor* of the fuel, and not small globules, that must be mixed with the proper quantity of air and ignited in the cylinder of the internal combustion engine. A spray is not a vapor; the former may be mixed with the air but the liquid will separate and condense as soon as it strikes the cylinder walls. Engines of the Diesel type inject either kerosene or crude oil into the cylinder in the form of a spray, but previous to ignition, the compression is increased to 500 pounds per square inch, or more, which generates sufficient heat to gasify the fuel particles immediately and ignite them. The compression of the gasoline motor, however, does not exceed 70 or 80 pounds per square inch, and this is insufficient to enable the engine, when cold, to vaporize the non-volatile particles that may be introduced into it in the form of the finely divided spray. A gasoline engine will become hot in a very few minutes of operation, and this appealed to the designers as a convenient source of heat for increasing the temperature of the liquid kerosene to the evaporating point; therefore, three-fourths of all the kerosene carbureters used at the present time employ a bowl or float chamber to contain a small quantity of the liquid, and this is surrounded by a jacket that communicates with the exhaust pipe of the

* Address: South Broadway and Post St., Yonkers, N. Y.

motor. A carbureter of this type is shown in Fig. 1. The fuel inlet is at *A* and the exhaust heat is admitted at *B*. The motor is started on a small amount of gasoline, and when the exhaust pipe has become sufficiently hot to vaporize the kerosene in the bowl, a two-way valve is turned which conducts the heavier fuel to the carbureter. The same carbureter is used for both the gasoline and the kerosene, although with some designs the gasoline is burned directly around the bowl containing the kerosene, to obtain the necessary heat.

Simple as such carbureters may appear, there are a number of problems that must be solved before the use of kerosene can give as good results as are obtained from gasoline. The fineness into which the kerosene jet should be divided, the amount of heat to which the fuel should be subjected, and the treatment of the mixture in order that the same "flexibility" as that delivered by a gasoline engine can be obtained from one using kerosene, are all subjects of vital interest to the designer and user. It has been found that the finer the spray into which the kerosene jet is divided, the more complete the combustion in the engine cylinder; atomization or pulverization probably more correctly describes the process to which the fuel should be subjected. The proper pulverization of the fuel, together with the application of heat, breaks it up into so fine a mist that actual gasification is not necessary, provided the intake manifold is made of such a shape and dimensions that the velocity of the mixture is kept high, to prevent condensation on the cool walls of the pipe. The temperature to which the fuel is raised before atomization is generally from 200 to 300 degrees, although in some carbureters the kerosene is subjected to a temperature of 600 degrees.

One of the drawbacks to the more general use of kerosene in automobiles has been its reputation for forming heavy deposits of carbon in the cylinder. When this condition exists, however, it is an indication of improper pulverization, condensation, or of faulty design or adjustment of the heat-

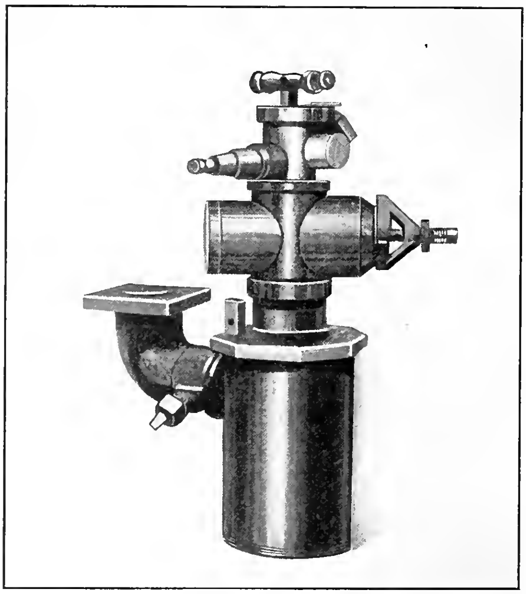

Fig. 3. Unique Type of Carbureter in which Spark Plug maintains a Continuous Flame in Path of Atomized Kerosene

and air-regulating apparatus. The best lubricating oils should be used when kerosene is employed as a fuel, but the formation of carbon in the cylinders or the presence of black smoke at the exhaust indicates that imperfect combustion is taking place.

Carbureter in which Variable Quantity of Water is added to Kerosene Mixture

An elaboration of the general type of kerosene carbureter previously referred to has been in successful use on many of the large traction engines used in the western section of this country. In this carbureter, cold air is supplied to the fuel immediately after pulverization, for it was found that this arrangement gave the greatest power and the best economy. It was also discovered that if the air admitted to this particular type of carbureter were heated, loss of power would result, attended by pre-ignition and other signs of an imperfect mixture. The unique feature of this carbureter, however, lies in an arrangement whereby a variable quantity of water is supplied to the mixture of kerosene spray and air before it is admitted to the cylinder. The water valve is connected with the crankshaft of the motor so that the supply of moisture to the mixture is increased as the throttle is opened and the spark advanced; when the motor is running

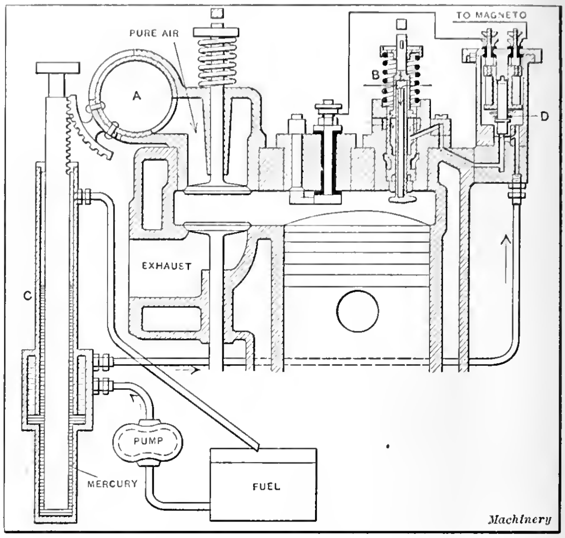

Fig. 4. Kerosene Carbureting Device which requires no Heat. It is equipped with electrically operated Valve for controlling Supply of Fuel

idle or is pulling very light loads no water is supplied to the fuel. The purpose of the water is to keep the temperature of the explosion within the limits from which the best results can be obtained, and also to assist in a more perfect combustion of the charge. At the same time that the water absorbs a portion of the excessive heat of combustion oxygen is liberated and the mixture is rendered more completely combustible. One of the troubles sometimes experienced with the use of kerosene in a gasoline motor is the inability of the engine to "pick up" with a load; full load can be maintained when it is once reached, but after throttling the motor—as on a hill, for example—the engine seems unable to respond when power is again desired. This lack of flexibility has been overcome by the introduction of the water spray that automatically accommodates its volume to the power demanded of the motor. It must be remembered, however, that the carbureter in question is designed especially for large, heavy-duty engines, and it should therefore be understood that the omission of the water spray from a kerosene carbureter designed for the average automobile in nowise indicates lack of flexibility in the power plant; in fact, many of the most successful carbureters in use on pleasure cars and trucks have no provision for the introduction of water into the air passage above the atomizing chamber.

The Wilcox-Bennett Carbureter Co., Minneapolis, Minn., makes a kerosene carbureter of the type described in the foregoing paragraph.

Heat for the Vaporization of Kerosene

While the heat for assisting in the vaporization of the kerosene is usually obtained from the exhaust manifold of the engine, the circulating water can sometimes be used for this purpose by jacketing the carbureter and connecting it with the water system of the engine. As the water in the jackets holds its heat for a greater length of time than does the exhaust manifold, it is evident that the motor could be started directly on kerosene—even after an appreciable interval had elapsed since its previous running—if the stored-

up heat in the water jackets were utilized. However, the operation of starting on gasoline, and then switching to kerosene, is neither difficult nor time-consuming and it is the surer method; but in order to obviate the necessity of even this slight trouble, some kerosene carbureters are supplied with an electrical coil placed within the vaporizing chamber. This coil is operated for a few moments by the current obtained from the lighting, starting, or ignition storage battery. But a short time is required to bring the finely divided spray from the atomizing nozzle to the vaporizing temperature, so that the current can soon be turned off, heat for further vaporization being obtained in the usual manner from the exhaust manifold of the engine.

Although the practice of heating the kerosene, either before or after pulverization, is almost universal, theories differ as to the advisability of warming the air with which this kerosene mist is first mixed. In one of the most successful types of carbureters the air is admitted cold after the kerosene has become thoroughly atomized by the mechanical action of the jet and the application of heat to the bowl. It is evident that the admission of the cold air will reduce the temperature of the resulting mixture to the point where condensation will be prevented when the charge comes in contact with the cool metal of the intake manifold. As previously mentioned, the intake manifold should be small enough so that the velocity of the mixture will be high and thus prevent condensation. By the use of cold air in medium-sized engines, however, this difficulty is overcome without the necessity of making any change whatsoever in the intake manifold of the engine. Another method of obtaining the same results, and one which is employed in one of the well-known kerosene carbureters designed especially for marine use, consists in jacketing not only the fuel bowl but the choke tube and throttle as well, so that the mixture is maintained at a high temperature throughout a good part of its journey to the hot cylinder. A carbureter of this type is shown in Fig. 2. The intake for the exhaust is at *H*, the outlet at *O*, the kerosene intake connection at *K*, the gasoline intake connection at *G*, the water intake connection at *W*, and the fuel spray nozzle at *S*. This type is manufactured by the Hampton Kerosene Carbureter Co., Inc., 1876 Broadway, New York City.

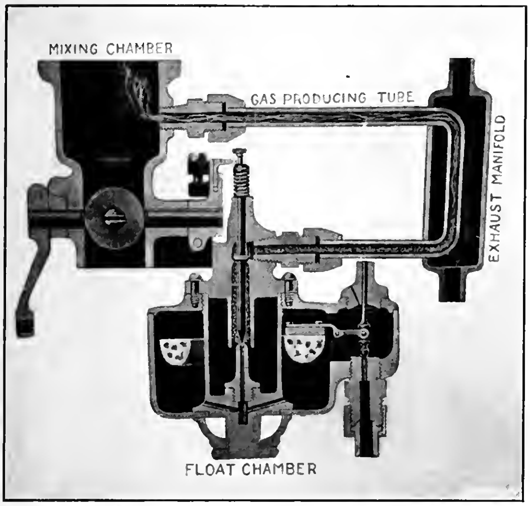

Fig. 5. Cross-section of Carbureter in which Exhaust Heat is not applied until Fuel has been well pulverized. Dotted and Wavy Lines indicate Transformation from Mist to Vapor after Application of Heat

Kerosene carbureter designers have long since discovered that the amount of heat supplied to the fuel before admission to the cylinder must be regulated to a nicety. It has already been pointed out that with insufficient heat, the kerosene is not properly vaporized. The application of too much heat, on the other hand, will result in what is known as the "cracking" process, in which the kerosene will be split up into its component parts, an ill-smelling exhaust will be ejected, and large quantities of carbon will be deposited on the piston and cylinder heads.

In one of the newest carbureters on the market (see Fig. 3) the mixture is given exactly the right composition in rather a novel way. The heat for assisting the vaporization of the fuel is obtained from the atomized kerosene itself, as soon as the motor is started, and no previous heating is required. The kerosene is atomized when cold in the usual manner; that is, by drawing it, by means of the suction of the motor, through a series of small orifices, which serves to break it up into globules, after which a strong current of air is passed over it for the purpose of further diffusion of the mist. If this mixture is discharged directly onto some cool surface, however, such as the hand, it will be observed that the kerosene will immediately condense and roll off in the form of drops. The atomizer and air inlet are at the top of the carbureter. Immediately below these is a small compartment into which projects the "business end" of a spark plug operated by a coil and set of dry batteries separate from those that may be used for the ignition system of the motor. As soon as the motor is turned over, the spark at the end of this plug is started. As this projects directly into the path of the recently atomized kerosene and air, a portion is ignited. This compartment is of such a size that only about two per cent of the kerosene spray is ignited, but this seems to be sufficient to "burn the excess carbon" out of the mixture and to transform it into an ideal combustible charge for the cylinders. This resulting mixture, if discharged into the air, appears in the form of a white cloud of vapor that does not easily condense, and seems to be as stable a gas as any yet used for internal combustion engines. This carbureter is manufactured by Alex. T. Porter Oil Utilities Co., 171 Broadway, New York City.

While the idea of burning a portion of the mixture directly in the path of the combustible charge may seem like a dangerous system, the flame is effectively prevented from spreading by the use of a wire gauze that holds the fire within the proper bounds in the same manner that the fine wire screen of the miner's lamp admits air to the burner but prevents any of the surrounding inflammable gases from becoming ignited. The location of this wire screen governs the proportion of the mixture that will be ignited by the spark plug, and the proper adjustment is important. A mica window is placed in one side of the spark plug chamber, so that the condition of the flame may be noted. The spark plug is used as long as the motor is in operation, but the inventor of the device is now working on a system which will require the use of the plug only at starting.

Kerosene Carbureting Device requiring no Heat

In view of the foregoing methods of carbureting kerosene, it is surprising to learn that a system has been devised in France which entirely does away with the application of heat, either to the raw kerosene or to the atomized mixture. In fact, a motor equipped with this device can be started when cold directly with kerosene as easily as though high-test gasoline were the only fuel used. The attachment can hardly be called a carbureter, in the ordinary sense of the word, inasmuch as it depends for its operation on several electrical and mechanical parts as well as physical properties, and requires a slight change in the design of the engine in order to make its installation satisfactory.

The first point in which this remarkable device differs from the ordinary carbureter lies in the fact that pure air only is admitted through the inlet valve. The amount of air so admitted is controlled by a slotted, hollow cylinder *A* (see Fig. 4), the orifice in which can be made to register with the opening in the inlet valve through an automatic control connected with the throttle or the gasoline pressure regulator. The raw kerosene is led from the pressure-regulating tank—into which it is forced by a rotary pump—into the atomizer *B* which is screwed into the cylinder head. This atomizer consists of an inverted automatic poppet valve, the head of which projects into the cylinder nearly over the head of the piston. The stem of this valve is hollow, and surrounding it is an auxiliary air space connected with the outer atmosphere. As the liquid kerosene under pressure rushes into the atomizer, it is broken up into fine particles and

united with the proper quantity of air admitted through the auxiliary opening and through the hollow stem. To be sure, this is not a *bona-fide* vapor (it is merely a fine spray), but it is admitted directly into the combustion space of the cylinder, mixed with the proper quantity of air entering through the inlet valve and immediately compressed; there has been no opportunity for condensation, for the atomization practically has taken place within the cylinder itself.

The pressure on the fuel is regulated by means of a variable column of mercury *C* extending into the space into which the kerosene is pumped. This pressure can be controlled by the same levers that throttle the supply of air admitted to the cylinder, but this would not be sufficient regulation to provide for the demands of the motor at all speeds, if the supply depended entirely upon this pressure and the suction of the piston in the cylinder. To obtain the proper regulation, there has been devised what is probably the most ingenious carburetion attachment to be found in use. Before the raw kerosene is admitted to the atomizing chamber, it is forced through a needle valve at *D*, the stem of which constitutes the armature of a solenoid. This solenoid is a coil of wire that is excited by the current derived from a low-tension magneto. The stem of the needle valve (assuming, of course, that it is made of a magnetic metal) serves as the plunger or armature of the solenoid and is drawn into the interior of the hollow coil whenever the current passes through the wire. When the coil is not excited, the needle valve is held in place on its seat by means of a spring that effectually prevents the passage of fuel to the atomizer when the motor is not running. By means of an electric circuit-breaker which may be geared to the crankshaft of the motor, the number of current excitations or "pulsations" imparted to the coil may vary with the speed of the engine, and a supply of fuel proportionate to the demands of the engine will thus be obtained. This kerosene carbureting device has passed the experimental stage and is now used on many French cars.

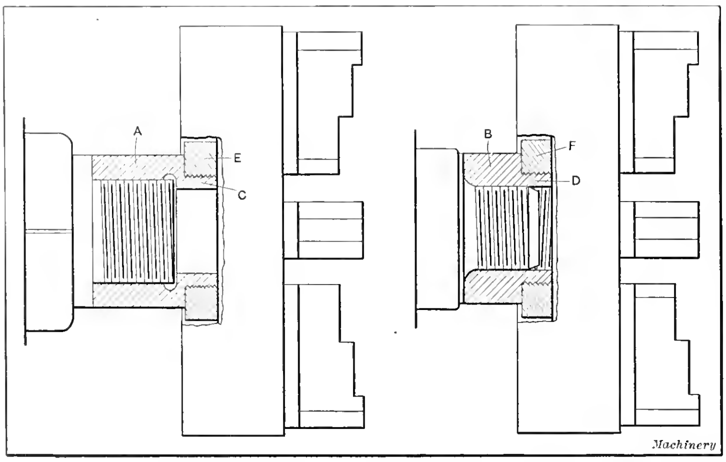

Fig. 1. Two Styles of Lathe Spindle with Standard Chuck mounted on them

To the ordinary motorist, familiar with the comparative simplicity and efficiency of the gasoline carbureter, these various devices for obtaining power from kerosene may seem somewhat complicated, but to the business man who will look deeper and see in them the real solution of the problem created by the constantly increasing cost of gasoline, they give evidence of the stability of the internal combustion engine and of its ability to adapt itself to whatever fuel may be used. These carbureters are in use today in all parts of the country, and if the owner of the pleasure car still prefers to pay the excessive price for gasoline, when a satisfactory substitute at half the cost is available, it may be but small consolation for him to know that the arrival of the time is inevitable when he will be forced to make the change. But whether the change will come soon or late, it is a satisfaction to the truck owner to know that one of the most important problems of his delivery and hauling system is being solved, and that the future of motor transportation is brighter than ever, even before that one universal fuel, gasoline, took its sudden upward leap in price.

INTERCHANGEABLE LATHE CHUCKS

BY GEORGE L. COLBURN*

Where threaded engine lathe spindles vary in pitch and diameter, it is evident that a chuck screw plate will not fit more than one of the spindles. This difficulty may be overcome by using intermediate screw bushings. Referring to Fig. 1, the bushings provided for this purpose are shown at *A* and *B*. The threaded ends *C* and *D* of these bushings are made of the standard pitch and diameter to fit the screw plates *E* and *F* of the chucks. Threads are cut on the inside of the opposite ends of the bushings to fit the different lathe spindles on which they are to be used. It will be evident that this is the means of enabling a standard chuck to be used on lathe spindles of various diameters and thread pitches, the only additional equipment necessary being bushings having the proper inside thread.

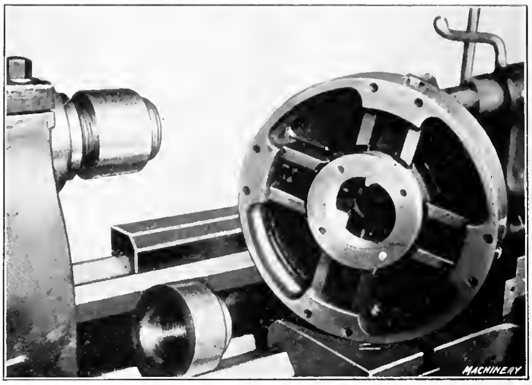

Fig. 2. Adapter Bushing partially screwed onto Spindle of Reed Lathe

Figs. 2 and 3 illustrate the screw plates fastened to the chucks by means of four screws. In Fig. 2 a screw bushing is partly screwed onto the spindle of a Reed engine lathe; a second screw bushing is shown resting on the bed of the lathe. In Fig. 3 is illustrated a screw bushing which is partly screwed onto the spindle of a Hendey engine lathe.

KEROSENE FOR STEEL HEATING FURNACES

ARRANGEMENT OF A WELL EQUIPPED HEAT-TREATING DEPARTMENT—COMPARATIVE VALUES OF FUEL OIL AND KEROSENE

BY HARRY C. SPILLMAN

During the last few months the price of fuel oil has steadily advanced and the oil refineries, in a number of states, have notified industrial plants that they will be unable to supply fuel oil after a certain date. At the present time it is almost impossible to enter into a contract with the refineries for a year's supply of this oil. This condition has caused many manufacturing plants to analyze the situation and try to find a substitute for fuel oil without installing new equipment in the heat-treating department.

The Continental Motor Mfg. Co., Detroit, Mich., has made numerous experiments with different kinds of oils and burners in order to be ready to meet the situation in case there is a shortage of fuel oil. Kerosene has proved most satisfactory after many experiments, and the data in this article show the results which have been obtained.

The furnaces show a very even temperature in all parts of the heating chamber, and a laboratory pyrometer fails to show over 10 degrees variation in any part of the heating chambers. Each furnace is equipped with both an indicating and a recording pyrometer (see Fig. 2) so that the operator can tell at a glance the temperature of each chamber. To facilitate the handling of material, the hearths of all furnaces, packing tables, trucks, quenching tanks and other equipment are made the same height from the floor. The door openings are made the full width of the heating chamber and are counterweighted.

The quenching tanks are of special design and are located in the center and opposite the furnaces so that they are readily accessible. Water, brine and oil are used for quenching, and by means of cooling tanks and circulating pumps the quenching mediums are kept at a constant temperature. The pumps deliver the liquid in the bottom of the tanks by means of perforated pipes which are protected by a wooden grating. This wooden grating also acts as a cushion for any parts which happen to fall in the tanks. The entire surface of the liquids is removed at a uniform rate by means of numerous outlets located near the top of the tank and connected with a common overflow pipe. The rate of flow can be governed by means of a valve fitted to the inlet pipe near the floor. The oil quenching tanks have a cover which can be closed very quickly in case the oil ignites. The quenching mediums are circulated through coils and are cooled by means of cooling water which is varied to suit conditions. The circulating pumps are direct motor-driven centrifugal pumps, located in the basement (see Fig. 3). The liquid is fed by gravity to these pumps, which does away with the troublesome feature of priming.

Fig. 1. Row of Furnaces and Quenching Tanks—Heat-treating Department of Continental Motor Mfg. Co.

The heat-treating room is of the most modern design and contains many unique features which are of interest. This department is housed in a fireproof building of structural steel and metal sash, and is entirely isolated from the other buildings. The steel sash has large ventilating sections and a monitor roof affords additional light and ventilation. All auxiliary apparatus, such as oil and circulating pumps, air compressor and storage and cooling tanks, is located in the basement, so that the entire first floor is given up to the furnaces and quenching tanks. A view of the first floor is shown in Fig. 1 which illustrates the general arrangement of the furnaces. These furnaces were made by the American Shop Equipment Co., and consist of four double-chamber casehardening furnaces of semi-muffle type, with heating spaces 54 by 27 inches and 18 inches high. The combustion chambers are 27 inches wide by 7½ inches high. The two burners in front of each chamber are supplied with oil at 18 pounds pressure and air at 1½ pound pressure. The three heat-treating furnaces are of the same make and size. The casehardening furnaces are built up from the floor and are of heavy construction in order to withstand the service required of them.

The oil is fed to the burners by direct-connected, motor-driven rotary pumps, in duplicate. The oil is pumped from a 12,000-gallon tank located outside the building, and the surplus oil is returned to the storage tank by means of a relief valve and overflow. This system allows a constant

*Address: 1537 Second Ave., Detroit, Mich.

pressure of oil at the burners at all times and the fuel oil is entirely drained back to the storage tank when the heat-treating room is not in operation. The elevation and plan, Fig. 5, show the storage tank and arrangement of the furnaces (oil and brine cooling coils, quenching tanks, etc.).

A General Electric turbo air compressor (Fig. 4) furnishes the necessary air for the burners at $1\frac{1}{2}$ pound pressure. The air lines were carefully laid out in order to reduce the friction to a minimum. The advantage of this type of air compressor is the constant pressure of air, regardless of the volume.

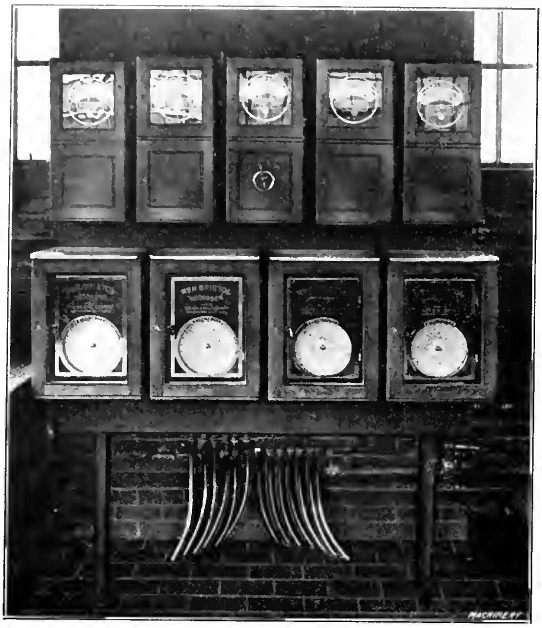

Fig. 2. Indicating and Recording Pyrometers of Plant shown in Fig 1

Tests were repeated for ten successive days on both kerosene and fuel oil. Both oils burned uniformly and needed very little attention after the proper regulation. One of the chambers of a double furnace was used for these tests, and in order to accurately measure the oil a tank of 60 gallons capacity was independently connected with one of the rotary pumps. The proper connections were made to maintain a constant pressure of oil, together with the necessary return piping for the overflow to the tank. A temperature record was obtained by means of smoke charts made on Bristol recording pyrometers. Both the indicating and recording pyrometers were carefully calibrated. The tests were made under actual working conditions and the same kind and quantity of material was heat-treated each day. The material placed in the chamber consisted of fifteen cam-shafts each weighing 21 pounds. Each cam-shaft was packed in a $3\frac{1}{2}$-inch steel pipe with the carbonizing material. The total weight of each tube, with shaft and container, was 55 pounds. All the tubes were placed on a form made of narrow strips of bar steel. This form held the steel pipes in position and made the total weight in each chamber 950 pounds.

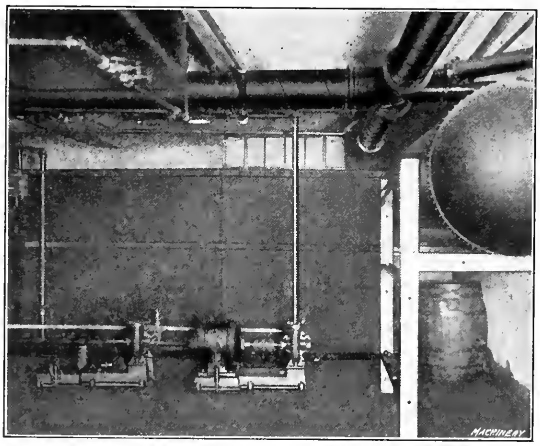

Fig. 3. Circulating Oil Pump in Basement of Plant shown in Fig. 1

This department is only operated ten hours each day. The material is taken out at 5 P. M. and the furnaces are allowed to cool over night. In the morning the furnace pyrometers register about 700 degrees F. At 6.30 A. M. the burners are lighted and the material is placed in the furnaces which are continued in operation until about 5 P. M. The furnaces reach 1700 degrees about 9 A. M., and they show a uniform heat throughout the working chamber about one hour later. The tests were made under these conditions. The furnaces would have shown higher efficiency if they were run continuously twenty-four hours every day.

The points noted in making these tests were: Time required for the furnace to reach 1700 degrees; time to obtain a uniform heat in the furnace; evenness of burning and regulation; and amount of oil consumed. The results of the tests follow:

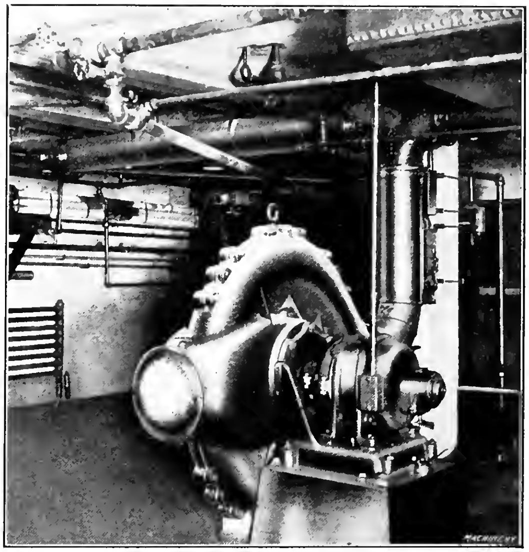

Fig. 4. Turbo Air Compressor for supplying Air to Burners

	Fuel Oil	Kerosene
Time tests started	6.30 A. M.	6.30 A. M.
Time required for chamber to reach 1700 degrees F	9.00 A. M. (2 hr. 30 min.)	8.45 A. M. (2 hr. 15 min.)
Time for chamber to reach uniform heat	10.15 A. M. (3 hr. 45 min.)	9.45 A. M. (3 hr. 15 min.)
Time test stopped	4.45 P. M.	4.15 P. M.
Fuel consumption required for chamber to reach 1700 degrees F	26.5 gal.	23 gal.
Additional gallons to reach uniform heats	3.5 gal.	3 gal.
Number gallons for operating furnace $6\frac{1}{2}$ hours after chamber reaches uniform heat	18 gal.	13 gal.
Number gallons per chamber, per hour after uniform heat is reached	2.77 gal.	2 gal.
Number gallons to heat-treat one pound of metal after uniform heat is reached	0.057 gal.	0.041 gal.
Specific gravity of fuel	41 deg. Baume	50 deg. Baume
B. T. U. per pound of fuel	19890	19917
Temperature of fuel	65 deg. F.	65 deg. F.

The comparative cost of fuel based on these tests shows that kerosene is from 23 to 25 per cent higher than fuel oil, but the tests also show that there is a saving of thirty minutes in order for the furnace to reach a uniform heat, and a saving of nearly 20 per cent in fuel, by using kerosene. Each burner has a $\frac{1}{2}$-inch oil line and a $1\frac{1}{2}$-inch air line and two burners are connected to each chamber. Power tests show that each burner requires 470 watts, which is equivalent to 0.63 horsepower.

* * *

Gradually the world is coming to the realization that even in the ordinary business affairs of life a man must consider the other fellow, and that he best serves himself who best serves his fellow-men.—*J. W. Pogue.*

THE TEST THAT COUNTS

BY WILLIAM A. WEBB*

It seems that steel makers have inexhaustible resources for bringing out new brands of high-speed steel which they claim to be better than the other fellow's. Although we continue to test out their samples, we sometimes find it difficult to tell just which one of the numerous brands is the best for our particular purpose. If we believe what the traveling salesmen tell us, however, the steel made by their respective companies is the best—but the method of testing has something to do with it.

I have listened to a great many interesting stories about how certain brands of steel have proved their wonderful superiority when tested on the glassy face of a worn car wheel, on a piece of chilled cast iron or on some other unusually hard metal that had been laid aside because the tools could not turn it. This method of testing might prove that high-speed steel is better than carbon steel, but when it comes to a show-down between different brands of high-speed steel, I believe this method would be wholly unsatisfactory, because the hardness of such metals is seldom uniform. The tool that gets the hardest part might stand up until it was just about to reach the softer metal and then give up, thus preparing the way for the next tool to make a good showing, although it might be of an inferior grade of steel. Then again, they tell about tests being made when the speed was shoved way up beyond all reasonable limits, and how one tool went two inches and another was unable to even start on the work. We have been guilty of such misdemeanors ourselves but after going through with a lot of such unsatisfactory testing, we came to the conclusion that the only way to get a fair comparison was to try the different steels out on regular work, where the stock was uniform, and let each tool show what it could do under everyday working conditions. This is the test that counts and gives the company the information it wants before buying steel in large quantities.

We have made it a practice of late years to take a selected number of sample tools, say half a dozen or whatever number it is desired to test, and grind them all to the same clearance and rake angles, and as near alike in every way as possible. These tools are put to work, one at a time, on regular stock where there is enough of it to allow each tool to make several trials. The speeds and feeds are arranged within reasonable limits and all the tools are set at exactly the same height in relation to the lathe centers (that is if a lathe is being used, which has been the case in most of our tests). A record is kept of how far each tool goes, and after they have all had six or eight trials apiece, we add up the totals and see how they compare. It appears to me that each tool should be given several trials before condemning or approving it, because in some cases it will make its best run the first time it is used after coming from the forge room, but more often the steel improves after the first or second grinding. Then again, a tool will make a freak run that looks incredible, but it will not do it every time, and after the test has been repeated several times the good tools will surely rise to the top. A test by this method can be repeated as often as desired without much extra expense to the company, as regular work is being turned out all the time. We never make expensive formed tools or milling cutters for other machines except from steel that has first been tested in the lathe and proved to be entirely satisfactory.

DISK AND SQUARE METHOD OF DETERMINING ANGULAR SETTINGS

BY GUY H GARDNER*

The method shown in Fig. 1 for determining angles for setting up work on a milling machine or planer possesses several advantages: No expensive tools are required, the method

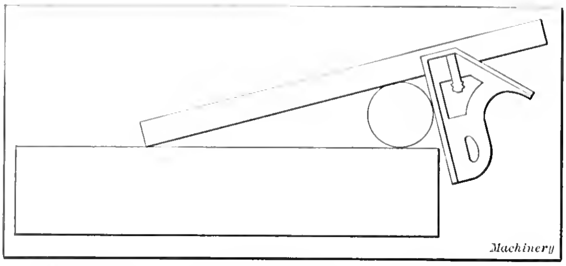

Fig. 1. Method of determining Angles by Use of a Disk and Square

can be quickly used, and the results obtained are quite accurate enough for any but the most exacting requirements. It will be seen from Fig. 1 that an ordinary combination square is used in connection with a disk, the head of the

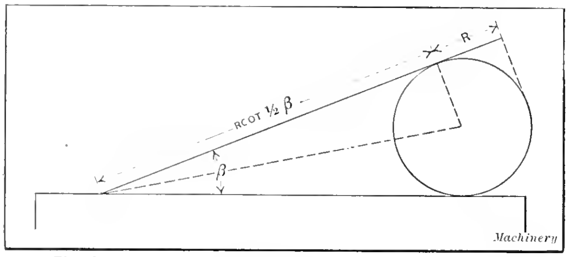

Fig. 2. Diagram illustrating Method of deriving Formula for setting of Square

square being set at different points on the blade according to the angle that is desired. Theoretically, a one-inch disk could be used for all angles from about 6 degrees up to a right angle, but in practice it is more convenient and accurate to employ larger disks for the larger angles. The table here given is calculated for three disks, 1, 2 and 4 inches in diameter.

When standard disks are not available, satisfactory substitutes can be made of machine steel, casehardened and ground. Satisfactory results can generally be obtained from disks which are left soft, although it is desirable to harden them when possible. It is a good plan to stamp on each disk, the diameter, the angles for which it is used and the points at which the head of the square is placed to obtain each angle.

The only inaccuracy resulting from this method is due to setting the square at the nearest "scale fraction" instead of at the exact point determined by calculation. This error is very small—less than two minutes in seventy-five of the angles in the table, and in five angles a trifle over three minutes—the error being negligible in practically all cases. When other than standard disks are used, the setting required for any desired angle can easily be found by multiplying one-half the diameter of the disk by the cotangent of one-half the desired angle, and adding to this product one-half the diameter of the disk. This rule is given in algebraic form by the following formula:

$R \cot \frac{1}{2}\beta + R =$ required setting.

The derivation of this formula will be readily understood by referring to Fig. 2. If, for example, it is desired to set the work at an angle of 31 degrees 10 minutes, the setting to be made with a 3-inch disk, we have:

$R = 1.5$ inches

Cot 15 degrees, 35 minutes = 3.5856

R cot 15 degrees, 35 minutes = 5.3784

Then the required setting is $5.3784 + 1.5 = 6.8784$. The nearest scale fraction is $6\frac{7}{8}$ inches; using this setting, the angle obtained is 31 degrees, 11 minutes and 8 seconds, the error of 1 minute and 8 seconds being negligible for most classes of work.

For angles less than 6 degrees, smaller disks or size plugs may be used, but the method illustrated in Fig. 3 will generally be found more convenient.

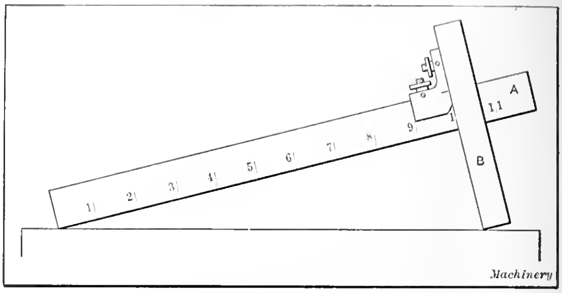

Fig. 3. Use of Small Scale in Place of Disk for determining Angles of less than Six Degrees

It will be seen that a small scale B is held on the blade of the combination square, set so that its edge coincides with the 10-inch mark and extends below A a distance equal to ten times the tangent of the required angle. The scale B is graduated to 0.01 inch to facilitate making accurate settings. If greater accuracy is required, the scale B may be graduated to fortieths of an inch and a vernier placed on the attachment which carries the scale. With such an arrangement this device may properly be classified as a precision tool.

* * *

The electric welding process is employed to some extent in the manufacture of taps. Orders for extra long shanks are filled by making the threaded part the same as for regular taps and then welding to it a shank of open-hearth steel. The practice is both economical and rapid. Orders for special taps can be quickly and cheaply filled. Welding shanks to regular taps saves turning down the long shanks.

SETTING UP AND OPERATING AUTOMATIC SCREW MACHINES—2*

APPLICATION TO THE "ACME" MULTIPLE-SPINDLE AUTOMATIC SCREW MACHINE

BY DOUGLAS T. HAMILTON†

In the previous installment of this article, which appeared in the May number of MACHINERY, a general idea was given of the method employed in setting up and operating the "Acme" multiple-spindle automatic screw machine, together with the "assumed" method used in calculating the product per hour. In this connection, it was mentioned that while the "assumed" method of determining the product per hour was quickly obtained it had the disadvantage of not being clearly understood by those who were not familiar with the construction and operation of this type of multiple-spindle automatic screw machine. Before going more fully into this subject, it might be advisable to give all the data necessary for laying out a new job on this machine. Following this, the formulas used for making the calculations will be given, and a practical example illustrating the various points taken up in the article will be presented in order to make this subject more clearly understood.

Working Relations of Side-working Tool-slides to Work-spindles

In laying out a job on the "Acme" multiple-spindle automatic screw machine, it is necessary to know the working relations of the tools on the side-working tool-slides to the end-working tools, in order to provide for tool clearance, etc. This information is especially necessary when special tools have to be designed to use in these various positions. In Table I are given the principal dimensions of the side- and top-working tool-slides and their relations to the work-spindles when in the extreme forward and backward positions, the latter dimensions being given as maximum and minimum in the table. It will also be noted that on the Nos. 515, 52, 55 and 56 machines two positions are given for the side-working tool-slides. The reason for this is that the cam levers and brackets on these sizes of machines are provided with two pivot holes, thus making it possible to increase the travel of the slides without changing the cams operating them. The capacities or diameters of stock which can be formed and cut off with the levers fulcrumed in the two positions were given in Table I of the January installment of the series "Acme Multiple Spindle Automatic Screw Machine."

Working Relations of End-working Tool-spindles to Work-spindles and Side-working Tool-slides

In connection with Table II is presented a diagram illustrating the relations of the end-working tools, side-working tool-slides and work-spindles, and in the table the principal dimensions noted on the illustration are tabulated. These data are necessary in order to determine the length of the shanks and bodies of the end-working tools and also their diameters. The extreme positions of the end-working tool-slide in relation to the face of the nose pieces enclosing the chucks are given by dimensions H and I, which are the minimum and maximum distances. The dimension C on the side-working slides is the distance from the inner edge of the tool slot to the face of the nose piece on the spindles when the center of the slide is directly over the center of the cam lever operating it. Of course this slide can be adjusted longitudinally on the machine, as was described in a previous article, in order to bring the cut-off and forming tools in the correct relation to each other and the work.

In laying out a job it is always advisable, whether standard or special tools are to be used, to determine whether there is sufficient clearance between the face of the tools and the ends of the work when the tool-slide is in its extreme backward position. This is necessary, of course, in order for

†Associate Editor of MACHINERY.

the cylinder to index. When designing special tools an endeavor should always be made to have the tool shank the full length of the hole in the tool-spindle. In order to decrease the liability to chatter and spring, it is preferable to have a tool with as long a body as possible, as this increases the rigidity of the tool considerably.

Another point to bear in mind is that the tools should be designed to correspond with the positions that they occupy on the work; that is to say, the box-tool which performs the second cut on a piece should extend out further than the first box-tool a distance equal to the advance made on the work by the first tool, and hence must be considerably longer. In laying out the job, therefore, it is essential that this particular point be borne in mind so that all tools in the main tool-slide will clear the work. This is particularly important, as on this machine the tools work from the end on different bars at the same time, and as these bars all project the same distance from the face of the chuck it is

evident that all tools must be so designed as to clear the work while the cylinder is being rotated. That is to say, the main tool-slide must be pulled back far enough to enable the longest tool to clear the work.

Calculating Speed of Work-spindles

The speed of the work-spindles obtainable by direct drive and through the back-gearing was given in the January, 1913, number of MACHINERY, but as it might be possible in some cases to secure more satisfactory speeds with gears having a different number of teeth than those given in the table, it may be advisable to carry through the calculations used in obtaining the proper gears to use for the required speeds. As was explained in a former article, the work-spindles are rotated from the main drive shaft through gearing. The gears on the main shaft drive the spindles through a friction gear that can be disconnected from the spindle when it is necessary to stop its rotation for performing operations such as threading, cross-drilling, milling, etc. As there are only two gears involved in this calculation, the method of obtaining the speeds of the spindle is simple and can be obtained from the following formula:

$$R = \frac{r \times N}{n}$$

in which:

R = R. P. M. of work-spindles;
r = R. P. M. of top or main drive shaft;
N = number of teeth in gear on top or main drive shaft;
n = number of teeth in friction gear.

For example, on the No. 54 machine $R = \frac{35 \times 480}{45} = 373$

T = Number of Teeth Gears P = Diametral Pitch in Inches

R. P. M., approximately. It might be mentioned here that in all future calculations particular reference will be made to the Nos. 54 and 55 machines, as these two sizes meet general commercial requirements. It might also be explained in regard to the tables that in all cases where the calculations for the gears do not work out to an even figure the nearest 5 or 0 is taken.

Calculating Speeds of Threading and "Second Position" Tool-spindles

A notable feature of the "Acme" multiple-spindle automatic screw machine is that, for threading, the work is stopped and the die is rotated, but in backing off the reverse is the case. In order to fulfill these requirements, it is necessary to gear up the threading-spindle to the main drive or top shaft. The diagram presented in connection with Table III shows the relation of the gears for rotating the threading-spindle and the spindle in the "second position." Two speeds for each speed of the top or main drive shaft are possible by shifting the gearing, one speed being obtained by driving direct through the sliding gear on the main drive shaft to the gear on the threading-spindle and the other by driving

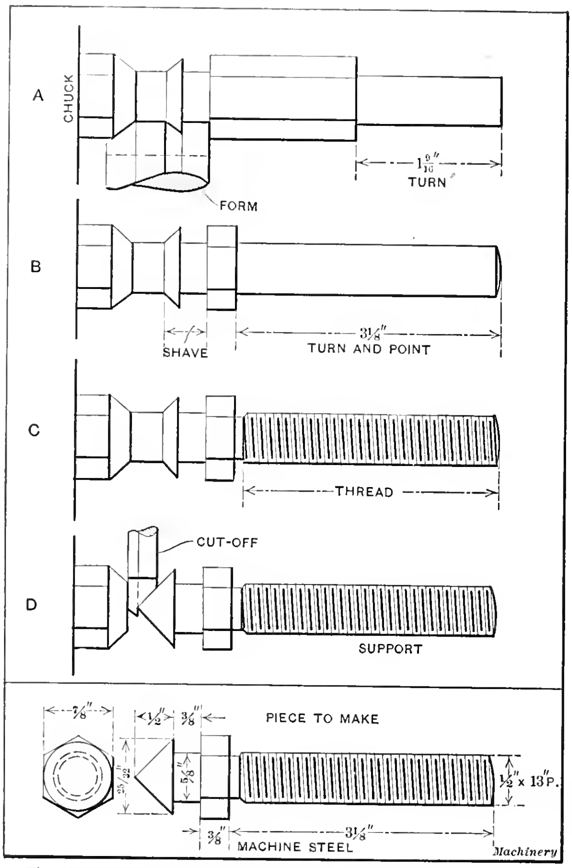

Fig. 11. Order of Operations followed in producing a Cone-headed Screw

through an intermediate and a compound gear. The following formula is used for obtaining the speed of the spindle when driven direct:

$$R_1 = \frac{r \times N_1}{t}$$

in which:

R_1 = R. P. M. of threading-spindle (direct drive);
r = R. P. M. of top or main drive shaft;
N_1 = number of teeth in sliding gear on top or main drive shaft;
t = number of teeth in gear on threading-spindle (also called direct gear).

As an example, assume that the speed of the top or main drive shaft is 480 R. P. M., then:

$$R_1 = \frac{480 \times 26}{55} = 227 \text{ R.P.M. approximately.}$$

(The numbers of teeth in these gears are listed in Table III.) The formula for obtaining the speed of the threading-spindle, when driven through the intermediate and compound gear, is as follows:

$$R_2 = \frac{r \times N_1 \times T}{n_1 \times t}$$

in which:

R_2 = R.P.M. of threading-spindle (gear driven);
r = R.P.M. of top or main drive shaft;

TABLE IV. TIME REQUIRED IN SECONDS TO PERFORM IDLE MOVEMENTS ON VARIOUS SIZES OF MACHINES

Number of Machine	Time in Seconds to complete Longest Single Operation	
	When Operation is performed from Main Tool or Form Slide	When Operation is performed from Cut-off Tool Slide
51	1.1	0.87
515	1.2	0.97
52	1.7	1.33
53	2.3	1.85
54	2.4	1.88
55	2.4	1.88
56	4.6	3.58

Machinery

N_1 = number of teeth in sliding gear on main drive shaft;
T = number of teeth in pinion gear;
n_1 = number of teeth in back-gear;
t = number of teeth in gear on threading-spindle (also called direct gear).

The "second position" tool-spindle which can be used for threading, if necessary, and which in many cases is used for driving small drills at their proper peripheral speeds, is also rotated from the top or main drive shaft through gears. The speed of this spindle can be obtained by the following formula:

$$R_3 = \frac{r \times N_1}{T_1}$$

in which:

R_3 = R.P.M. of "second position" tool-spindle;
r = R.P.M. of top or main drive shaft;
N_1 = number of teeth in sliding gear on main drive shaft;
T_1 = number of teeth in gear on "second position" tool-spindle.

For a practical example, assume that the speed of the main drive shaft is 480 R. P. M., then:

$$R_3 = \frac{480 \times 26}{36} = 346 \text{ R.P.M. approximately.}$$

Main Cam-shaft Computations

The main cam-shaft on the "Acme" automatic carries all the cams for operating the various slides, spindle stopping mechanism, etc., and also the fan gear for indexing the cylinder. As shown in Fig. 9, which is a developed plan view of the cam-shaft with the drums and cams on it, it will be seen that one revolution of this cam-shaft completes one cycle of the machine; that is, one revolution of the cam-shaft would mean the completion of one piece, or four revolutions the complete indexing of the cylinder. The rotation of the cam-shaft is not connected directly with the rotation of the work-spindles, but indirectly the cams on it govern the rate of travel of the tools on either the top- or side-working tool-slides, and also the end-working slide. It is therefore necessary to determine for each job the relation between the speed of the spindle and the speed of the cam-shaft in order to determine the production per hour, minutes or seconds.

The cam-shaft is driven from the main drive pulley through bevel gearing and a Johnson clutch. The clutch forms the connection between the direct drive and gear drive to the cam-shaft, so that it is possible to rotate the cam-shaft at a much higher speed for the idle movements than the speed at which it is operating when the tools are cutting. To obtain the speed of the cam-shaft in revolutions per minute, when

driven direct, we can use the first figures given in the first column of Table VI (see January number), as these will give the number of revolutions the cam-shaft makes in one hour. Dividing this speed—585—by 60, we find that the cam-shaft on the Nos. 54 and 55 machines makes 9.75 R.P.M. or 0.1625 revolution per second. As there are 360 degrees in a circle and as any point on the cam drum makes 0.1625 revolution per second, the number of degrees passed through in this time equals $0.1625 \times 360 = 58.5$ degrees, approximately. Now, if it takes one second for the cam-shaft to rotate through a space of 58.5 degrees, we can easily find the time required to complete the idle movements, when the number of degrees taken up by the idle or non-productive movements are obtained. By referring to Fig. 10, in which the various drums and cams have been laid out in their respective positions and at the point in their rotation at which the machine is indexing, we can see at a glance that the non-productive movements come in between the time that the lead cam A starts to operate and finishes. This applies when the longest single operation is performed by the end-working tools or from the forming slide. Where the longest operation is performed from the cutting-off slide, the idle time is less because there are 30 more degrees taken up on productive work. It is safe to

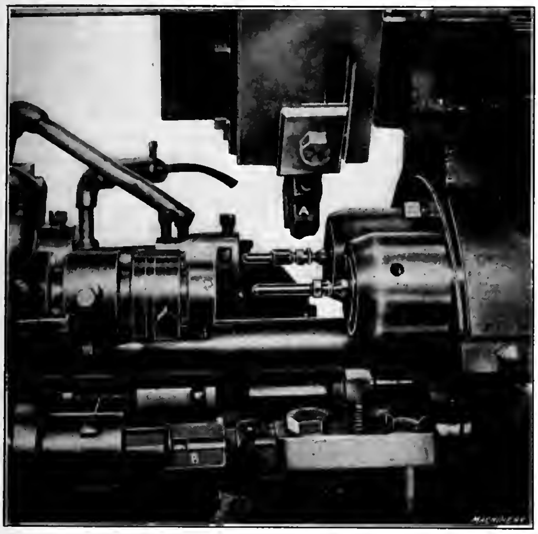

Fig. 12. The "Set-up" used for producing the Cone-headed Screw shown in Fig. 11

assume that on 75 per cent of the jobs set up on this machine the longest operation is performed from the end-working tool-slide; hence, we can base our calculations on the number of degrees of drum surface between the starting and finishing points of the cam. This we find is $360 - 220 = 140$ degrees. When the longest single operation is performed from the cut-off tool-slide, the idle movements occupy 110 degrees of the drum circumference.

Calculating the Time required for Idle Movements of Machine

The idle movements of the machine consist in advancing and withdrawing the tools to and from the work and indexing the cylinder. The stock is fed out and the chuck closed while the cylinder is indexing on the smaller machines and in the "first position" on the larger machines, but in all cases, as can be seen from a study of Fig. 10, the idle movements for which we have made provision more than compensate for the time required to feed out the stock. We therefore have three main idle or non-productive movements of the machine to take into consideration in calculating the actual time required. Upon referring to Fig. 10, we find that these movements are all confined to the space between B and C on the circumference of the cam drum. As all the non-productive movements are accomplished while the cam-shaft is being driven at its highest speed—direct through the Johnson clutch, and not through the chain gearing—it is necessary to find out what part of the cam circumference these movements occupy and also the speed at which the drum is being rotated when driven direct. We have just found that the idle movements or the space on the cam circumference from B to C equals 140 degrees, and that on the Nos. 54 and 55 machines the cam-shaft, when driven direct, is rotated at a speed of 0.1625 revolution per second. Then, if it takes one second for the cam-shaft to rotate through a space of 58.5 degrees, it will require $140 \div 58.5$ or 2.4 seconds approximately for the idle movements. This if added to the time required for the longest single operation will give the actual time required to complete one piece.

Example

In order to carry through the calculations which have just been given and to put them in such a form that they can be used in practice, it might be advisable to give an example. We will assume that it is necessary to make the cone-headed screw shown in Fig. 11, the tool "set-up" for which is shown in Fig. 12. The first point in the calculation is to determine the speed at which the spindle should be rotated for turning the material from which the screw is made, and also the longest single operation. This, of course, is the turning of the body. As a general rule, cold-rolled steel can be worked at a surface speed of from 90 to 120 feet per minute and the nearest speed on the No. 54 machine that we can use is 375 R. P. M. The distance that the first box-tool has to travel on the work is $1.562 + 0.038$ or 1.600 inch; then using a feed of 0.004 inch per revolution, we find that it requires 400 revolutions of the spindle to complete the first cut on the body of the screw. This is equivalent in time to 64 seconds.

Now, to obtain the time required for the idle movements, we calculate the time required for the cam-shaft to pass through 140 degrees, as was previously explained, and add the result to the time required for the longest single operation to obtain the time to make one piece. We found the time for the idle movements to be 2.4 seconds, so the total time required to complete one piece is $64 + 2.4$ or 66.4 seconds. Now to convert the time required to make one piece into production per hour, it is necessary to divide 3600 by 66.4, which gives a product of 54 pieces per hour. By referring to Table VI which appeared in the January number of MACHINERY, we find that the nearest product to the result of our calculations is 50 pieces per hour. As it is impossible to obtain a gear ratio to give the calculated product, it is necessary to do one of two things. First, if the box-tool performing the longest operation will stand a greater feed, we can raise the production up to 58.5 pieces per hour; if not, it will be necessary to drop down to 50 pieces per hour, and in so doing reduce the feed on the tools.

When the time required for the idle movements has once been calculated it is not necessary to go through this calculation again except in cases where special fixtures or tools are used that would necessarily require more than the usual clearance space, or where the lead cam is cut up to divide cuts, etc. As this is very infrequently the case, the actual time in seconds utilized in the performance of the idle movements is given in Table IV for the various sizes of machines.

As the various steps followed in setting up a job similar to the one illustrated in Fig. 12 on the "Acme" were described in the previous installment it will not be necessary to go into this subject here. This particular job differs only in two respects from the one previously referred to. Part of the head is finished by a shaving tool A and the work when being cut off is steadied by a support B to secure a good job. This support prevents the thrust of the cut-off tool from breaking the piece off before the cone-head has been completely formed with the cut-off tool.

Calculating Speed of Main Cam-shaft

The following formulas are used for calculating the speed of the cam-shaft when driven direct and when driven through the change gears. For direct speed:

$$R_4 = \frac{r_3 \times N_2}{n_2 \times W}$$

in which:

R_4 = R. P. M. of main cam-shaft;

r_3 = R. P. M. of clutch shaft;

N_2 = number of teeth in sprocket on clutch shaft;

n_2 = number of teeth in worm-gear sprocket;

W = number of teeth in worm-wheel on the cam-shaft.

For an example on the No. 54 machine, where the clutch shaft is rotated at 493 R.P.M., the result is as follows:

$$R_4 = \frac{493 \times 24}{16 \times 76} = 9.73 \text{ R.P.M.}$$

The formula for calculating the speed of the cam-shaft when driven through the change gearing is as follows:

$$R_5 = \frac{r_3 \times A \times D \times N_2}{C \times B \times n_2 \times W}$$

in which:

R_5 = R.P.M. of main drive shaft (gear driven);
r_3 = R.P.M. of clutch shaft;
B = first gear on clutch shaft (driven);
C = second gear on stud (driven);
N_2 = number of teeth in clutch shaft sprocket;
A = number of teeth in second gear on clutch shaft (driver);
D = number of teeth in first gear on stud (driver);
n_2 = number of teeth in worm-gear sprocket;
W = number of teeth in worm-wheel on cam-shaft.

With the aid of these formulas it is possible to calculate the production per minute or hour given in Tables II to VII in the January number of MACHINERY.

A FEW QUESTIONS ABOUT RING-OILING BEARINGS

BY A. DE SIGNER

One of the subjects about which there seems to be little reliable information in the way of results of actual tests, is concerning the ring-oiling bearing. Here are a few of the questions which arise in designing these bearings to suit certain conditions. What are the limits of speed at which it is safe to use this method of lubrication? It seems that there must be a high limit at which the oil would be thrown off the ring by centrifugal force before getting high enough to be deposited on the journal, or else the retarding effect of the oil in the reservoir into which the ring dips may slow it down so much, relative to the speed of the shaft, that it will not deliver enough oil to properly lubricate the journal. Then there must be a low limit at which the oil would run down the ring faster than the ring moves, and consequently too little oil would be delivered to the journal. It would not require very many experiments to arrive pretty accurately at these limiting speeds and the information might be very useful to the designer.

What is the best shape for the ring? I have seen rings of square and rectangular section, triangular section, half-round section and an inverted T-section made of two angles riveted together with the adjacent legs standing out from the journal. This last section is used by one of the largest engineering concerns in the country, yet I have known it to fail completely to deliver the necessary supply of oil. We replaced it by the rectangular section and had no further trouble. The triangular section was used on the outboard bearing of a direct-connected engine-generator running at moderate speed, which gave trouble by running hot from the very start. We replaced it by a ring of half-round section with very good results, the bearing running cool from that time on, with other conditions unchanged.

What is the best material for the rings? I have seen them made of cast iron, wrought iron and bronze, with apparently equal success. The cheapest rings I ever saw were made of half-round wrought iron in the rough, the only machine work being the joining of the halves and they were apparently very satisfactory. They were used on bearings from 2½ inches to 22½ inches diameter, with equally good results. My own opinion is that these were not only the cheapest but the best as well, because they could not be broken under ordinary running conditions, while I have seen broken rings of bronze. If made of good wrought iron, there is less danger of hard spots, which might cut the shaft, than there is with either bronze or cast iron. However, I don't think this a serious consideration, for there is little danger of any of them cutting a shaft. One of the very best rings I have seen was of rectangular section with the outer corners chamfered and was made of bronze. This ring was knurled on the inside, giving it the maximum driving power.

How many rings are needed for a given length of bearing? How far is it safe to figure on spreading the oil each side of the ring? To what extent does the diameter of the journal affect this point? It seems as if the area to be lubricated must have a considerable influence, and yet I cannot believe that the same area could be lubricated on a 2½-inch journal as on one 22½ inches in diameter. Of course, proper grooving must have a good deal to do with it, too.

What is the best grade of oil to use in a ring-oiling bearing? An oil that is too stiff might retard the ring to such an extent as to interfere with lubrication, while one that was too light might not be carried to the top of the journal and might be of insufficient body for lubrication. Where are these limits to be set? Other questions might be: the best depth to which the ring should be immersed in the oil; whether the diameter of ring (within reasonable limits) has any effect on its ability to deliver the oil; how much the ring swings to one side at different speeds. It is customary to allow rather a limited clearance for the ring in order to keep down the size of the bearing casing, but it is conceivable that the ring might rub against one side of the casing to such an extent as to interfere with its proper operation.

Another question which confronts the designer is: How large an oil reservoir is needed? In some bearings which I have seen, the object sought, apparently, has been to keep this down to a minimum, giving the bottom a cylindrical shape to conform with the shape of the ring, while others are made rectangular and have a capacity for a considerable quantity of oil. To my mind the latter is the right idea, since the oil will keep cooler and the flat bottom of the box allows quite a space for the collection of sediment before it will pile up sufficiently to retard the ring.

A little point which I have known to be overlooked is to provide a passage for the oil to flow from one end of the bearing to the other in the oil reservoir. With the ball and socket type this is not always easy, but I know from personal experience that it is advisable, having neglected it in some of my first designs, and had to connect the two reservoirs by a pipe afterward in order to prevent all the oil being carried to one end. Just why this action should take place, I do not see, but it certainly did.

It seems to me that most of the above questions might be systematically investigated to the advantage of the multitude of designers who are continually being called on to get out bearings for various duties. Why could not some of our colleges take this up and make systematic tests of different kinds of rings at different speeds and with different grades of oil? This is an investigation which would not require an expensive equipment and might furnish some very valuable data, and I commend it to the readers of MACHINERY in the hope that some of them may take it up. If such tests have already been made, I should be glad to see the results printed in these columns.

* * *

The New Britain Machine Co.'s plant in New Britain, Conn., built a year or two ago, is a four-story and basement building. The high price of land in New Britain made the factory type of building imperative. Plunger elevators are provided to serve the floors and an automatic system keeps the water pressure constant. The water is used over and over again, thus avoiding water waste and unnecessary expense. Employes use the elevators freely when going from floor to floor. Before the building of the new plant, they were not allowed to use the elevators because of the cost of power, attendance, etc. When making the plans, the management decided "that power generated in the power plant from coal is cheaper than that made from mince pie," and provided liberally for the substitution of mechanical power for human effort when travel vertically was necessary.

SOME MANUFACTURING KINKS USED ON CONTRACT WORK

WAYS AND MEANS USED IN MACHINING ADDING MACHINE PARTS AT W. H. NICHOLS CO.'S SHOP, WALTHAM, MASS.

BY CHESTER L. LUCAS*

In shops where contract work is done it is highly important that effective methods be used, thereby keeping the manufacturing costs down and leaving a margin of profit. The ways and means which must be devised for each job vary with the character of the work and the number of pieces required; therefore a great deal of ingenuity is required to get out tools which will produce the work without great expense or delay for initial equipment.

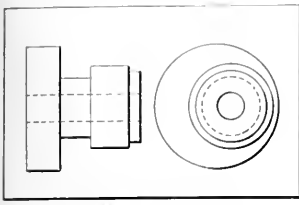

Fig. 1. An Eccentric Cam for Adding Machine Use

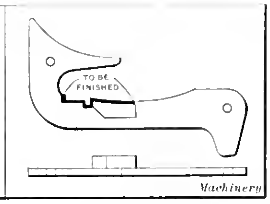

Fig. 2. Lever with Awkward Section to finish

Oftentimes, the methods which must be used for producing the parts may not appear to be quite mechanical, but considering the small number of pieces which are required and the limited expense for tools permissible, the unmechanical way is often the more practical. An example of this point is well illustrated in the turning of the eccentric cam that is reproduced in Fig. 1. This is a steel part for an adding machine, and its greatest diameter is 1¼ inch. The length is 1⅛ inch. A ¼-inch hole passes through the piece, being located 3/16 inch off center, and with the exception of the eccentric part, the rest of the piece is concentric with this hole. As the shop equipment did not include a large turret lathe at that time, it was quite a problem to produce these pieces without installing an expensive turret lathe that would handle 2-inch bar stock. The method finally adopted was to use 1¼-inch cold-rolled bar steel, which was first cut to lengths of 2¼ inches. A round block of steel was then threaded to the spindle of an ordinary 14-inch lathe, and in the working end an eccentric hole was bored to a diameter of 1¼ inch and a depth of 1 inch, the eccentricity agreeing with that of the piece to be turned. The 2¼-inch length of steel was then inserted in this improvised chuck and held by hollow set-screws. On the cross-slide of the lathe a forming tool was fitted that was shaped to turn down the entire width of the piece as shown in Fig. 4. Where the cross-slide was run in, this tool turned the stock down to the required size, leaving the original surface of the bar to form the eccentric part. By means of a drill in the tailstock, the central hole was drilled, and a cutting-off tool mounted on the cross-slide at the rear side of the work was set at the proper distance from the end of the piece to cut it off to the exact length when the cross-slide was withdrawn. Of course this method of doing the job resulted in a piece of stock one inch long being wasted for each piece made, but these ends were available for other work. In view of the number of pieces to be made, however, and the equipment at hand, it proved to be satisfactory.

Another little kink in turning which has helped in producing duplicate work is illustrated in Fig. 3. Many of the adding machine parts are roughed out on small screw machines and must be re-turned in bench lathes, usually being held on an arbor for the operation. In Fig. 3 is shown the method of locating the work in the lathe so that each piece will be gaged from the same point. The piece shown at *A* is held on an arbor *B* which, in turn, is held in the usual manner in the spring collet *C*. Before inserting the arbor in the collet a thin walled bushing *D* is introduced, which bears against the spindle of the lathe on one end and against the reverse side of a shoulder of the work at the other end. When the drawing-in bar of the lathe is tightened, it pulls the work firmly back against bushing *D*. As the turning tool has been set to perform the machining at an exact distance from the end of the bushing, the cuts must all be gaged from the face of the shoulder—that is, against the bushing. While comparatively unimportant, this is a good method to employ on bench lathe work of this kind.

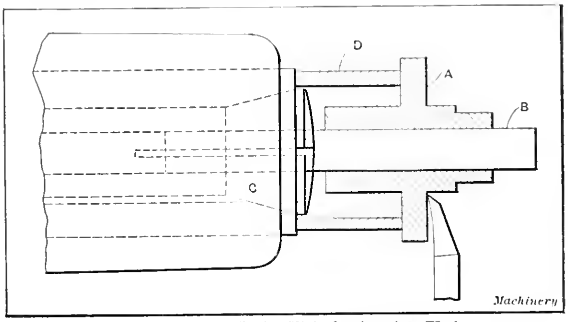

Fig. 3. A Bench Lathe Kink for locating Work

Fig. 4. Turning the Eccentric Cam in a 14-inch Lathe

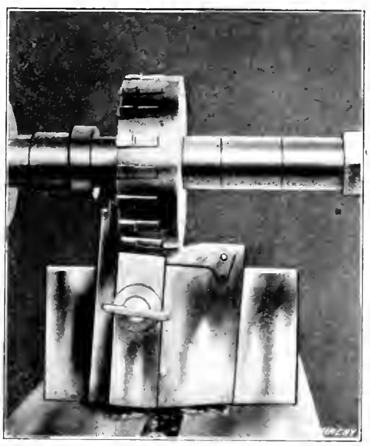

Fig. 5. Milling the Internal Section of a Computing Machine Lever

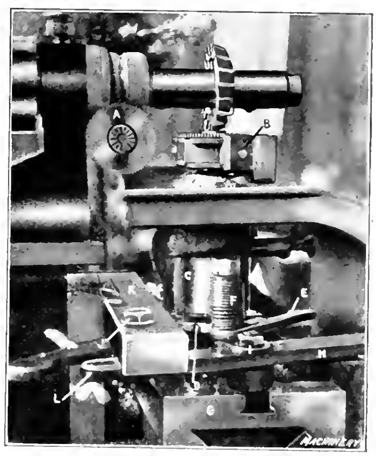

Fig. 6. Milling Ratchet Teeth on a Gear Blank

A puzzling proposition was presented in the machining of a steel computing machine lever. The surface to be finished is indicated by the heavy line on the work shown in Fig. 2. This piece is a hook-shaped punching upon which has been riveted a small block. After riveting, it is necessary to mill

* Associate Editor of MACHINERY.

the section indicated true with the two holes in the punching. Of course the natural way to do the job would be to mill it, but trouble arises because of the shape of the punching which extends back over the surface to be milled. Broaching would do the work satisfactorily, but would be a little slow and would require expensive equipment. As is the case in most of these contract jobs, the number of pieces

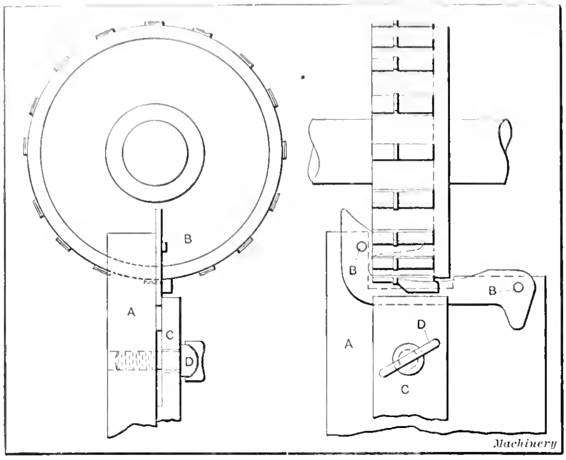

Fig. 7. Details of the Milling Fixture used in finishing the Computing Machine Lever

required was limited and it was doubtful if repeat orders would be called for; therefore it was necessary to devise a method requiring as inexpensive tools as possible. The method adopted involved the making of a special cutter which was recessed to clear the hook-shaped projection. The illustration Fig. 5 gives a general idea of the operation, and Fig. 7 shows the cutter and the method of holding the pieces. Obviously the pieces must be milled one at a time, because the interference of the cutter prevents a long table stroke.

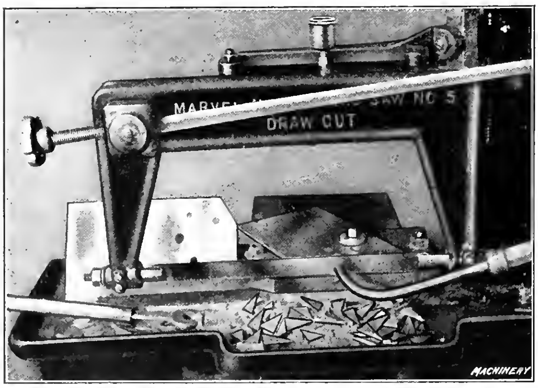

Fig. 8. Sawing the Corners from Steel Plates

The pieces are located on fixture *A* by means of two pins *B*, and are supported by clamp *C*, operated by thumbscrew *D*. The cutter is held upon an arbor in the usual manner. The work is hooked inside the cutter, set on the pins and clamped in place, and the milling cut started. The travel of the table is less than three-quarters of an inch, but it is enough to allow the surface to be milled properly. The piece is then removed and another blank inserted. It will be readily appreciated that the cost of tooling up for this job was not great, and the work produced was highly satisfactory.

Milling the ratchet teeth on the face of a gear blank, as shown at *A* in Fig. 6, is another machining operation that is handled very rapidly in this shop. The gears, as well as parts of adding machines, are turned with a raised panel around the central hole, and upon this panel ratchet teeth must be milled. The gears are located by means of three toothed blocks *B* which engage the teeth and hold the gear centrally upon the arbor *C*.

At the lower end of this arbor is an index-plate *D*, having equidistantly spaced notches; in this case there are fourteen. A pawl *E* engages this index-plate, and is mounted upon stud *F*, being kept constantly in contact with the index-plate by means of a spiral spring. The usual table feed mechanism is dispensed with and the table, which is indicated at *G*, is reciprocated by means of hand lever *H*, fulcrumed at bolt *I* attached to the T-slot of the table. The short end of the lever is slidably mounted on bolt *J* which passes through arm *K*, the latter being bolted to the frame of the machine. Also mounted on arm *K* is the indexing finger *L*, that, when brought into contact with the ratchet plate at each return stroke of the table, causes the arbor to turn one notch. The arbor is held stationary for the milling operation by pawl *E*. The milling of these ratchet teeth is performed as quickly as the operator can manipulate the lever, and after going once around the work a second cut is taken even more rapidly than the first, to remove any burrs and clean up the teeth.

Some excellent work is done on the "Marvel" draw-cut hacksaw and one of the sawing operations is shown in Fig. 8. This consists in sawing off the corners of steel plates 1/8 inch

Fig. 9. A Kink for holding Small Punchings on the Magnetic Chuck

thick, one of which is shown bolted onto a fixture on the farther side of the saw blade. Of course these corners could be clipped, but as one of the requisites is that the plate be perfectly straight and true when finished, sawing is considered the safer method of accomplishing this operation. The gear blanks, upon which the previously described ratchet cutting operation is performed, are cut from the bar on this

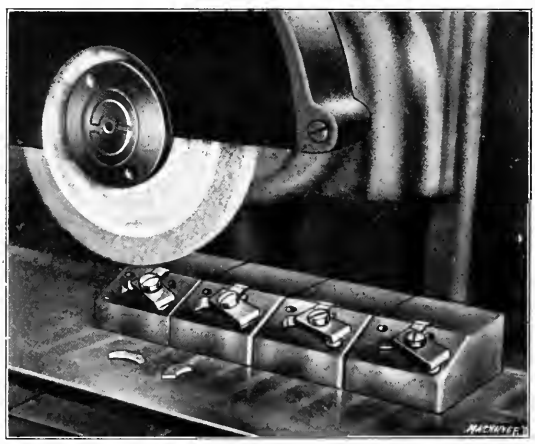

Fig. 10. Holding Small Punchings for a Bevel Grinding Operation

machine. A feature of its operation is that it automatically feeds the bar up after each cut and starts again, requiring no attention from the operator until the entire bar has been cut. The speed with which it works is extraordinary; on the gear blanks previously mentioned, which are 2 1/4 inches in diameter, the pieces drop from the saw every four minutes.

There are numerous surface grinding operations connected with the production of these adding machine parts, and Figs. 9 and 10 show two which are representative. In Fig. 9 a method of holding small irregular pieces on the magnetic chuck is worthy of note. These pieces are punchings made from 1/8-inch steel. They are held upon the magnetic chuck in strips which have punched holes of the same shape as the blanks. These strips are made from thinner stock than the steel punchings and the same blanking die is used. Afterward the openings are relieved by filing and allowing the blanks to fit in loosely. This is a very effective way of holding these parts, and has the advantage of being quickly provided.

Fig. 10 shows a grinding operation on the ends of the same pieces. These are beveled on each end at an angle of thirty degrees and the grinding is done after the pieces are clamped onto the inclined blocks shown on the chuck in the illustration. The pieces are located on pins and each is clamped in place by a single screw. Two finished parts may be seen lying in front of the blocks on the chuck.

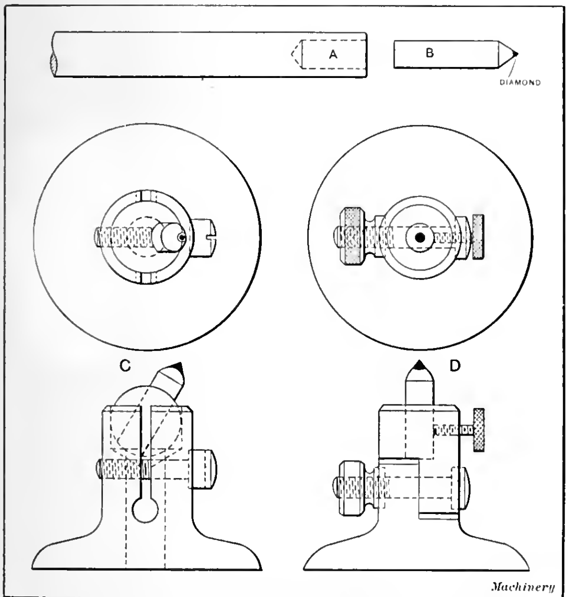
MOUNTING AND SETTING DIAMONDS

BY W. C. BETZ*

I have worked in a number of shops where a great deal of fine grinding was done, necessitating the use of diamonds for truing the wheels. C. L. L.'s article on the subject in the July issue of MACHINERY gave one good method of setting diamonds, but the writer would like to add the result of his experience in this work for the benefit of MACHINERY'S readers.

To reset a dull stone, the first step is to remove it from the holder which is drilled and reamed (as shown at *A* in the



Method of setting Diamond and Two Methods of mounting

accompanying illustration) to the proper size to receive a piece of copper rod *B* in which the diamond is set. The diamond is then gaged through an ordinary twist drill gage, the stone being passed through a hole in which it just clears at the point where it is mounted in the holder. If a new diamond is used the holder is drilled as previously described; the copper rod in which the diamond is mounted is then chucked in a lathe and drilled to receive the diamond, the drill being of the size determined by gaging the diamond in a drill gage. The hole is drilled to a depth of 1 1/4 times the length of the stone, after which the copper rod is thoroughly annealed.

A small asbestos pad is next prepared from fiber secured from a piece of sheet asbestos, this fiber being moistened with saliva to enable it to be worked up into a small ball. This ball is made of such size that it half fills the hole in the copper rod when pushed down into place. The diamond is now put in position in the copper rod, after which the metal is upset around the edge with a light hammer in order to prevent the stone from coming out while the next operation is being performed. While this work is being done the copper rod is held in a three-jaw lathe or miller chuck held in a bench vise. After the metal has been upset around the diamond, the copper rod is removed from the chuck and the metal worked in close against the diamond with a light hammer. Some of the asbestos will be forced out of the end of the hole as the hammering progresses and care must be exercised not to strike heavy enough blows to risk crushing the diamond. The copper rod is then replaced in the chuck to enable the metal to be worked down close around the diamond with a hammer and a carpenter's nail-set ground off square at the end.

Now for a brief discussion of methods of mounting. An improved mounting for truing the wheel of a surface grinder while in the regular position is shown at *C*. This mounting consists of an ordinary commercial steel ball 3/4 inch in diameter which is annealed to enable a 5/16-inch hole to be drilled and reamed through it. The stone is set in a copper rod 5/16 inch in diameter by 1 inch in length, the rod being a light driving fit in the hole in the ball. The base of the fixture is made either of cast iron or machine steel and it will be evident that the diamond can be brought into practically any position that is required by rotating the ball and then clamping it in place by means of the binding screw in the base. In this way the stone can be rotated from one position to another so that it is possible to bring a fresh edge into contact with the wheel as the diamond becomes dull. The form of holder shown at *D* possesses the same features which have been described for the preceding type of holder. In this case, the position of the diamond is changed by swinging the upper half of the holder about the pivot which secures it to the base. The diamond can also be rotated by loosening the small binding screw and then turning the copper rod in which the stone is mounted.

STROBOSCOPIC ACTION OF MOVING PICTURE MACHINES

A curious action of the wheels of rapidly moving vehicles is often noticed in moving pictures of street scenes. The wheels are apparently standing still or moving slowly forward or backward. The reason for this strange appearance of wheels that are actually revolving rapidly forward is coincidence or near coincidence of spoke position and shutter action. Suppose that a carriage wheel has sixteen spokes and that it is revolving at the rate of sixty turns a minute or once every second. The average speed of moving picture film exposure is sixteen pictures a second. Under such conditions the spokes apparently will be photographed in exactly the same position at every opening of the shutter, and when projected on the screen the wheel will appear to be standing still although moving ahead with the carriage. If the rate of rotation is slightly out of step with the shutter action the spokes will then be photographed in slightly different positions, and the wheel will appear to rotate slowly ahead or backward, depending on whether the shutter action is slower or faster than the change of spoke position. The action is essentially the same as that of the stroboscope, a well-known scientific apparatus used to study the action of rapidly moving mechanism, engine governors, etc.

YEARLY INDEX OF MACHINERY

The yearly index of MACHINERY is ready for distribution, and copies will be sent to any address on request. Subscribers saving their copies are urged to bind them with the yearly index and thus preserve the volume so that its contents can be readily referred to.

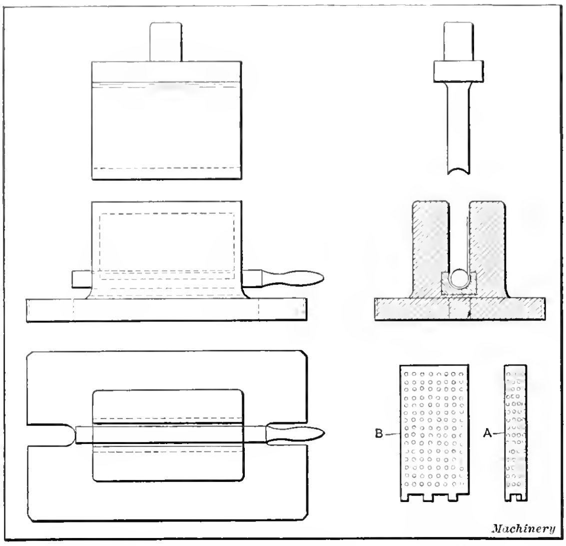
LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY.

ROLLING TUBING FROM SHEET METAL

The accompanying illustration shows the tools used for rolling the perforated tubing *A*, the blank from which the tubing is rolled being illustrated at *B*. The design and method of using these tools will need little description to make the operation clear to the reader. The die was made with a tool-steel bottom inserted in a cast-iron frame to reduce its cost. The punch and die were finished to approximately the desired form, after which they were fitted together and the hole reamed to the required size of the tubing.

In operating the tool, the mandrel is placed in the die and a blank put in the position shown in the cross-sectional view. When the press is tripped, the punch descends and forces the blank down in such a way that it is rolled around the mandrel. When the ram has reached the bottom of its stroke, the pressure applied sets the joint so that the tube retains the desired form.



Tools used for making Tubing out of Sheet Metal—Blank and Finished Tube

Meriden, Conn. JAMES GALLIMORE

WHY UPPER FORGING DIES FILL BETTER THAN LOWER ONES

The question was asked in the April number of MACHINERY "Why are the impressions for bosses on drop-forgings preferably put in the upper die?" The reason suggested in the answer that inertia of the metal is more active in filling the upper die than in filling the lower die is not, in my opinion, correct. The reason the upper die fills with metal more easily and quickly than the lower die is that when the forging blank or bar is laid on or placed in the lower impression the lower die immediately begins to withdraw the heat from the piece to be forged. Consequently, the metal on the lower side of the forging is several degrees cooler than that on the upper part and at every stroke of the hammer the forging fits closer to the shape of the die, cooling with every stroke, thus retarding the downward flow of the metal. On the other hand, the metal on top is always hottest as the die, coming down and instantly rising again, leaves the metal about as hot as before it was struck. Thus the metal obeys one of the great laws of nature—it "follows the line of least resistance" and shoots up and fills the upper impressions easily. This has been our experience in the Union Forging Co.

C. F. BRAINERD,
Union, N. Y. Supt. Union Forging Co.

[The cooling effect of the lower die undoubtedly retards the filling of deep impressions. This is proved by the fact that if the piece being forged is lifted from the lower die after each stroke, the lower die will fill more rapidly and effectively than if it is allowed to remain closely in contact with the die. This is well understood by drop-forgers generally. Another very practical reason for placing deep impressions in the upper dies when possible is that it eliminates trouble from scale. Deep impressions in lower dies are very troublesome because of the scale collecting in them. If the scale is not swept out it quickly ruins the dies, causing them to crack, and produces a rough finish on the forging.—EDITOR.]

ETCHING RESIST AND SOLUTION

The following gives a formula which has been successfully used by the writer for etching operations:

The ground or "resist" is compounded as follows: Melt 2 ounces of white wax and add to it 1 ounce of gum mastic in powder, the gum mastic being added a little at a time and stirred thoroughly so that a uniform mixture is obtained. Then add 1 ounce of bitumen powder in the same way. This mixture is dissolved in chloroform or oil of lavender, when it is ready for use.

The formula for the biting solution is as follows:

Hydrochloric acid	100 grams
Chlorate of Potash	20 grams
Water	880 grams

In compounding the biting solution the water is heated, after which the chlorate of potash is added. After the chlorate of potash is entirely dissolved the hydrochloric acid is added to the solution. H. N. HAMMOND

Erie, Pa.

METHOD OF ETCHING BRASS

In the "How and Why" department of the August number of MACHINERY, I note that M. R. states that he has experienced trouble in etching brass and asks for information regarding a satisfactory method. If M. R. will follow the instructions given below, I think he will find the result entirely satisfactory.

The first step in etching is to see that the parts that are to be etched are carefully ground and polished. The only cleaning which will be found necessary can be satisfactorily done by wiping the work with a dry rag. The next step is to heat the work and then dip it into molten paraffine, after which it is removed and allowed to stand until cool. The pattern which is to be etched is marked in the paraffine in order to expose the metal.

The etching is done with undiluted nitric acid. If the etched lines are to be very deep, the work should be immersed in lukewarm water occasionally to remove the copper nitrate which forms in the etched lines. This will prevent the lines from spreading. It is only necessary to leave the work under water for a few seconds in order to remove the copper nitrate.

The preceding instructions also apply to etching steel with the important exception that the etching solution is composed of one part of nitric acid and one part of hydrochloric acid. The paraffine may be removed from the work by first dipping it in boiling water and then in cold water; this treatment causes the paraffine to contract and peel off.

East Orange, N. J. GEORGE GARRISON

ETCHING STEEL AND BRASS

In response to the request in the August number of MACHINERY for reliable methods of etching brass, I will describe my method of etching which has been successfully employed on all kinds of machinist's tools, also on brass and watch cases. First I heat the article slightly, making it just

warm enough to melt the beeswax with which the article is coated, care being taken to make the coating very thin and to apply it evenly. After the wax has cooled, I mark the design or name in it with a hard pencil having a very thin, sharp point. The design or letters are cut through the wax down to the surface of the metal and care should be taken to have the marking cleanly done so that no wax is left where the design is to be etched. The etching is done with a solution consisting of six parts of nitric acid and one part of muriatic acid. I use a glass medicine dropper to apply the solution, covering the design to be etched with the acid. After allowing the acid to etch about five minutes, it is removed with a piece of cotton waste, care being taken to soak up all the acid that can be removed. Then the wax is scraped off and the surface is cleaned with a piece of waste soaked in lard oil. The result will be a nice clean etching.

Of course, like everything else, etching requires some practice in order to insure a good job. I generally brush the surface of the article with lard oil where there is no beeswax. The oil prevents the fumes of the acid from penetrating the surface and the acid from adhering to the parts if it is inadvertently dropped on them. To etch brass requires from ten to fifteen minutes for the solution to bite.

I have etched levels, scissors, indicators, surface gages, scales, etc., for the company I work for with good results, using the method described in the foregoing. Etching tools is far better than stamping them with a steel stamp. A steel stamp will almost invariably damage the tool, whereas etching will not. In this connection I might say that I have known men to pay from 50 cents to $1 for an etching kit which was of little use for the purpose intended. Ten cents worth of the solution given above and five cents worth of beeswax is sufficient to etch one hundred or more names on tools and other articles.

Pearl River, N. Y. WALTER BUTZ

MAKING ECCENTRIC SCREWS ON AN AUTOMATIC SCREW MACHINE

In the following article, the writer wishes to describe a simple fixture used with great success on the Cleveland auto

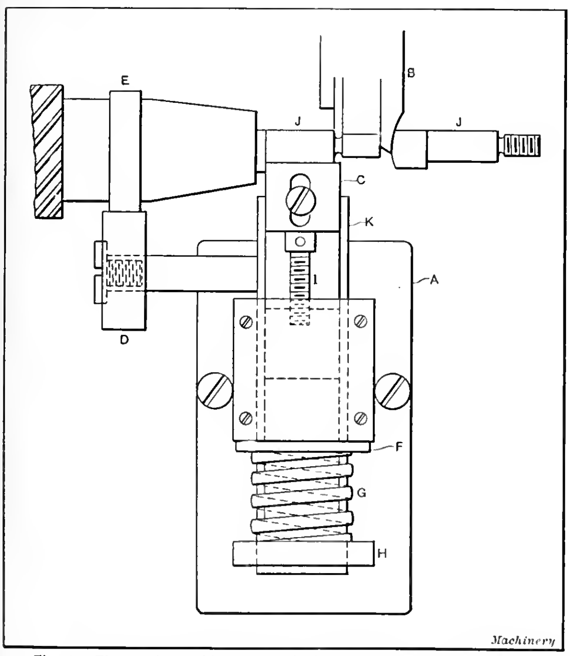


Fig. 1. Fixture for making Eccentric Screws on the Cleveland Automatic Screw Machine

matic screw machine in the manufacture of eccentric screws. Referring to Fig. 1, A is the fixture used to form the eccentric shoulder J, while at B a combination cut-off and form tool is shown which is used to sever the finished screw from the bar stock, and to form the small shoulder to be threaded on the next screw.

Before proceeding further, it should be mentioned that the chuck used on this job is central; thus it is understood that the threaded shoulder and the head of this screw are central, but the formed shoulder J is eccentric. The forming of the eccentric is accomplished by the form cutter C held in the fixture A, and adjustable by means of the screw I. An eccentric ring E is pressed over the spindle nose, as shown, and as the roller D is brought to bear against E by advancing the fixture to the work, the rotation of E causes the cutter C to form the eccentric portion of the screw as desired.

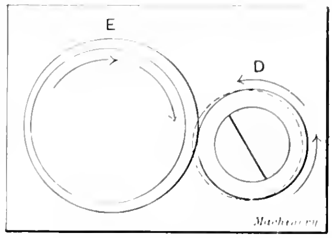

Fig. 2. Diagram showing Relation of Cam E and Roller D

A pin is shown at F fastened in the tool-slide K, which causes a compression of the spring G against the block H, serving to return the cutter C to the work when the small diameter of E is in contact with D. Thus it is understood

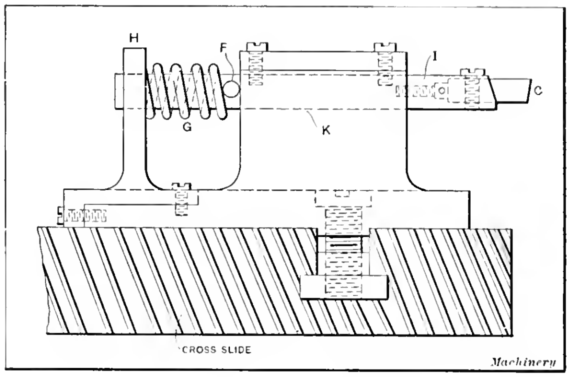

Fig. 3. Side View of the Eccentric Screw-making Fixture

that the forming of the work by the cutter is controlled by the relation of D and E, until the set-screw on the cross-slide stops further cutting and the fixture is tripped away to allow threading the small shoulder. Fig. 3 shows a side view of the fixture and Fig. 2 illustrates the relation of D and E to each other.

O. GORDON

CLUTCH DESIGN

The writer read Mr. J. W. Brassington's article on clutches in the August issue of MACHINERY and desires to comment on this interesting subject, not from the standpoint of an authority on clutch design but rather as an interested observer. In deriving formulas for the proper relative capacities of clutches, it appears that J. W. B. has failed in an important but seriously neglected point regarding the work done by a clutch, *i. e.*, the proper analysis of what constitutes the load. Taking the example cited by J. W. B. of a load of 10,000 pounds started from rest and accelerated to a velocity of one foot per second in one case, and to a velocity of three feet per second in another case, he arrives at the conclusion that a clutch of nine times the capacity of the one required in the first case is necessary in the second case.

The statement is then made that most clutch manufacturers would recommend a clutch of one-third the size required in the first case for the second case, owing to the higher speed. Assuming that loaded to 10,000 pounds means the tangential load or resistance at the periphery of the clutch—which it may be remarked is very much higher than the tangential load of any clutch that has come to the writer's notice—acceleration to a velocity of one foot per second makes the load $10{,}000 \times 60 = 600{,}000$ foot-pounds per minute.

$\frac{600{,}000}{33{,}000}$ = 18 horsepower (approximately). In the second case the speed is accelerated to 3 feet per second and it is thus obvious that the clutch is doing three times the number of foot-pounds of work in the same period of time, *i. e.*, 1,800,000 foot-pounds per minute or 54 horsepower. Now does it not seem rather unlikely that a lighter clutch would be recommended by a manufacturer for use in the latter case? Had the horsepower remained 18 and the speed been increased three times, then the torque would have fallen to 1/3 of 10,000 pounds and a much lighter clutch could have been used. Here is where the writer believes that many "get lost" on the speed proposition, but it is clearly explained by the somewhat antiquated theroem of the three constituents of work, *i. e.*, time, space and weight or resistance in pounds.

Regarding the question of the pick-up capacity of a clutch, it has always appeared to the writer that the starting resistance was not particularly destructive to the mechanism unless the leverages of the clutch were such that it "seized" suddenly. Automobile designers have decided that such a seizing action is only likely to occur when the angle of a cone clutch is less than 12 degrees or its equivalent on a clutch of the toggle type. In an improperly designed clutch where such an action can occur, the mechanism is not only subjected to a violent shock but the torque is also increased due to inertia. Aside from this consideration, the only difference which the writer has observed in the behavior of a clutch while starting or when under way is that the coefficient of friction of rest is somewhat higher than the coefficient of friction of motion, the stresses being somewhat greater in the former case.

In conclusion, it may be stated that the writer has obtained satisfactory results with friction clutches designed according to these principles, and that he has designed at least one clutch which all of the shop men were prepared to wager was too small for the load it had to carry. After this clutch had been placed in service, it was found to be quite satisfactory and afforded a surprise to the men in the shop who did not have a "speaking acquaintance" with our friends "time," "space" and "weight."

Cleveland, Ohio. J. E. McMahon

MACHINE TOOL COUNTERSHAFT

On large hand screw machines much time is lost because the belt from the countershaft to the cone pulley of the spindle cannot be shifted from one step to another. If it could be shifted quickly, the production of machines engaged on many classes of work might be considerably increased

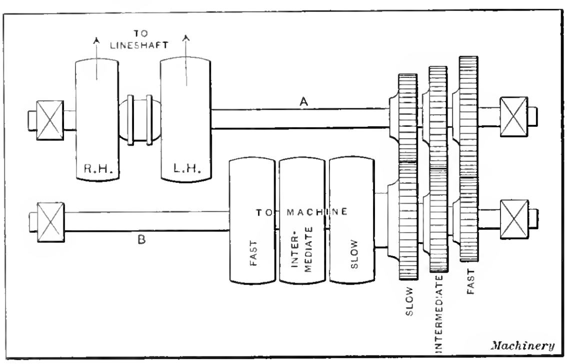

Fig. 1. Plan View of Machine Tool Countershaft

since some tools in the turret can be operated at a much higher surface speed than others. It is obvious that the speed of the spindle is limited by the speed that is suitable for the slowest tool in the turret.

The illustrations presented herewith show a countershaft which might be used to advantage in overcoming the difficulty referred to. It consists of two shafts *A* and *B* supported by double shaft hangers. The shaft *A* carries the regulation right- and left-hand pulleys with belts running to the lineshaft. This shaft also carries three gears (or chain drives as a substitute) which mesh with corresponding gears on the shaft *B*. Two of the gears on the shaft *B* are mounted on sleeves which run on rollers and have pulleys mounted on their opposite ends. The third gear is keyed direct to the shaft *B* and drives a pulley keyed to this shaft. A drum is mounted on the spindle of the machine in place of a cone pulley and the belt which drives the spindle runs from one of the pulleys on shaft *B* to this drum. As the belt can readily be shifted onto either of the pulleys on the counter-

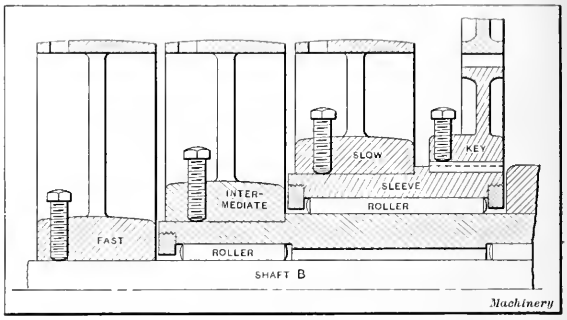

Fig. 2. Sectional View of Machine Tool Countershaft

shaft three speeds are provided for the spindle, which are in proportion to the ratios of the gears through which the pulleys are driven. The relative difference between the speed of adjacent pulleys is not great, so that the wear on the rollers and sleeves is reduced to a minimum.

The pulleys are crowned in the usual way and made about fifty per cent wider than standard pulleys for the width of belt which is used. The belt is moved by the usual form of shifter and the additional width of the pulleys enables it to get off the crown of one pulley before it goes onto the crown of the adjacent pulley. When the belt is shifted, the speed is gradually slowed down, or increased as the case may be, and as the belt is not on the crown of two pulleys at the same time it follows that the slippage and wear is reduced to a minimum.

Chicago, Ill. R. W. Ullmann

SIMPLE RULES FOR OBTAINING GEAR DIAMETERS

The rule of adding 2 to the number of teeth required on a gear, and dividing by the diametral pitch to obtain the outside diameter of a spur gear blank, is probably known to all mechanical draftsmen. There are two equally simple rules for obtaining the diameters of the circles representing the working depth of the teeth and their root diameters.

For the diameter of the circle representing the working depth of the teeth, subtract 2 from the number of teeth in the gear and divide by the diametral pitch; the result is the required diameter.

For the diameter of the root circle, subtract 2.314 from the number of teeth and divide by the diametral pitch; the result is the required diameter.

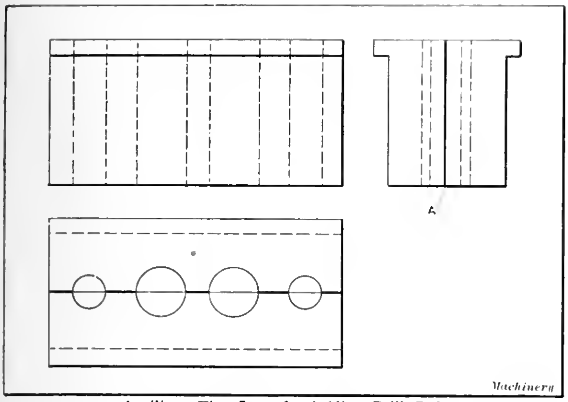
As an example, suppose a gear has 48 teeth and is of 4 diametral pitch; then $\frac{48+2}{4} = \frac{50}{4} = 12\frac{1}{2}$ inches outside diameter of the gear blank. And $\frac{48-2}{4} = \frac{46}{4} = 11\frac{1}{2}$ inches, diameter of circle representing the working depth of the teeth. $\frac{48-2.314}{4} = \frac{45.686}{4} = 11.4215$ inches, diameter of circle representing the bottoms of the tooth spaces.

Having never seen these rules in print, it occurred to the writer that they might be good enough to pass along to other draftsmen.

Los Angeles, Cal. John A. Wood

VISE ATTACHMENT FOR HOLDING DRILL ROD

A practical and very effective vise attachment for holding drill rod for cutting or finishing the ends is shown in the accompanying illustration. In order to make a vise of this kind, two pieces of machine or cold-rolled steel are planed to produce a shoulder 1/8 inch wide and 1/8 inch deep. The two parts of the vise are then placed together with a shim *A* about 0.010 inch in thickness between them as shown in the end view. They are then clamped in this position and the required number of holes to receive the standard sizes of drill rod for which the vise is to be used are drilled and



Auxiliary Vise Jaws for holding Drill Rod

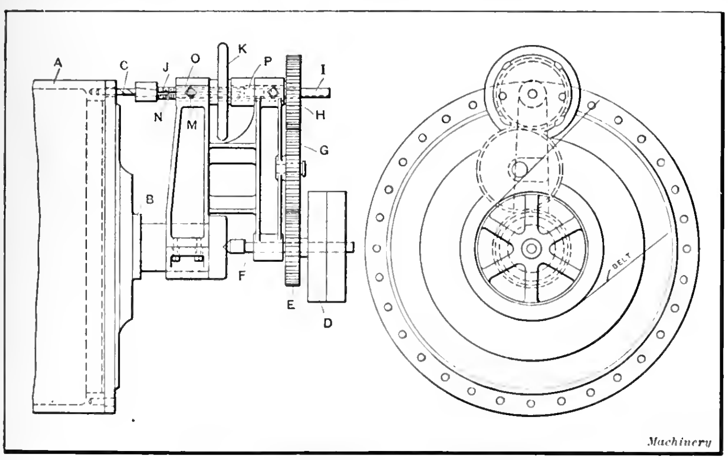
reamed. An allowance of 1/4 inch is made at either end and from 1/8 to 3/16 inch between the holes for adjacent pieces of drill rod to provide the necessary wall strength.

The vise jaws are now ready to use. They are placed in an ordinary bench vise or the vise of a milling machine and the shoulders hold them in place. The removal of the shim *A* allows the jaws to come closer together than the position in which they were machined, and consequently a very firm grip is secured on any size of drill rod for which the jaws are intended. When a large number of pieces of round stock are to be slotted in a miller, this is a very cheap and practical device and its use enables drill rod to be securely held without marring its surface in any way.

Union Hill, N. J. G. J. Johnson

FIXTURE FOR DRILLING LARGE CYLINDERS

Some time ago we had quite a large number of cast-iron cylinders to machine, the heads of which were fastened in place by thirty-two 3/4-inch cap-screws. The heads were easily drilled on a drill press, but we were "up against it" when it came to the cylinders. As this work was somewhat out of our regular line, we did not feel inclined to buy any new and expensive machinery for the purpose, and so it became necessary to do the work as best we could. The accompanying illustration shows a simple fixture that we made for handling this work, in which *A* is the cylinder to be drilled and *B* the cylinder head. After the head had been drilled, and two holes had been drilled and tapped in the cylinder with a ratchet drill, the cylinder head served as a jig for locating the remaining holes. The fixture was fastened to the journal of the cylinder head and could be swung about this center to bring the drill *C* into any position on the periphery of the cylinder. The drill was secured in a socket at the end of the shaft *I* which was driven by the tight pulley *D* through gears *E*, *G* and *H*. The tight and loose pulleys and gear *E* are mounted on the shaft *F*. It will be seen that the spindle *I* is partly enclosed by a bushing *J* which can be moved longitudinally along the spindle by means of the handwheel *K*, but is prevented from rotating by the set-screw *M* which fits in the slot *N*. The parts *O* and *P* form two oil chambers which were kept full of oil at all times. This fixture was quite inexpensive to make, and as we used gears from a lathe and took the pulleys from a pump that we had on hand, it will be evident that it was unnecessary to machine any expensive parts. The use of this fixture enabled two unskilled men to drill one end of a cylinder in one hour and fifteen minutes, and the design insured having the holes drilled perfectly straight.

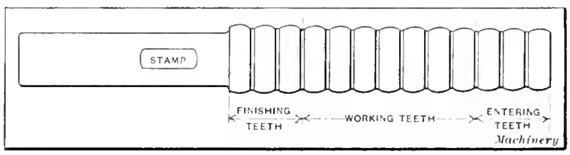


Fixture used for drilling Large Cylinders

Sherbrooke, Quebec, Canada. Olaf Melby

SMOOTH TOOTH BROACH

The illustration shows a broach of novel design which has the teeth rounded at the top instead of being finished to a cutting edge as in the ordinary type of broach. These teeth are highly polished, and experience has shown that the higher the degree to which this polish is brought, the better will



Smooth Toothed Broach used for machining Bearings

be the results obtained with the tool. It will be seen that the first few teeth are small enough to enter the hole which is to be broached, the intermediate teeth are of slightly larger diameter, and the last three teeth are of the size to which it is desired to finish the work.

This tool is used for broaching bearings and for operations on other classes of work where the metal is relatively soft, the tool compressing the metal, and thus giving it a surface hardness. This is of particular value in the case of bearings, on which class of work this broach has found wide application. The amount of metal displaced by the broaching operation is about the same as that removed by reaming, depending largely on the class of metal, lubrication and the construction of the broach. Although the tool is primarily intended for operations on babbitt and white bearing metal, it has been used satisfactorily for producing glazed surface on cast-iron bearings.

The distance from center to center of the teeth depends somewhat on the length of the work which is to be broached. It is desirable to have at least six or eight teeth working at all times. This broach is usually made according to the design shown in the accompanying illustration and is pushed through the work instead of being pulled in the ordinary way. An arbor or screw press may be used for this purpose and it is generally advisable to apply lubricant to the broach while in operation.

Hartford, Conn. S. Victor Brook

[The noteworthy feature of the operation of a broach of the type described in the preceding, as compared with an ordinary plug, lies in the reduction of friction. It will be evident that the teeth of this broach are fully as efficient as a plug for handling the class of work for which the tool is intended. At the same time, the area of the tool in contact with the work is greatly reduced, with a corresponding reduction of friction and the amount of power required to drive the tool. The provision of teeth also makes it possible to apply lubricant to the work, which could not be done if an ordinary plug were used.—EDITOR.]

REDUCING FLATS ON HOBBED WORM-WHEEL TEETH

The larger the diameter of a hobbed gear—the pitch remaining the same—the more closely the tooth outline approaches the shape of a rack tooth. The flats left on the teeth by the hobbing operation also become perceptibly less as the size of

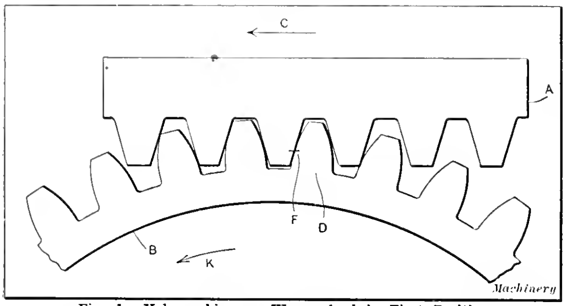


Fig. 1. Hob working on Worm-wheel in First Position

the wheel increases. The flats on the teeth of hobbed worm-wheels with a small number of teeth can be reduced by the use of a hob having a large number of flutes. Where a fly cutter hob is used, the flats can be further reduced by moving the hob along its axis after the first cut has been taken and moving the worm-wheel on its arbor a corresponding amount. By making five or six such shifts of the hob, a very smooth worm-wheel is produced. The fly cutter hob and gear blank must be geared together and the blank cut to depth before shifting the hob on its axis as previously described.

In Fig. 1, the tooth D of gear B is in contact with the hob A at the point F. In this position, a series of flats are produced on the gear as it revolves in the direction indicated by arrow K. By moving the hob along its axis a distance equal to a small fraction of the circular pitch in the direction

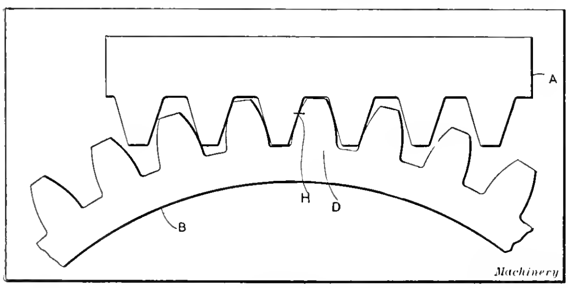

Fig. 2. Conditions after Hob has been shifted, showing Change in Relative Position of Hob and Work

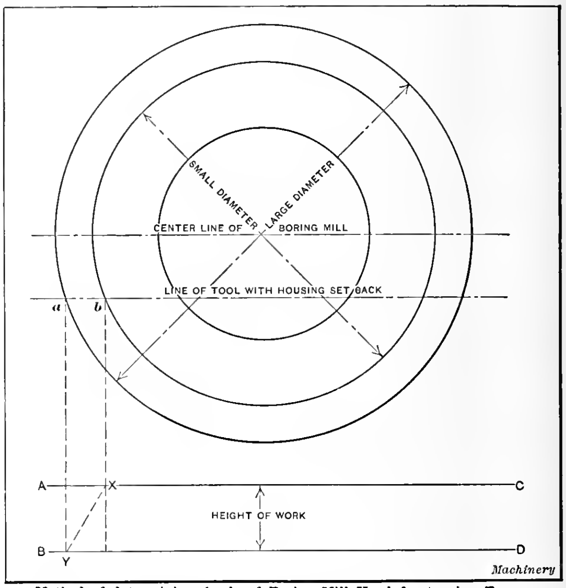
shown by the arrow C, the hob A is brought into contact with the tooth D at the point H as indicated in Fig. 2. A new series of flats is produced in this way causing the corners to be sheared off the flats which were produced when the hob was in the position illustrated in Fig. 1. By repeating this process, moving the hob along its axis a number of times, the flats produced in hobbing a worm-wheel in this way can be practically eliminated. The total distance through which the hob is moved is from one to two times the circular pitch. The movement of the hob along its axis can be accomplished automatically by suitable apparatus properly timed and operating in connection with the driving mechanism of the gear and hob. Although it takes slightly longer to hob wheels by this method, the increased accuracy of the work more than pays for the additional time which is necessary for the operation. This method of gear hobbing is used by the Boston Gear Works where a smooth worm-wheel is required.

Wollaston, Mass. GEORGE L. COLBURN

TURNING TAPERS ON A BORING MILL

In turning tapers on a boring mill with the housings set back, the determination of the proper angle at which the head should be set depends largely upon the judgment of the operator. It is a well-known fact that in operating a machine of this type with the cutting tool behind the center, the elements of the tapered surface are slightly curved instead of being straight lines, as they would be if a true conical surface were produced. This curvature is very slight, however, and does not cause trouble in turning such work as bells, bellhoppers, etc.

The accompanying illustration shows a method of determining the exact angle at which the head should be set for turning tapered work. First, draw a circle of any size to represent the table of the boring mill. Second, draw a line through the center of this circle to represent the center line of the machine. Third, draw a straight line parallel with the center line and at a distance from it which represents the distance that the housings have been set back, to some convenient scale. This line is called "the line of the tool" with the housings set back to the position indicated. Fourth, with the center of the table as a center, draw a circle which represents the



Method of determining Angle of Boring Mill Head for turning Tapers

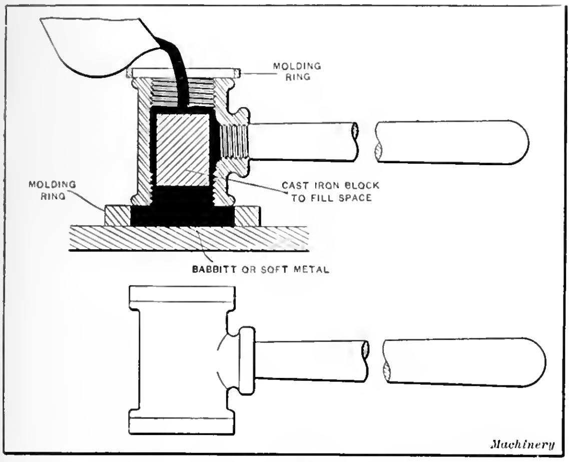
large end of the finished tapered work to scale. Fifth, with the center of the table as a center, draw a circle which represents the small end of the finished tapered work to scale. Sixth, draw the line AC parallel to the center line of the boring mill. This line is called "the line of the large diameter." Seventh, draw the line BD parallel with AC and at a distance from it which represents the height of the finished tapered work to scale. This line is called "the line of small diameter." Eighth, drop two perpendiculars from the line of the tool at the points where this line intersects the two circles which represent the large and small diameters of the work. It will be evident that the space enclosed between these two lines and the lines AC and BD forms a parallelogram. Ninth, lay a protractor on the diagonal XY and measure the angle which this line makes with the line BD; this is the angle at which the head must be set to produce the required angle on the tapered work with the housings set back the distance shown in the illustration.

Youngstown, Ohio. S. P. ROBINS

[In the October, 1911, issue of MACHINERY, the curve formed in turning tapers with the housings set back was discussed, and it was pointed out that this curve is a hyperbola. —EDITOR.]

SOFT-FACED MACHINE SHOP HAMMER

For fitting mandrels, and in any other work requiring heavy driving where work must not be marred or scratched, a simple and effective all-metal hammer may be inexpensively and quickly made of a standard T-pipe fitting as shown in the accompanying illustration. The dimensions, of course, will vary according to the work for which the hammer is intended. To make a hammer of this kind, turn a smooth handle of mild steel, thread one end with a pipe die, and assemble as shown in the illustration. Then, with a suitable mold to shape the faces, pour the tee full of lead or babbitt metal. To fill the inner space, any kind of scrap metal may be used inside of the pipe fitting. After the metal has cooled, and if the mold has left the faces rough, unscrew the handle, turn the soft faces smooth in a lathe, replace the handle, and you have a



All-metal Hammer, for use in the Machine Shop where Work must not be marred

hammer that is as serviceable as anything you could want.

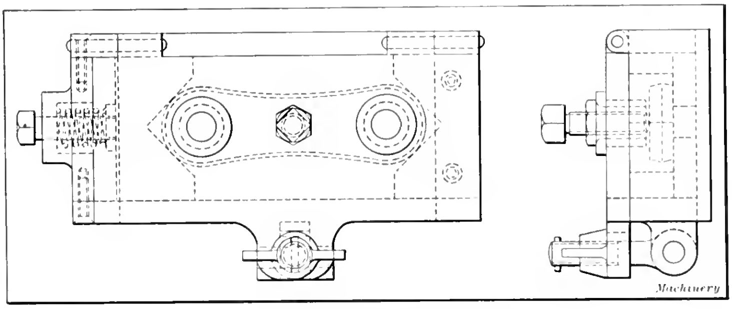
As soon as the faces are worn, it is a simple matter to repair them by throwing the whole hammer into the melting pot, melting out the soft metal, and remolding the hammer according to the preceding instructions.

Brooklyn, N. Y. W. F. SCHAPHORST

JIG FOR DRILLING AUTOMOBILE SPRING SHACKLE LINKS

Automobile spring shackle links are generally made from low carbon steel and are sometimes very hard, due to being improperly annealed after having been removed from the forging die. It will be obvious that such hard pieces of work would be very difficult to drill. The accompanying illustration shows a fixture which has been successfully used in drilling these automobile spring shackle links. It is of the box type and consists of a body, cover, end and two V-blocks. One of these V-blocks is fixed and the other adjustable for slight variations in the length of the work. The permanent V-block forms one end of the fixture while the adjustable V-block is held in position by a spring which brings it into contact with the end of the work. The cover of the fixture is hinged to the body and provided with a wing nut lock. A set-screw is carried in the center of the cover and tightened on the work to assist the V-blocks in holding it in position. The holes are drilled through the ordinary form of hardened bushings, and the same fixture can be used for reaming the holes by providing suitable bushings for this purpose. Where it is desired, however, the reaming operation may be done on the bench by hand.

St. Louis, Mo. C. T. SCHAEFER



Fixture for drilling Automobile Spring Shackle Links

WHERE IS THE FALLACY?

Replying to your question "Where is the Fallacy?" on page 50 of the September number of MACHINERY, I beg to submit the following explanation:

To repeat the last three lines of the "proof":

$$(a-c)^2 = (b-c)^2$$
$$a-c = b-c$$
$$a = b$$

The first equation is correct but the second one is not. After extracting a square root from the first equation the correct result should read:

$$\pm(a-c) = \pm(b-c)$$

thus giving us four possible combinations, namely:

$$a-c = b-c \quad (1)$$
$$a-c = c-b \quad (2)$$
$$c-a = b-c \quad (3)$$
$$c-a = c-b \quad (4)$$

Results (1) and (4) are absurd, but (2) and (3) are correct, each reducing to $a+b=2c$, or just what we started with.

The "proof," as stated in MACHINERY, will remain a proof as long as one forgets that extracting a square root always gives two answers, a positive and a negative.

Flint, Mich. M. TERRY

[Correct solutions of this problem were also obtained from G. Brunn, Wilkinsburg, Pa.; T. G. Carlbom, Meadville, Pa.; Asher Golden, New York City; Walter Gribben, Brooklyn, N. Y.; Miss Bernice Haynes, Oxford, Ohio; R. A. Jewett, Rochester, N. Y.; S. G. Koon, Boston, Mass.; Arthur C. Maxfield, Providence, R. I.; E. F. McCaleb, Erie, Pa.; Bernard W. Noel, St. Louis, Mo.; Elof Nordstrom, Hartford, Conn.; R. J. Quinlan, Peterboro, Ontario, Canada; Percival K. Reed, Philadelphia, Pa.; W. A. Rose, Bridgeport, Conn.; J. R. Sheldon, New Haven, Conn.—EDITOR.]

TWO SHOP FORMULAS

The writer was interested in several shop formulas which were presented by Mr. Jos. H. Cheetham in the June issue of MACHINERY. The following gives formulas for two solutions which have been found particularly useful for stripping brass or copper plate from iron or steel articles and for removing rust or scale from various classes of work. The stripping solution is compounded as follows: Dissolve ½ pound of cyanide of potassium and ¼ ounce of cream of tartar in 1 gallon of water. The pieces to be stripped are immersed in the solution and allowed to remain until the plating has been removed. The solution will not injure the work in any way and will leave it nearly as bright as it was before being plated.

The solution for removing rust or scale from iron or steel pieces consists of acetic acid. The work is immersed and allowed to remain until the necessary result has been obtained.

Winsted, Conn. CHARLES W. RICHARDS

* * *

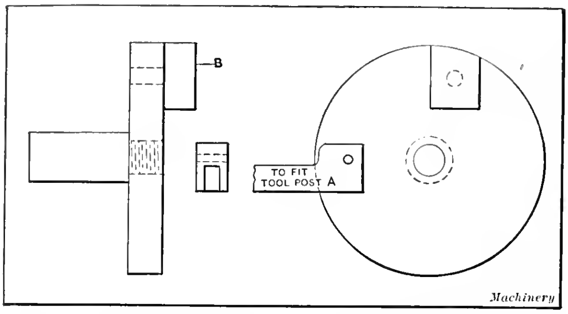
It is difficult to keep a machine from rusting and depreciating in value when it stands idle for a long time. The same is true of men.

SHOP AND DRAFTING-ROOM KINKS

INGENIOUS MEANS AND SHORT CUTS FOR SAVING LABOR AND MATERIALS

CUTTING OFF PINS ON A BENCH LATHE

A convenient bench lathe attachment for cutting off blanks for pins or rivets is shown in the accompanying illustration. The operation of this device will be readily understood by any mechanic after referring to the illustration. The block *A* is carried by the toolpost of the lathe and has a hole drilled in it of the same diameter as the wire from which the blanks are to be cut. The wire is carried on a reel mounted in some convenient position at the end of the lathe. The block *B* shears the wire off when it comes into contact with block *A*. Block *B* is made of the same width as the length of the blanks which are required. The operator keeps the wire pushed against the faceplate and a blank is sheared off for each revolution of the lathe. The writer operated a machine at 900 revolutions per minute and was able to cut off a blank at each revolution, which gave a productive capacity of 900 blanks per minute.



George R. Haub

Bridgeport, Conn.

ERASING INK FROM DRAWINGS

In the April issue of Machinery I noticed two methods described for erasing ink marks on tracings. E. C. McMeans tells of using a blotter to blot out the ink before it gets dry. This I have found by experience to work very well, but, supposing a man cannot find his blotter in time, what then? My experience has been that to wipe the ink off with your fingers before it gets dry is the best method in preserving the gloss on tracing cloth.

As to the method of using water before erasing, I would suggest the use of apple juice or vinegar; this will remove all ink without erasing and the effect on tracing cloth is about the same as that of water. If a number of changes have to be made it is time well spent to make an entirely new tracing, thus avoiding confusion and the consequent possibility of making errors.

P. P.

CURVE FOR DRAWING AUTOMOBILE SPRINGS

The writer recently had occasion to draw a number of automobile springs of the form shown in Fig. 1, and as an ordinary irregular curve was not suitable for this purpose, he designed the special curve shown in Fig. 2. This curve is made from a 12-inch hacksaw blade, the ends of which are connected by fine wires and a turnbuckle as shown in the illustration. The screw of this turnbuckle was made from the familiar form of screw used in dry batteries, and by regulating the turnbuckle, the curve could be adjusted to the shape of the various leaves of the springs. In this way it became a very easy matter to make the necessary drawings, as the lines could be swept out at one stroke of the ruling pen.

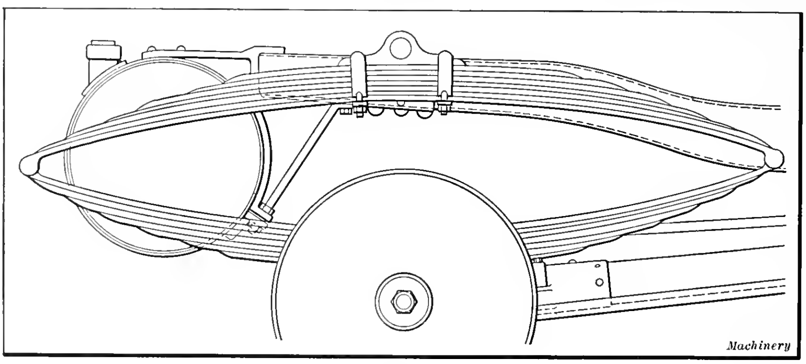


Fig. 1

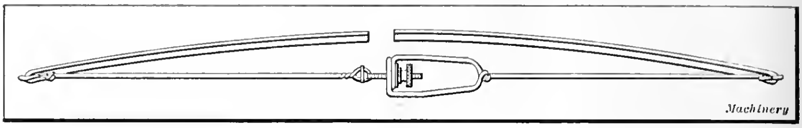

Fig. 2

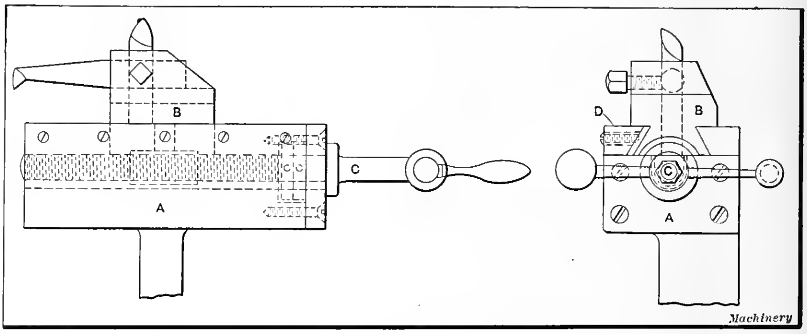
Jackson, Mich. Alex. Moncrieff

AN AUXILIARY COMPOUND REST

On some of the old types of lathes, it is found very awkward when a job comes along that requires a short taper hole to be bored or an angle turned when the machine is not equipped with a compound rest. In order to overcome this difficulty, the rest was designed that is shown in the accompanying illustration. *A* is a forged block with a shank to fit the toolpost of the lathe. The block *B* slides in *A* and is operated by the screw *C*. There are two holes in *B*; the one parallel to the slide is for a boring tool and the one perpendicular to the slide is for the turning tool; one set-screw locks either tool. To set the rest at the required angle, it is necessary to have a bevel protractor of some sort, the setting being done from the faceplate of the machine, or from an arbor which is between centers and the face *D* of the block *A*. This auxiliary rest will be found handy where there is no lathe available with a compound rest.



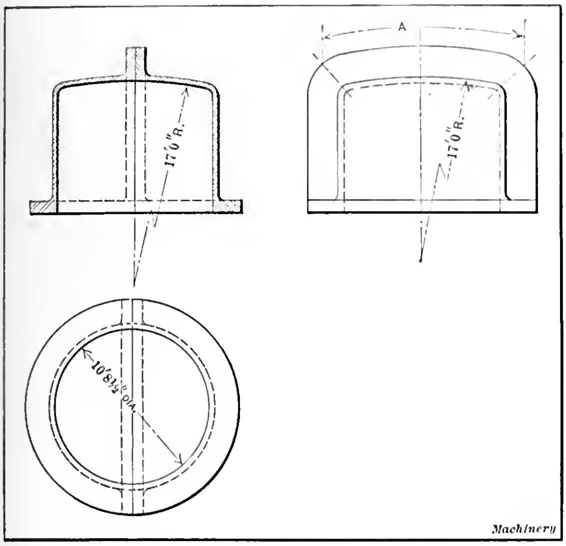
New Britain, Conn. W. C. Betz

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

BOLTS REQUIRED TO JOIN RECEIVER PARTS

W. N.—What is the proper way to figure the number and size of bolts required to unite the flanged halves of a receiver over the spherical part marked *A* in the accompanying illustration? The receiver is of cast steel and carries an internal



pressure of 125 pounds per square inch. In making calculations, allow 12,000 pounds per square inch fiber stress in the cast-steel bosses and 15,000 pounds per square inch fiber stress in the bolts. I would like to see a discussion of this problem by MACHINERY'S readers.

A PROBLEM IN "HEXING"

H. L. B.—We have received an order for 10,000 machine steel plugs like that shown in Fig. 2, which is shown in actual size. We wish to tool-up for this job as there is a likelihood

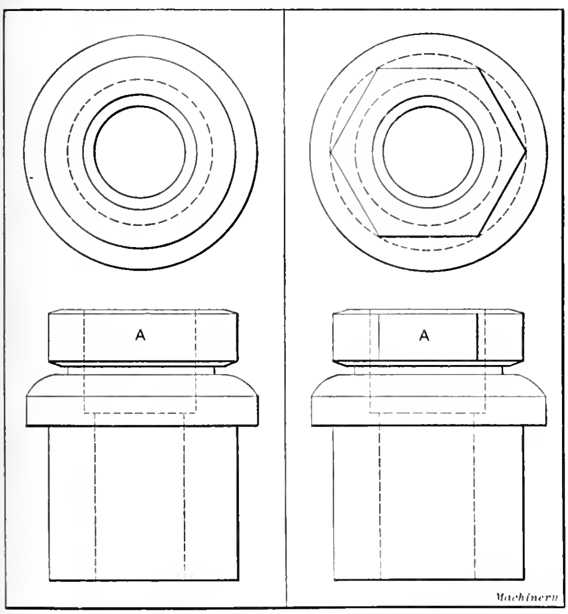


Fig. 1 Fig. 2

that we will receive similar orders of 10,000 lots from time to time. At the same time we cannot go to the expense of making a single-purpose machine unless very simple. We have already the average machine shop equipment, screw machines, power and hand millers, etc. Of course, we know that the job is a plain screw machine proposition as far as shown in Fig. 1, but the phase of the matter which is troubling us is milling the hexagon of the part *A*. We want to do this economically and accurately, although the presence of tool marks on the finished work will not be objectionable. The main thing is to get the pieces out quickly and without a great expense for special fixtures, as competition is very keen on this particular product.

DOUBLE-PLY BELT DRIVE

J. W. W.—I have the care of a belt drive 42 feet from center to center of shafts, the driver being an 18-inch diameter, 24-inch face paper pulley and the driven member a 48-inch cast-iron pulley. A double belt 24 inches wide and ½ inch thick connects the pulleys, and runs at a speed of 3390 feet per minute, the smaller pulley running at 720 R.P.M. I have been unable to keep the belt glued together in the center and will appreciate an expression regarding the cause of the difficulty.

A.—The quality of belt glue and workmanship is of first importance in joining heavy double-ply belts. These must be of the best, but even if they are, the opinion of power transmission experts is that a 24-inch pulley is too small for a half-inch, double-ply belt to run successfully without riveting in the center.

* * *

BROACHING AT THE BOSTON AUTO SHOW

The commercial development of the broaching machine has been coincident with the development of the automobile. The broaching machine is applied to the cutting of square holes in

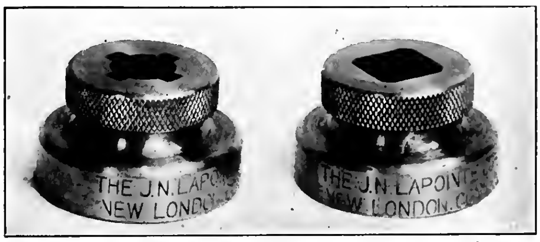

Fig. 1. Paper Weights broached at the Boston Auto Show in Thirty-five Seconds each

gears and multiple keyways for splined shafts characteristic of the design of gear boxes, etc. The J. N. Lapointe Co., New London, Conn., exhibited one of its broaching machines at the Boston Auto Show, in operation, broaching samples similar to those shown in Fig. 1, which were given away to

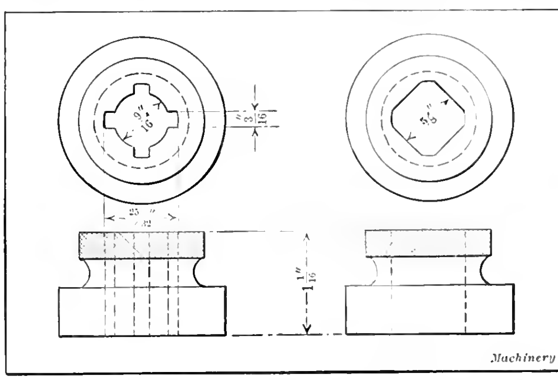

Fig. 2. Showing Dimensions of the Broached Holes and Spline Ways

be used as desk weights. Fig. 2 gives the dimensions of the broached holes and spline ways. The samples shown in Fig. 1 were broached in the remarkable time of thirty-five seconds each, including putting on the broach and removing from the machine.

* * *

Some great and revolutionary improvements in machinery or methods are so simple that when demonstrated we wonder why they were not thought of before. The greatest improvements are often of the simplest character.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

PRATT & WHITNEY HORIZONTAL SURFACE GRINDER

For a number of years the Pratt & Whitney Co., Hartford, Conn., has been manufacturing surface grinders equipped with cup wheels which are well adapted for work on simple, plane surfaces. This machine was not, however, adapted for grinding work having surfaces lying at different heights or angles, and work of this character was slow and expensive

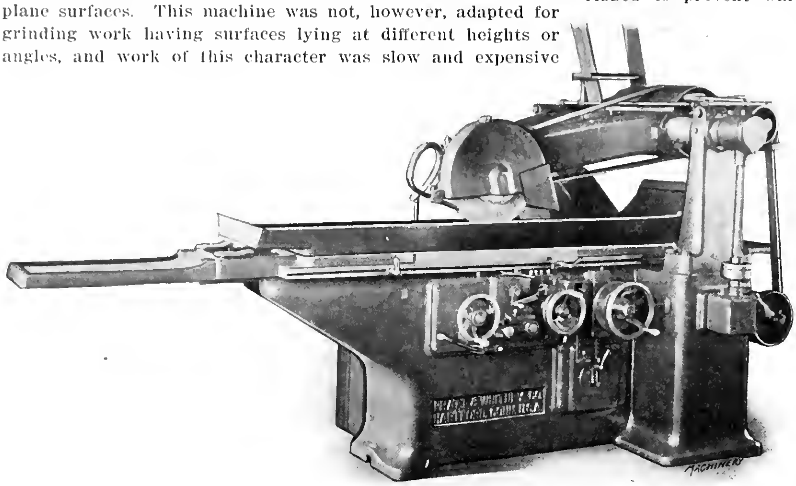

Fig. 1. Front View of Pratt & Whitney Horizontal Surface Grinder

to handle. Either the planer type or tool-room type of surface grinder has been used for such work. The wheels of both types of machine are mounted on slides which provide either vertical or horizontal adjustment, or both. The design is usually such that the wheel has an unsupported overhang, and in order to get accurate work, the adjustment of the slides must be maintained very closely. Trouble has also been experienced from wear in the slides resulting from emery dust or water getting into them.

With the view of eliminating these troubles the Pratt & Whitney Co. has developed the horizontal surface grinder shown in the accompanying illustrations. This machine is adapted for general classes of surface grinding, although it has been designed particularly for grinding work with surfaces lying at different heights or angles. This machine is equipped with large wheels which are powerfully driven and the design has been worked out to provide the maximum rigidity and also to enable a liberal supply of water to be utilized during the grinding operation. During recent tests to which machines of this type have been subjected in the factory of the Pratt & Whitney Co., it has been fully demonstrated that they are capable of handling grinding operations on surfaces lying in different planes, with great efficiency.

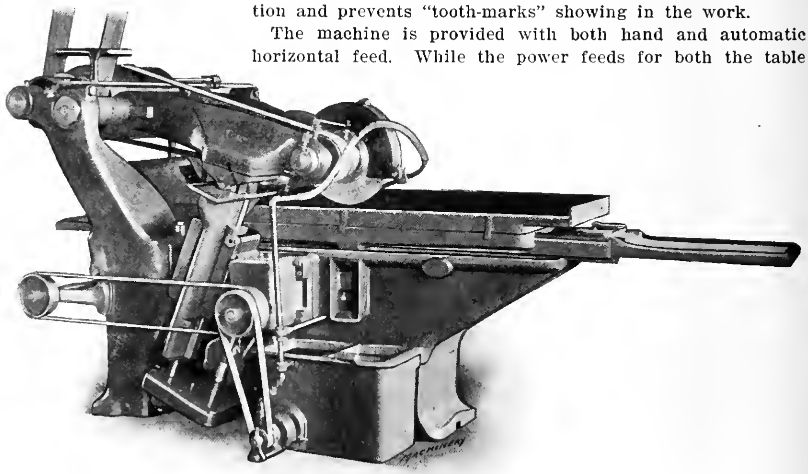

Fig. 2. Rear View of Horizontal Surface Grinder

The bed is very massively proportioned and internally braced in a manner that insures ample rigidity and permanent accuracy. It is very compact in design, the various units being located so as to be conveniently accessible. Wide bearing surfaces of the vee and flat types are provided. Oil reservoirs are located in the bed to provide for automatically oiling the ways by means of rolls. The pan which surrounds the rear of the bed for collecting the water and receiving the chips is of liberal proportions and is easily accessible for cleaning. The table is of heavy construction and powerfully ribbed to prevent warping and to resist torsional strains. Both the bed and the table are scraped perfectly true by means of masters, the table being slightly longer than the bed; and the traveling action tends to keep these members perfectly true. The table is provided with guards at each end, which, at all times, cover and protect the bearing surfaces from injury. A spacious water pan is cast integral with the table.

The table is provided with automatic reciprocating motion, any length of stroke up to four feet being readily obtainable by means of adjustable table dogs. The table feed mechanism is of a most efficient and substantial design. It is made in a simple, compact unit which is very easily accessible. Two table feeds are provided, both of which are instantly controlled by means of a lever conveniently located at the front of the machine. This lever when adjusted to the central station also serves as a means for stopping the table; when adjusted to the upper station the slow feed is engaged, and the lower station engages the fast feed in a similar manner. The table is driven through a rack and pinion vertically located, which eliminates vibration and prevents "tooth-marks" showing in the work.

The machine is provided with both hand and automatic horizontal feed. While the power feeds for both the table and horizontal wheel movement are engaged through the same trip, the feed units are entirely independent of each other. This is very important, as by having a separate mechanism for each feed there is no extra load thrown upon the table feed mechanism when the wheel feed is engaged, and it is a well-known fact that when intermittent loads are thrown upon the grinding table it will invariably show in the work.

The feed mechanism operates a screw mounted inside the hollow arbor upon which the arm is mounted. This screw engages a nut clamped to the arm, both the screw and nut being of liberal proportions and easily accessible. It will be observed that the feed mechanism is entirely enclosed so that it is impossible for emery or dirt to injure it in any way. Any variation of feed is readily obtainable by means of a ratchet wheel and pawl. The feed is operative in either direction and is governed by the direction in which the pawl is engaged. A safety device is also provided, which prevents injury to the feed mechanism in case the arm should come into contact with the uprights, due to neglecting to disengage the feed mechanism. The feed, however, may be very accurately governed by means of a handwheel, the periphery of which is graduated in thousandths; and the diameter of this wheel is so large that these graduations may very readily be observed. The feed operates at the end of each stroke when the wheel is entirely clear of the work.

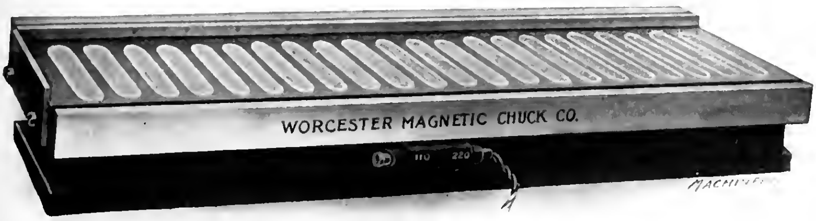

Fig. 1. Worcester Magnetic Chuck for use on either 110 or 220 Volt Circuits

The vertical wheel feed is through hand only, a graduated handwheel being conveniently located on the front of the machine for this purpose. The inclined ram, by means of which the wheel is raised or lowered, is rigidly supported in long bearings. The construction is such that this ram is raised or lowered by means of a heavy screw and nut, the screw being driven through a worm and worm-wheel, actuated by the handwheel referred to. A hardened and ground plate is mounted on top of the ram, which engages a similarly treated block on the under side of the arm. The construction is such that the block always has a full bearing on the plate, irrespective of the height or horizontal position of the wheel. The ram and block take the full weight of the arm, which entirely eliminates backlash in the mechanism. This is a most important feature and one directly conducive to accurate work.

A most important and original feature is the method of mounting the wheel in an arm, which entirely eliminates the use of a slide construction. The arm has a perfect fit on an arbor, which is substantially supported upon two uprights, both the arm and the arbor being proportioned to insure absolute strength and rigidity. With this construction, the wheel is adequately supported without overhang. Furthermore, it simplifies the control of both the vertical and horizontal feeds. It will be noted that the arm has a liberal bearing on the arbor, the bearing surfaces being absolutely protected by means of wipers.

The spindle is of tool steel, hardened, ground and lapped, special treatment and care being exercised to insure the highest possible efficiency of this important member. The boxes are made of bronze and mounted in conical seats. They are made and located so as to be easily accessible for adjustment, and are absolutely dust- and water-proof. Extra precautions have been taken to insure proper lubrication, large self-feeding oilers being provided. The wheel-mount is self-contained and constructed so as to hold the wheel firmly and perfectly true. The spindle end is made conical and provided with a key for the accommodation and positive driving of the wheel-mount. The machine is designed with a view of using wheels up to 18 inches diameter by 2-inch face. Suitable packing rings, however, are provided which permit the use of wheels as thin as 1-inch face.

The wheel spindle drive is of liberal proportions throughout, so that there is no question as to whether the wheel will have sufficient power for any requirement. Two speeds are provided by means of a two-step cone, so that when the wheel is reduced by wear, its speed may be increased. The mechanism for shifting the belt to obtain the increased speed of wheel is so designed that it also becomes necessary to proportionately decrease the table feed. The wheel is driven from a drum, which is finished perfectly true, so that there is no vibration.

A most important feature in these machines is the liberal and perfectly controlled water supply. It is well known that in order to keep the wheel free and prevent clogging, as well as to prevent heating of the work, a liberal supply of water is absolutely necessary. The type of pump used is made and located so as to entirely dispense with the usual idler pulleys. It is capable of supplying an abundance of water for any condition under which the grinder may be operated. An exceptionally large water tank is located on the back of the machine, where it is in an accessible position so that it may be readily cleaned. This arrangement also permits the return of the water without requiring it be carried through pipes; in fact, the design is of such a nature throughout as to make the collection of dirt or grit in inaccessible places impossible. The pipe through which the water is conveyed to the wheel is attached to the guard and may be easily adjusted or instantly removed as desired. Both the table and wheel are provided with guards to prevent the escape of the water.

WORCESTER MAGNETIC CHUCKS

Two forms of electro-magnetic chucks which are now being manufactured by the Worcester Magnetic Chuck Co., 47 Hermon St., Worcester, Mass., are illustrated in Figs. 1 and 2. Referring to these illustrations, it will be seen that the faces of the chucks are designed with "holding spots" which are made of steel. These holding spots are at the ends of the pole-pieces about which the electro-magnetic fields are wound. The use of steel for this purpose has two advantages; it adds to the wearing capacity of the chuck and also affords a stronger magnetic action. As each pole constitutes an independent unit, any accident which may put one pole out of commission does not affect the efficiency of the other poles. The chuck is both heat- and water-proof and does not require ventilation.

Fig. 2. Worcester Round Magnetic Chuck

Fig. 2 shows a round chuck which is capable of holding work as small as rings of $1\frac{1}{4}$ inch diameter. Each of the electro-magnetic coils in these chucks is enclosed in a fiber case which makes it impossible to ground the chuck. The rectangular chuck (Fig. 1) is designed to hold pieces from ½ inch in diameter up to the full size of the chuck. This chuck is wound for connection to either 220 or 110 volt circuits. In order to change from one voltage to the other, it is only necessary to take off the "volt box" on the side of the chuck and change the wires. No resistance is required with these chucks.

"NATIONAL" HEAVY-PATTERN FORGING MACHINE

On account of the general adoption of high-carbon and alloy steel in engine and machine construction, a gradual development has taken place in the design of machine tools to increase their power and capacity. In the railroad, automobile and industrial shops, for instance, there is a general tendency to use forged parts made from wrought iron, soft steel, high-carbon and alloy steel, to replace castings of iron, steel and malleable iron, due to the greater strength possessed by forged parts, and also to the fact that forgings last longer and are much cheaper when produced under proper conditions. The automobile industry particularly has made a great advance in the adoption of forged parts made from alloy steels, and heretofore forging machine equipment has not had the capacity or strength for making these parts economically.

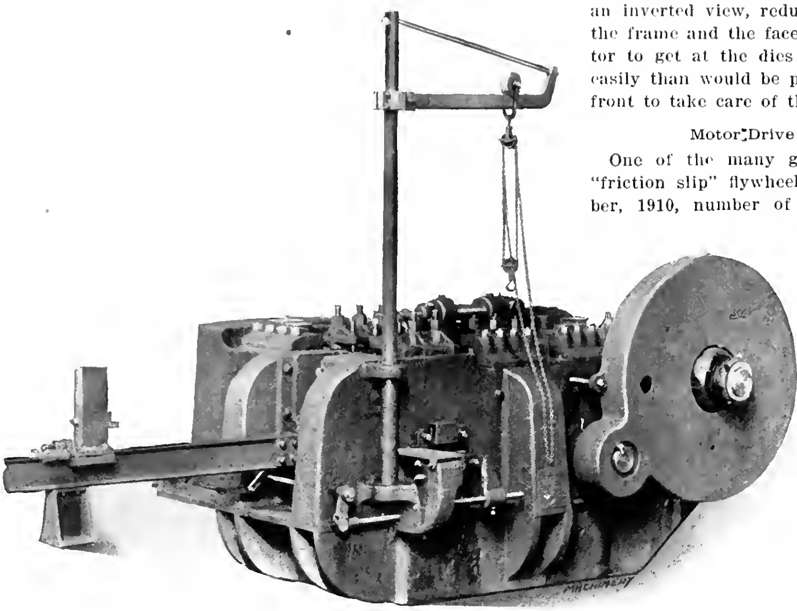

Fig. 1. "National" Four-inch Heavy-pattern Forging Machine

The National Machinery Co., Tiffin, Ohio, manufacturer of bolt, nut and forging machinery, has recently brought out a new design of forging machine which embodies some radical departures in its construction. It has been designed not only for handling forgings much more economically than machines formerly built, but will operate on high-carbon and alloy steels with the same facility as on wrought iron or mild steel. It is designed along lines that give it a higher factor of safety than is customary in forging machines, and it is provided with reliefs on the gripping and heading slides.

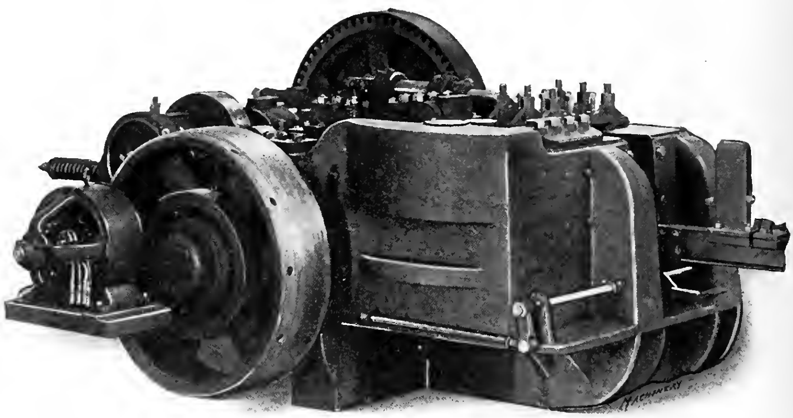

Fig. 2. "National" Four-inch Heavy-pattern Forging Machine with Direct Motor Drive, the Motor being geared directly to the Friction Slip Flywheel

Bed-frame Construction

Figs. 1 and 4 show the bed frame construction which extends considerably below the floor line, is heavily ribbed and is of trussed frame section. This bed frame is one massive steel casting of heavy pattern type designed to secure a high degree of stiffness, as well as great strength. The aim in designing this frame has been to distribute the metal in the paths of the stresses so as to overcome the objectionable spring prevalent in forging machines made from steel beds of lighter design. It also eliminates the use of tie rods and similar stiffening members, making the machine much more accessible. By carrying the frame below the floor line, and providing the ribbing illustrated clearly in Fig. 4, springing at the gap of the bed is eliminated. This is a very important feature in a forging machine, because if the bed frame is not rigidly constructed near the gap, it weakens the gripping power of the machine, allowing the work to slip and produce excessive fins and flashes on the work. Making the bed frame like the construction illustrated in Fig. 4, which is an inverted view, reduces the distance between the front of the frame and the faces of the dies, thus enabling the operator to get at the dies and operate the machine much more easily than would be possible if the frame were built out in front to take care of the stresses mentioned.

Motor Drive and "Friction Slip" Flywheel

One of the many good features of this machine is the "friction slip" flywheel, which was described in the November, 1910, number of MACHINERY. While this flywheel is intended primarily to furnish a means for safety or relief on the heading movement, it also provides an element of elasticity which is highly essential between the motor and a machine of this type. This is due to the varying strains thrust upon the motor by the gripping and heading movements, and especially when the machine is accidentally "stalled" by cold stock or excessive metal. The motor carries a rawhide pinion that meshes directly with a gear bolted to the flywheel. This forms a compact and simple design, insures quiet operation and eliminates the excessive upkeep incident to the chain or flexible joint drive.

Automatic Grip Relief

The top view of the machine, Fig. 3, shows the gripping dies in their closed position and the heading tool or plunger just as it starts gathering the stock on the upsetting stroke. The heading slide is actuated by a crank, while the gripping slide is controlled by two cams, one effecting the closing of the dies and the other serving to open the dies. By employing two cams for the operation of the gripping dies, the opening and closing movements are so timed as to secure practically the entire stroke of the heading tool for useful operation. This gives the machine an unusually large gathering capacity, that is, the ability to upset a large amount of stock at one stroke of the heading plunger. The double cam mechanism also enables the dies to be opened wide, and this, with the large gathering capacity, makes this machine capable of handling large and difficult shaped forgings.

The safety relief for the gripping slides as shown in Fig. 3 consists of a by-pass toggle, the action of which is illustrated in the diagrams Figs. 5 and 6. This relief is so designed that but a small part of the gripping pressure or power is dependent upon the toggle and spring which holds the toggle

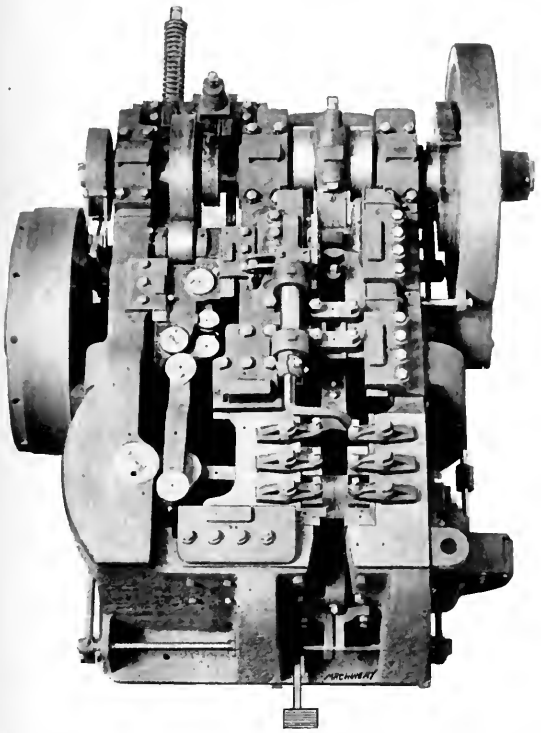

Fig. 3. Top View of "National" Heavy-pattern Forging Machine, showing Method of operating the Gripping Mechanism and Heading Slide

in the normal position, and does not relieve the machine until the same strains are secured in the dies, which in ordinary relief designs would shear the breaker bolt or pin. This design provides for a powerful gripping action in the dies and also enables squeezing or swaging operations to be performed

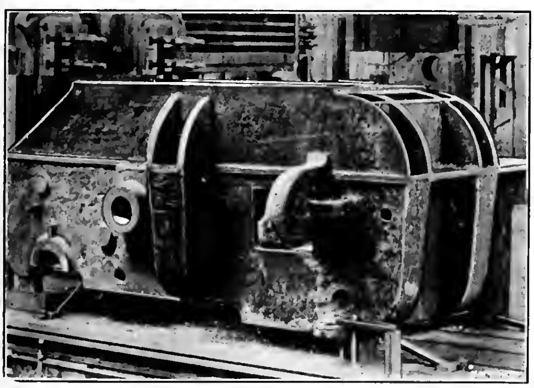

Fig. 4. Steel Bed Casting of National Heavy-pattern Forging Machine, showing the Heavy Under-ribbing that extends below the Floor Line

between the opposing faces of the gripping dies, as is illustrated by the examples shown in Fig. 7. These bars range from 2 to $3\frac{1}{2}$ inches in diameter and were flattened or squeezed in a heated state between the surfaces of the dies in one operation. The ability to handle such squeezing or swaging operations enables a wider range of work to be accomplished, and this feature has met with much favor by forge-shop superintendents.

Briefly stated, the automatic grip relief operates in the following manner: When a piece of stock or other object becomes caught between the gripping dies, or in shop vernacular, the operator gets a "sticker" in the dies, the gripping action continues until the strain incurred in the dies exceeds the combined gripping power derived from the main or fixed toggle and the by-pass toggle, causing the by-pass toggle to open and compress the relief spring, thus stopping the movement of the gripping slide. The heading tool or plunger, however, completes its full stroke, and upon the return stroke of the machine the by-pass toggle resets automatically, without any attention on the part of the operator. This, of course, eliminates all shutdown, which is necessary with the ordinary safety devices, such as the breaker bolt, etc., sometimes provided.

Suspended Gripping and Heading Slides

Another valuable feature that has been incorporated in this design of forging machine is the suspended type of head-

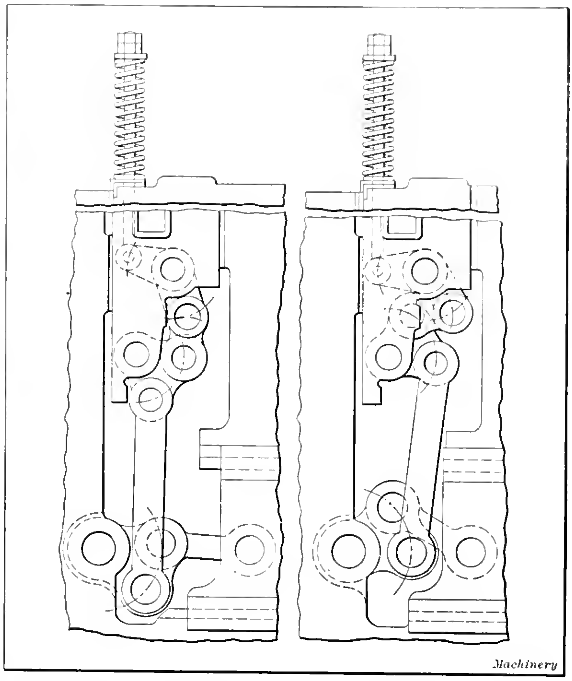

Fig. 5. Automatic Relief for Gripping Slide in its Normal Position

Fig. 6. Automatic Relief in its Tripped Position

ing and gripping slides as shown in the sectional views Figs. 8 and 9. In this type of slide it can be seen that the supporting bearings are at the top instead of at the bottom. This feature removes the bearings from the line of water and scale, increases perfect lubrication and eliminates the causes of "cutting out," as it prevents the water and scale from getting in between the working surfaces. With the ordinary

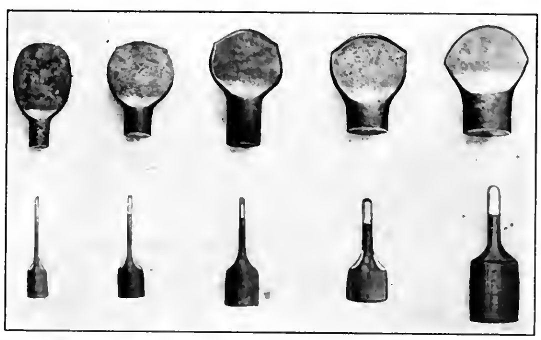

Fig. 7. Squeeze Jobs or Swaging Operations accomplished between Gripping Dies of National Heavy-pattern Four-inch Forging Machine

type of slide where the bearings are at the bottom, water and scale drop down upon the ways and are picked up by the reciprocating movement of the slides, thus causing friction or abrasion with attendant wear. This makes it difficult to maintain alignment. Figs. 7 and 8 also show the wedge

construction back of the side liners on the heading and gripping slides. With this construction shimming can be added when needed without removing the slides or liners, thus providing an easy means of maintaining a snug contact between the slides and liners, and preserving perfect alignment.

Miscellaneous Features

The slide, toggle and shaft bearings are of especially large area and a special effort has been made to minimize the wear by facilitating lubrication. Large oil boxes provided with covers furnish a means of lubricating the slides and main shaft, and oil cups with connecting ducts take care of the bottom toggle bearings and the suspended slides, thus eliminating the source of the greatest trouble in the lubrication of forging and upsetting machines. This new heavy-pattern forging machine is built in sizes ranging from 2- to 5-inch capacities, but due to the larger movement and greater strength of this design, the range of all sizes is increased so that they will safely handle any forge-shop work that has been taken care of on so-called 6-inch machines, and various smaller sizes. A 5-inch "National" machine will easily handle work that has heretofore been only possible on a regular 6-inch machine. A number of these 4-inch machines have been supplied to the automobile trade for use on high-carbon and alloy steels, and have been viewed with interest by shop managers and superintendents when in operation in the shop of the manufacturers where demonstrations are made at the completion of each machine.

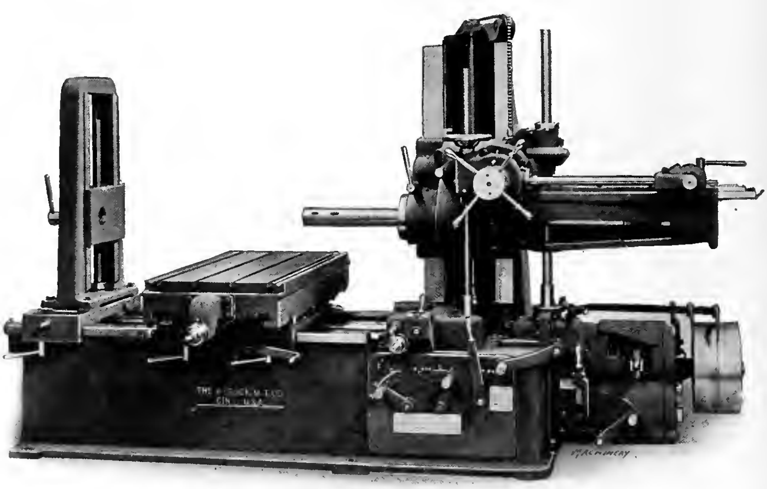
Fig. 9. Sectional View showing "Suspended" Type of Heading Slide and Method of lining and gibbing

FOSDICK BORING, DRILLING AND MILLING MACHINE

The No. 0 horizontal boring, drilling and milling machine shown in this connection is a product of the Fosdick Machine Tool Co., Cincinnati, Ohio. This company has been manufacturing a machine of this type for several years, but the present design has been improved in many ways. Among these improvements may be mentioned: The control has been centralized to facilitate convenience in operation; all gears are of steel and the bevel gears are planed to a theoretically correct outline; self-oiling bearings are used which are provided with phosphor-bronze bushings; all clutches, gears and other moving parts are thoroughly incased; and precision micrometer dials are provided which can be set back to zero from any position.

The bed is of deep section and well ribbed to provide adequate rigidity without the use of any special foundation. Chip chutes are provided which carry the chips and dirt away to the rear of the machine. The head and outer support are raised and lowered simultaneously by means of a rapid power traverse, by hand or by the feeds, the elevating screw being suspended from a ball bearing at the top in order to avoid buckling. Automatic safety trips are provided at both extremes of the travel. The spindle is driven by two long keys and slides in a sleeve with a phosphor-bronze bearing, which is tapered to provide compensation for wear. The thrust is taken on a ball bearing. The quick advance and return turnstile is placed at the front of the head where it is within easy reach of the operator. The sleeve surrounding the spindle is so designed that the spindle is held in perfect alignment regardless of wear.

The table is of heavy construction and is scraped so that it is absolutely square with the spindle. It is provided with an oil channel running all the way around and has automatic safety trips at either extreme of its movement. The feed mechanism is enclosed, all of the feed gears being of steel. The changes are made by means of two handles at the front without the necessity of stopping the machine. A safety friction device, which is adjustable from the outside, prevents the possibility of damage to the feed mechanism. The rates of feed are given on a metal feed-plate and are the same for the spindle, table and saddle or head, so that the selection of the proper feed is made by means of only one handle. This makes it impossible to get any but the desired movement. The direction of the feed reverses when the spindle is reversed and stops when the spindle is stopped.



Fosdick No. 0 Combination Boring, Drilling and Milling Machine

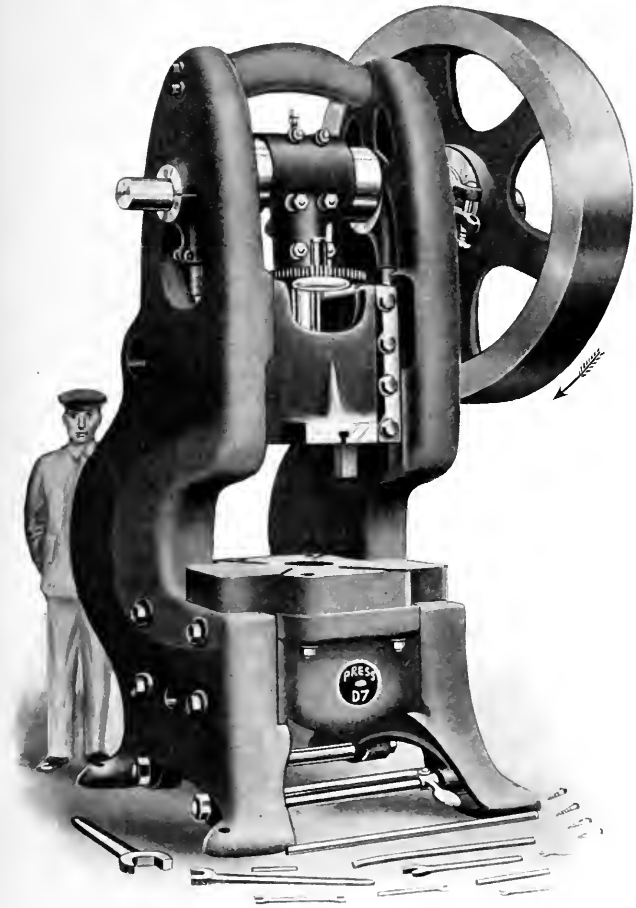
An independent feed reverse lever is provided and power rapid traverse for all members of the machine is always in the opposite direction to the feed.

The drive is direct, so that no countershaft is required, and the machine is equipped with a direct reading index over the speed-changing handle which gives the revolutions per minute of the spindle. An overtake clutch keeps the machine running at a reduced speed while making changes, so that any possible shock is reduced to a minimum. A re-

verse mechanism is embodied in the construction and is operated by a lever located at the front of the machine. All levers are secured by latches. Motor drive may be added to this machine at any time, a five-horsepower constant-speed motor of the required speed being suitable for this purpose. The principal dimensions of the machine are as follows: Traverse of the spindle, 26 inches; vertical adjustment of the head on the column, 25½ inches; maximum distance from the table to the center of the spindle, 26 inches; cross travel of the table, 30 inches; longitudinal travel of the table, 32 inches; number of feeds, 18; range of feeds, 0.004 to 0.396 inch; approximate net weight, 8500 pounds.

FERRACUTE SINGLE-ACTION PRESS

The Ferracute Machine Co., Bridgeton, N. J., has recently brought out a line of throated, single-action power presses which are made in sizes capable of exerting pressures of 100, 150 and 200 tons. These machines are built with either a heavy flywheel or gearing, the flywheel type being shown in the illustration, which shows a machine capable of exerting a pressure of 150 tons.



Ferracute Single-action Power Press equipped with a Pin Clutch

The shaft of this machine is a high-carbon steel forging which is 6½ inches in diameter at the journals and 7½ inches at the crank. The hole through the bed is oblong in shape, being 20 inches from front to back and 18 inches from right to left. The distance between the columns is 32 inches and the throat—from the center of the ram back to the frame—is 15 inches. The height from the bed to the ram when at the top of its stroke and adjustment is 21 inches; the stroke of the ram is 3 inches and the maximum adjustment of the ram 4 inches. Machines can be built with different lengths of stroke to meet the requirements of individual cases. The flywheel is 55 inches in diameter by 10 inches face width and weighs 2600 pounds. The bolster is 4½ inches thick and measures 28 inches from front to back by 26 inches right to left. The total weight of the press is about 26,200 pounds.

POTTSTOWN AUTOMATIC VALVE MACHINE

The illustration shows a semi-automatic 4-inch valve tapping, reaming and seating machine which has been brought out by the Pottstown Machine Co., Pottstown, Pa. It is intended for finishing semi-steel valve bodies, pieces with flanged or threaded ends, split return bends and similar work which requires two or three operations in one chucking. The machine is of heavy construction, which gives such rigidity that any possibility of the work shifting while the machine is in operation is practically eliminated. Eight spindles are provided, either or all of which can be used according to the work on which the machine is engaged.

The turret is revolved and indexed by means of a pneumatic cylinder. This turret has four sides, each of which is provided with chucks, the work in three of the chucks being operated upon while a piece is being set up in the fourth. The first operation is performed on the work at the left-hand side of the turret, where the three roughing tools enter the valve and remove all scale surfaces. The work is then carried to the second position, where the finishing tool at the rear (which does not show in the illustration) comes into action. Two spindles are provided in this position—one horizontal and one vertical—for finishing either straight through or angle valves. After the work has been carried to the third position, two facing tools come into action which finish the male and female members. The turret then moves to the fourth position where the finished valve is removed and a fresh casting mounted in its place.

On the right-hand side there is an additional wrist plate, cam and lever mechanism. This is the tapping side of the machine. It is possible to throw the automatic reversing mechanism out of commission and make the spindles rotate in one direction only, thus permitting finish-facing tools to be mounted in these spindles for machining flanged work. The machine is shown operating in this manner in the illustration. By disconnecting the wrist plate, placing lead-screws on the spindles and putting the reversing mechanism into commission, the machine is made ready for operations on tapped openings.

The turret is held and indexed by means of a substantial latch bar and is further supported by an automatic locking device which holds it securely to the main frame of the machine. This arrangement insures absolute alignment and accurate work. The turret may be revolved without the tools coming into operation as long as the cam trip is not pressed down. After the work has been placed in the chuck and the turret moved to its first position, the machine passes through the cycle of operations which is necessary to finish the piece. After the tools have been set, there is nothing further to be done except to take out the finished work and replace it by a new blank.

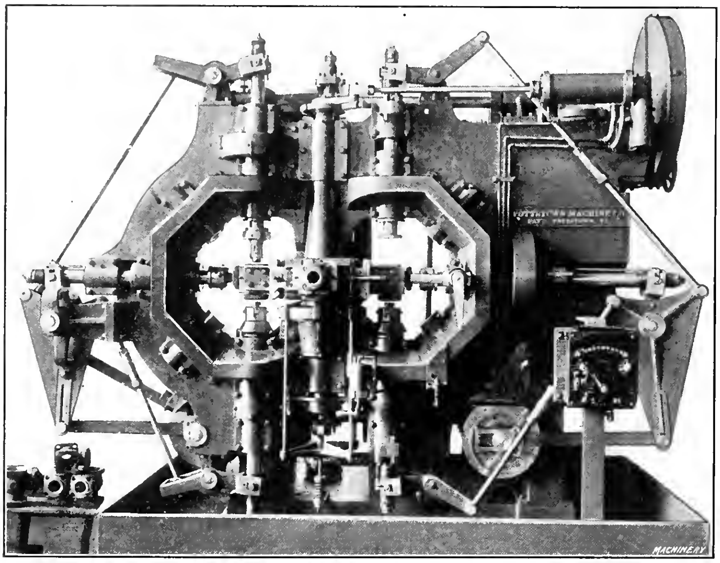
The adjustments are adequate for the range of the machine from the largest to the smallest sizes of work. In order to secure rigidity, the chucks are provided with right- and left-hand screws that are coupled in the center by a sleeve; this sleeve receives the two ends of the screws which are machined to fit it. The action of the wrench on one end of these screws is to tighten the jaws on the work, causing them to separate slightly in the middle and come up solidly at either end of the chuck. No dependence is placed on a bracket or collar to provide the necessary rigidity. Consequently, when the work is fastened in the chuck, it is practically as solid as the turret itself.

Solid taps are used, the taps being fed in by adjustable lead-screws. In order to facilitate gaging, the leader nuts

are castellated and the use of a spring latch enables the nuts to be revolved from one notch to another to regulate the depth of thread. The lead-screws are removable and can be readily changed for different pitches. The taps are started automatically by the cam-shaft, but the reversing is done by a stop carried on the reversing disk. Any depth of thread can be cut by simply adjusting these stops. The variation in the thread is adjusted by the lead-screws as explained.

The four-sided turret used on this machine enables the work to be brought close to the operator, and thus greatly facilitates chucking. The simplicity of the method of setting up the machine for different jobs is also a material advantage. In starting on a piece of work, the turret can be moved back and forth to the different tools so that all testing and gaging may be done on the first piece. The ability of the machine to perform the third operation described in the cycle is also a valuable feature. For machining globe valve bodies, roughing tools may be used to remove the surplus stock and for rough-reaming, while finishing tools are used for accurately finishing all of the openings at a single chucking. When handled in this way, the work will be more accurate and the tools will last longer.

All gears used in this machine are made of either cast or forged steel with cut teeth. All of the clutches are made of



Pottstown Machine for tapping, reaming and seating Valves

hardened tool steel and the spindles are of a special steel which is particularly adapted for this purpose. The spindles are provided with taper bushings for taking up wear. All of the bearings are of ample proportions and provided with oil grooves to facilitate lubrication. The hand levers which govern the various movements of the machine are conveniently placed for the operator. The floor space occupied is

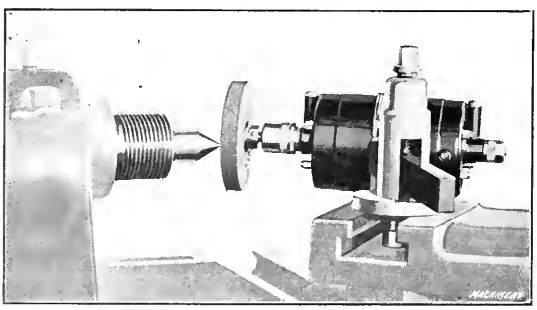


Fig. 1. Method of using Racine Lathe Center Grinder

9 feet 6 inches by 6 feet 1 inch and the weight of the machine is 20,800 pounds. During a recent test, the machine turned out 2-inch semi-steel valve bodies at the rate of twenty per hour.

RACINE PORTABLE ELECTRIC GRINDERS

The Racine Electric Co., Racine, Wis., with sales offices in the Matthews Building, Milwaukee, Wis., is now manufacturing the portable electric grinders shown in Figs. 1 to 4.

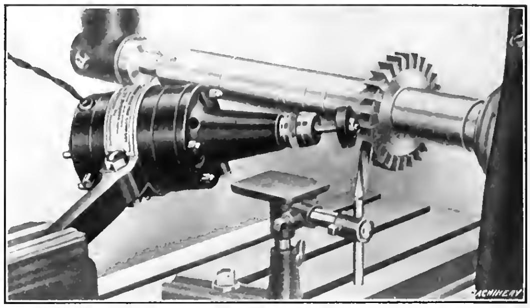

Fig. 2. Grinding a Milling Cutter with the Racine Toolpost Grinder

Referring to these illustrations, it will be seen that one of these tools is intended for grinding lathe centers while in position and that the other is a toolpost grinder. The illustrations show several uses to which this grinder can be put.

Fig. 1 shows the method of using the lathe center grinder, the operation being obvious to any mechanic without requiring a detailed description. It is merely necessary to place the grinder at the proper angle in the toolpost and drive the lathe and grinder in opposite directions. In this way, lathe centers can be ground in far less time than it takes to remove them from the machine, draw the temper and true them in the ordinary manner. The grinder is equipped with a 3½ by ½ inch wheel and the spindle runs in adjustable bearings. The motor develops 1/6 horsepower and drives the wheel at 6000 revolutions per minute. This grinder is adapted for use in any standard sized lathe and can be used for large internal and external work in addition to grinding centers.

Figs. 2 to 4 show another portable electric grinder of this company's manufacture engaged on three typical operations. In Fig. 2, the grinder is shown sharpening a cutter while in place on the milling-machine arbor. Used in this way, the tool is capable of producing very accurate results and saves the time necessary to take the cutter off the machine and set it up on a tool grinder. Fig. 3 shows the grinder engaged upon internal work. For this purpose, wheels

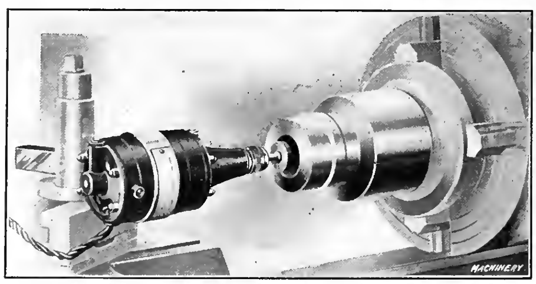

Fig. 3. Racine Toolpost Grinder engaged on Internal Work

ranging from ¼ inch to 2 inches in diameter can be used, and for very small work an extension is furnished. For work on which a very smooth surface is necessary, oil-stone wheels can be used. In Fig. 4 it will be seen that the grinder is mounted in the toolpost of a shaper and is engaged in grinding a plane surface. Many dies and other hardened pieces warp slightly during the heat-treatment, and by using the grinder in this way, a convenient means of eliminating such errors is provided.

The following gives a brief description of the construction of the motors used to drive these tools. The armature is built up of thin laminations of steel and is pressed onto a steel shaft which has been ground to an accurate finish. The windings are of double silk-covered wire and are thoroughly impregnated with insulating varnish. The commutator is built up from twenty-four hard-drawn copper segments separated by mica insulations. The brushes are made of carbon and provided with means for automatic adjustment. The armature spindle bearings are lined with babbitt of a special mixture adapted for high speed; after the babbitt lining has been put in the bearings, the motor casing is chucked in a screw machine and the bearings are reamed, burnished and faced. By this method perfect alignment of the bearings is insured. The motors are "universal" in that they are capable of operating on either alternating or direct current of 100 to 130 volts.

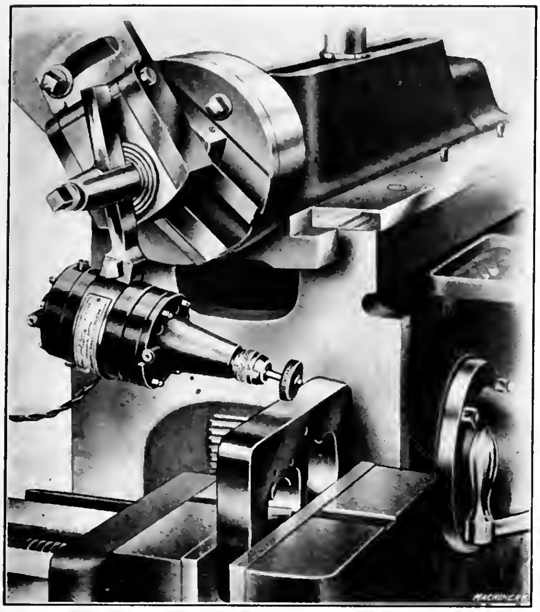

Fig. 4. Grinding a Plane Surface with the Racine Toolpost Grinder

DRESES SIX-FOOT UNIVERSAL RADIAL DRILL

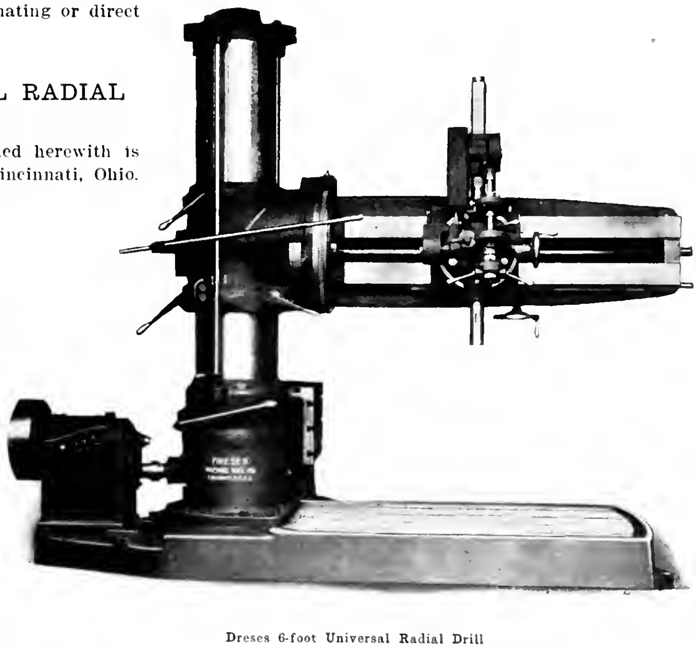
The six-foot universal radial drill illustrated herewith is a product of the Dreses Machine Tool Co., Cincinnati, Ohio. Referring to the illustration, it will be seen that the base is high and is provided with an oil groove running all the way around it. The oil drains into this groove which carries it away to a reservoir under the table. The outer column swings on a fixed inner column and both are made of particularly large size at the lower end to provide for the application of a roller bearing which supports the outer column. The inner column also carries an annular ball bearing at the top to insure an easy movement of the arm.

The arm is double webbed and strongly ribbed, and a shoe attached to the saddle and fitting between the two faces of the arm combines them into a solid box section when the saddle is clamped. The arm is lowered at twice the speed at which it is raised, and automatic knockouts are provided at either extreme of the travel. One of the special features of this machine consists of the design of the arm girdle. The socket which receives the arm is offset to one side of the center of the column to allow a long central shaft to be used in the head saddle and also to bring the spindle more nearly in line with the center of the column. The head is graduated for angular setting and can be swung through a complete circle.

The spindle is provided with twenty-one speeds and the quick advance and return mechanism has two handles, either of which instantly engages or disengages the feed. The feed mechanism is of novel design. A dial plate is provided on the feed shaft and makes one-quarter of a revolution for each revolution of the shaft, the movement of the dial being provided by means of planetary gearing and a pinion cut directly on the feed shaft. A fixed dog on the dial plate acts upon a lever and stops the feed automatically. There are eight changes of feed—four in a series—which are operated by the small handle on the left-hand side of the feed shaft, the number of feeds being multiplied by the horizontal handle above the handwheel.

The initial driving and speed mechanism is located at the rear of the arm girdle which simplifies the construction. The back gears are of the automobile transmission type, three changes being provided by means of the small lever at the front of the girdle which shifts the gears. The tapping, starting, stopping and reversing mechanism is of the friction type described in connection with one of this company's drills which was shown in the "New Machinery and Tools Section" of the November, 1911, number of MACHINERY. This mechanism is operated by the long telescopic lever which is always within reach of the workman. All of the gearing is completely enclosed and runs in oil.

The speed variator is of the well-known tumbler type; it has seven changes, and by means of a self-releasing overtake clutch the machine is run at the slowest speed when making changes in order to decrease the momentum and consequent shock as far as possible. All of the gears are hardened and the teeth are of the 20-degree involute pointed form to give added strength and to insure easy engagement. The pulley shaft has an annular ball bearing to reduce friction which would otherwise be very pronounced owing to the heavy lateral belt pull. All high-speed bearings are lined with removable bronze bushings and ball bearings are provided at points where the service is severe. Machines of this type are built in four-, five- and six-foot sizes and are furnished with cone, motor or speed variator drives to meet the requirements of different shops.



Dreses 6-foot Universal Radial Drill

DIAMOND FACE GRINDING MACHINE

The grinding machine shown in the accompanying illustrations is a recent product of the Diamond Machine Co., Providence, R. I., and is particularly adapted for grinding railway locomotive guide bars. By using the face of the 30-inch ring wheel with which this machine is equipped, the entire surface of the guide is ground at each traverse of the table. The machine is also well suited for a variety of heavy surface grinding operations.

One of the most interesting features of this machine is the method by which the reciprocating motion of the table is

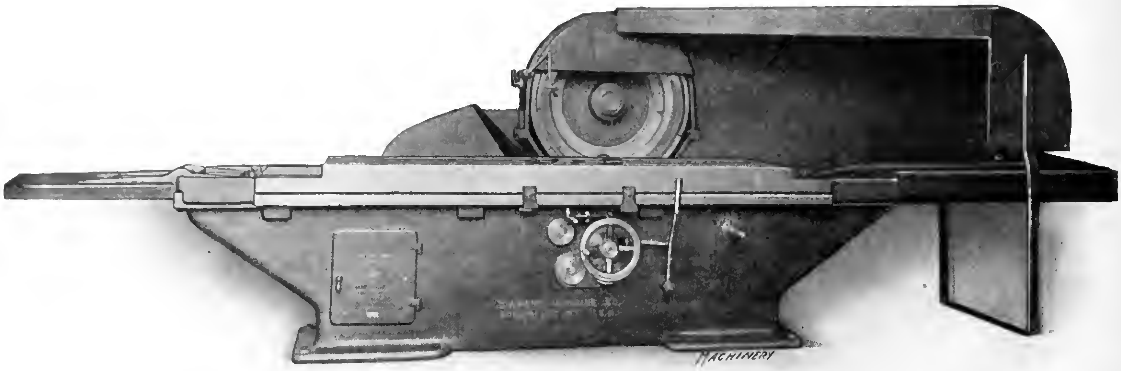


Fig. 1. Front View of Diamond Face Grinding Machine

obtained. The arrangement is similar to the familiar form of planer belt shifting mechanism, but has been modified to adapt it for use on a grinding machine. A three-step cone pulley fastened to the rear end of the spindle transmits power to an intermediate shaft on the right-hand side of the machine. From this intermediate shaft the drive is carried back to the left-hand side of the machine by means of

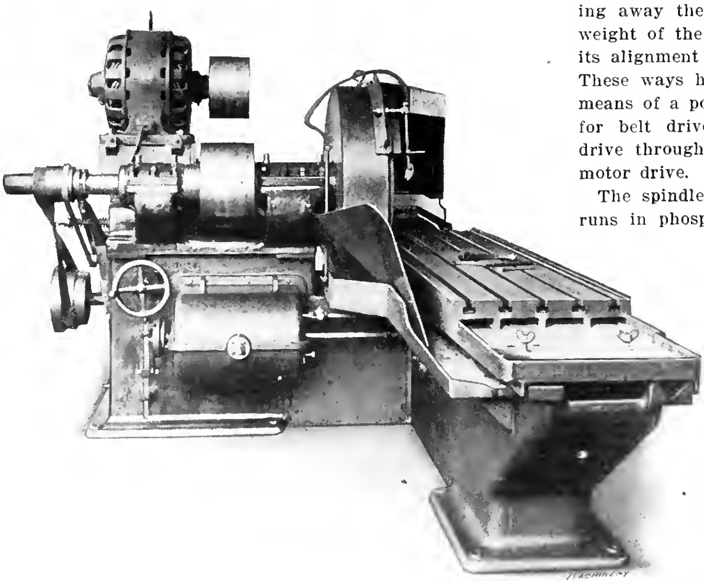

Fig. 2. Left-hand Side of Grinding Machine

two-inch open and crossed belts, which pass through the column to the table driving shaft. A detail of this construction is shown in Fig. 3, where it will be seen that two loose pulleys are arranged at each side of a tight pulley. So far the arrangement is similar to the planer drive, the distinctive feature lying in the fact that the dogs do not carry the shift of the belt but merely actuate the shifting mechanism. For this purpose a fourth pulley is loosely mounted on the table driving shaft, this pulley being driven from the intermediate shaft by means of an open belt. This pulley drives the spiral cam at its right-hand side by means of friction. When the tripping dogs come into action, the cam is released and carried through one-half revolution. During this movement the cam pulls over the lever which shifts the driving belts in the same way as on an ordinary planer drive. By this arrangement the shock of shifting is not felt by the table, and, at the same time, the operation of the mechanism is absolutely positive. The table drive is direct through a four-shaft reducing train.

The bed of the machine is of heavy construction and internally ribbed to give sufficient stiffness to prevent the slightest vibration when the machine is engaged upon heavy work. The ways are of ample proportions, a vee being used at the front and a flat bearing at the rear. The column is of the same form of ribbed construction as the bed, to which it is securely bolted. The table has five T-slots planed from the solid metal, and large runways are provided for draining away the water which is supplied to the wheel. The weight of the wheel-head is borne by the column ways, but its alignment is preserved by means of narrow inner ways. These ways have a taper gib and any play is taken up by means of a powerful spring. The machine may be arranged for belt drive from an overhead countershaft, for motor drive through a belt to the spindle, or for direct-connected motor drive.

The spindle is of 0.50 per cent carbon machine steel and runs in phosphor-bronze bushings which are cast in halves and provided with means for adjustment. These bearings are of ample size to insure permanent alignment. The thrust load is carried by a ball thrust bearing, and any end play which may develop is taken up by threaded collars. The wheel chuck is made of cast iron and carefully turned to insure perfect balance. The body of the chuck is tapered on the outside and slotted so that it may be compressed by a steel ring, which is drawn up on the taper by bolts to give the chuck a secure grip on the wheel. A backing plate, which is adjusted by means of studs, brings the wheel forward as it wears, and, in addition to serving this purpose, it affords additional support. A feature of this method of holding a ring wheel is that a narrow wheel, which removes the stock with less drag and heating, may be safely used.

Another feature of this machine is the provision for control from either the front or rear. This saves the time that is lost by the operator in walking around the machine or leaning over to watch the progress of the work. The customary procedure on work requiring a relatively long time for grinding is for the operator to place the work in position

and adjust the dogs for the required travel. He then goes around to the rear of the machine while the grinding is being done. Without the provision of control at the rear of the machine, it would be necessary to walk around to the front in order to stop the machine. The automatic feed is located at the rear of the machine, as this is the normal position for the operator when using this device. When two machines are used, they are usually placed back to back so that one operator can control both of them. The front and rear spindle bearings are lubricated by the ring-oiling system and the ways are grooved to facilitate oil travel. Oil pockets with broad rollers are also provided in the bed to insure efficient lubrication.

In face grinding the provision of an adequate supply of water for the wheel is of particular importance. The water performs three functions: it keeps the wheel clean so that it will cut freely at all times, it keeps the work cool and settles the dust. In order to provide an ample supply of water, this grinder is equipped with a centrifugal pump which is driven from the spindle by means of a cone pulley and belt. The stream of water is delivered diagonally onto the wheel, and the amount supplied can be adjusted to meet the requirements of different classes of work. It has already been mentioned that runways are provided in the table to carry away the water. These runways deliver it to troughs under the table from which the water flows into a settling tank where the emery and metal dust is removed. The clean water flows back to the main tank where it is ready to be delivered to the wheel as required. Water guards are fastened to the ends of the table and cover the ways at all times. A guard is also placed on the left-hand side of the machine; this guard is close to the hood and in front of the rear control, thus completely preventing the water being splashed onto the operator. The main water guard is located on the right of the machine and catches all water that is thrown off by the wheel. This guard empties into a water trough.

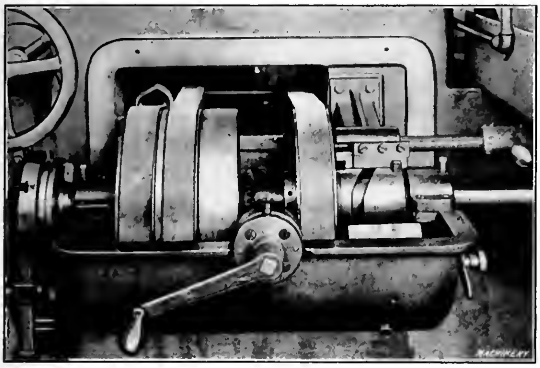

Fig. 3. Belt-shifting Mechanism of Diamond Grinding Machine

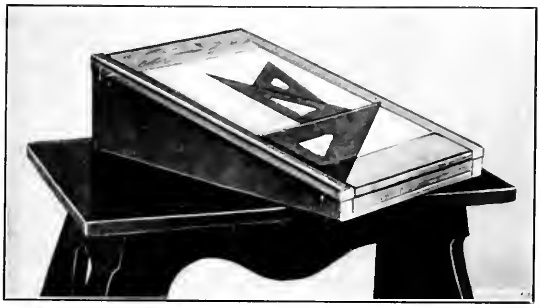
DOWD "NO-TACK" SKETCHING BOARD

An entirely new idea in the way of a drawing or sketching board is being placed on the market by Albert A. Dowd, Bridgeport, Conn., and the illustration shown herewith gives a general idea of its appearance. This board was primarily designed for the use of estimators, engineers, chief draftsmen, and tool designers, but it is also very convenient for others having occasion to make small drawings or free-hand sketches. A notable feature of the board is its freedom from obstructions of any kind, no thumb-tacks being necessary to hold the paper in position. This point will be appreciated by those using the ordinary type of small drawing board in which the protruding thumb-tack heads are a great nuisance, giving continual trouble by interfering with the free use of the T-square and triangles. No T-square is needed for this board, as the mahogany straightedge along the left-hand side is trued up along its inner side so that a large triangle may be placed against it, and used in place of the T-square. It will be noted by referring to the illustration, that the straightedge extends far enough below the end of the paper to insure a good bearing for the triangle, even when work is being done at the extreme lower edge.

The board is made in one size only, for drawings 9 by 12 inches or smaller, and the paper is carried on a roll underneath the upper end of the board or it may be used in small sheets if desired. Space is provided to accommodate a fifty-yard roll of paper. When it is used in the roll, the paper is pulled up through the spring actuated wing at the top of the board and drawn down across it and through the slot at the bottom, where there is another wing similar to that above. Rubber disks are inserted in the edges of these wings and they hold the paper in such a way that it may be stretched as tightly as a drum-head. The convenience of the board and the rapidity with which drawings and sketches may be made upon it are points which will find favor with those using it.



Dowd "No-Tack" Drawing Board for making Rapid Sketches

INDUSTRIAL PEN LIFTER

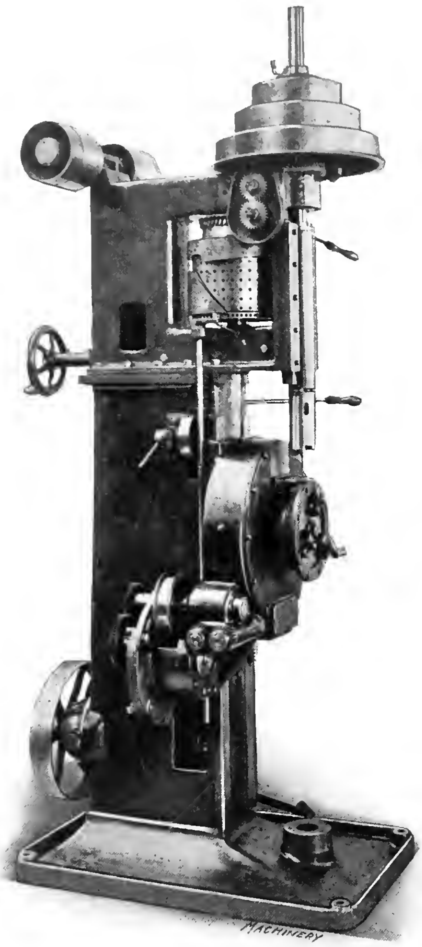
The Industrial Instrument Co., Foxboro, Mass., has just perfected a new attachment for use on the recording meters of its manufacture. This attachment is styled an automatic release pen lifter and is illustrated herewith. It is a simple device consisting of a strip of German silver pivoted on a holder, which is secured by one of the screws that holds the chart disk. By exerting a slight pressure on a small lever, this strip of German silver is raised and lifts the pen out of contact with the chart. The lifting device is held up by friction, so that both of the operator's hands are left free to remove the chart and place a fresh one in its place. When the door of the meter is closed, the pen arm is automatically released and the pen returns to its marking position on the chart. This automatic feature makes it impossible for the operator to leave the instrument out of commission. In addition to the convenience of this attachment when changing charts, its use does away with the necessity of handling the pen arm, and the consequent danger of straining it and thus affecting the accuracy of the instrument.

Pen Lifter for use on Industrial Recording Gages and Meters

BAKER AUTOMATIC DRILLING MACHINE

The accompanying illustration shows a development of the automatic drilling machine built by Baker Bros., Toledo, Ohio, which is intended for drilling radial holes in a flange or similar part. The operation of this machine is entirely automatic, the spindle being fed in to the work and returned by means of the cams located near the top of the machine, while the indexing is done by an index plate and change gears. Any number of divisions may be obtained. For this purpose it is, of course, necessary to set the change gears. After this adjustment has been made, it is merely necessary for the operator to remove the finished piece and replace it by a fresh blank.

The illustration shows the machine set up for drilling twenty-four radial holes in a flange, these holes being 7/16



Baker Bros. Automatic Drill for drilling Radial Holes in Flanges

inch in diameter by 7/16 inch deep. During a recent test to which this machine was subjected in the manufacturers' shops, the holes were drilled in a twenty-four hole flange in fifty-five seconds. From this it will be evident that the operation of the machine is very rapid, and the design is such that the holes are accurately spaced without requiring the use of a jig. The capacity of the machine is for flanges ranging from 3 to 24 inches in diameter. In addition to drilling radial holes in flanges and similar classes of work, the machine can be arranged to drill individual pieces held in a series of chucks mounted on the periphery of a disk. This machine is equipped with radial ball bearings which reduce friction and make it well adapted for operation at high speed.

NIAGARA FOLDER AND BENDING BRAKE

The folder and bending brake illustrated in Fig. 1 is a recent product of the Niagara Machine & Tool Works, Buffalo, N. Y. Examples of the bends which can be made on this machine are illustrated in Fig. 2, from which it will be seen that a large variety of work can be handled. Close edges can be turned for making lock seams and work with circular bends can be formed with equal facility. The machine can

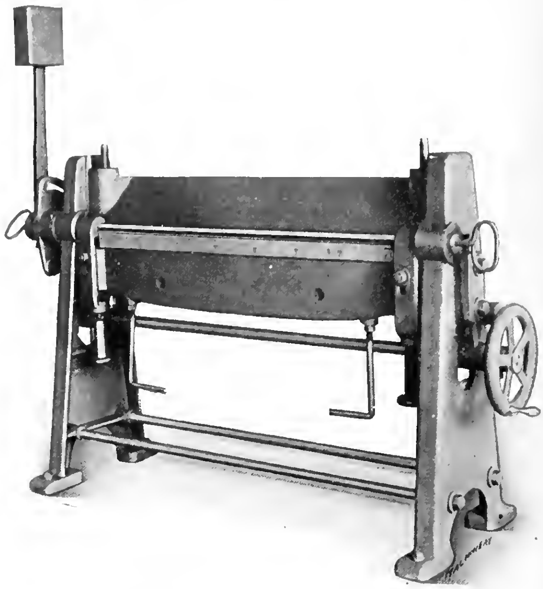


Fig. 1. Niagara Folder and Bending Brake

also be used as an ordinary bending brake, and tubes can be formed over a mandrel of suitable diameter. The production of circular bends is accomplished by mounting the folding and lower clamping bars in such a way they can be set up 2 inches below the folding axis. This adjustment is obtained by means of bevel gears and screws actuated by a handwheel, both ends of the clamping bar being adjusted at the same time. The ends of the folding bar are adjusted separately by means of screws. The upper clamping bar can be

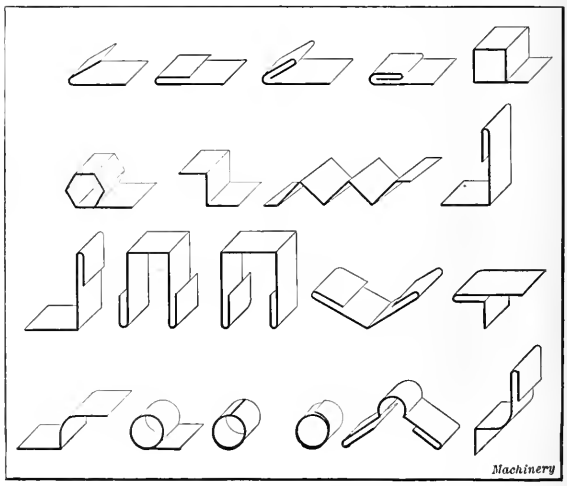

Fig. 2. Examples of Work done on Niagara Machine

raised to a height of 4 inches above the folding axis, thus affording ample space for a variety of sizes of mandrels about which the work is to be formed.

The construction of the machine is simple and rigid, the proportions being such that no tie-rods are necessary. A quadrant gage is provided at the left-hand end of the machine and is equipped with adjustable stops to regulate the motion

of the folding bar. The edge of the regular folding bar is ⅜ inch wide and a removable angle shaped bar is provided for forming heavy material. The folding bar is so attached to the upper clamping bar that it may be instantly removed.

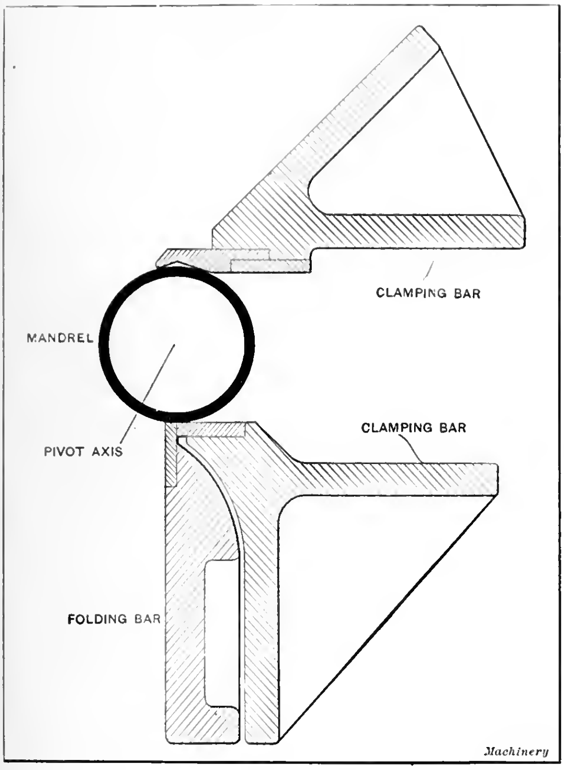

Fig. 3. Cross-sectional View through Clamping and Folding Bars arranged for Circular Bends

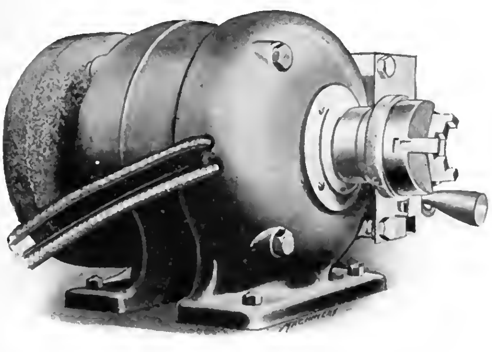
Using the ⅜-inch edge of the folding bar, the machine will handle stock up to 18 gage, while the use of the angle shaped bar increases the capacity up to 16 gage stock.

FORBES & MYERS POLISHING MACHINE

Forbes & Myers, Worcester, Mass., have recently added to their line the electrically driven polishing machine illustrated herewith. This machine is designed for finishing small parts which can be held in either a 2-inch scroll chuck or a ½-inch spring chuck with which the machine is equipped.



Forbes & Myers Combination Polishing, Grinding and Buffing Machine

The illustration shows the machine with a chuck at one end of the spindle and a small grinding wheel at the opposite end. This makes a useful form of equipment, but when so desired either a buffing wheel or a second chuck can be mounted in place of the grinding wheel.

The motor is of the same type that is used on the standard motor-driven grinders of this company's manufacture. It is of the squirrel-cage induction type and is capable of furnishing ½ horsepower intermittently, as in the case of ordinary polishing work. The motor is suitable for use on two or three phase sixty-cycle circuits of any voltage. The customary operating speed is 3600 revolutions per minute, but when so desired these machines are built with motors running at 1800 revolutions per minute. The motor is started or stopped by means of a switch lever, and in stopping, this lever applies a brake at the same time that it breaks the electric circuit. This automatic brake action adds greatly to the productive capacity of the machine, as it does away with the necessity of waiting for the spindle to come to a stop.

BROWN ELECTRIC PYROMETER

Fig. 1 shows an electric pyrometer for measuring temperatures up to 3300 degrees F., which has been brought out by the Brown Instrument Co., Philadelphia, Pa., and an instrument is shown in Fig. 2 with the case removed in order to give an idea of the construction of the mechanism. The distinctive features of this pyrometer are that the spindle which carries the indicating needle is mounted in jeweled

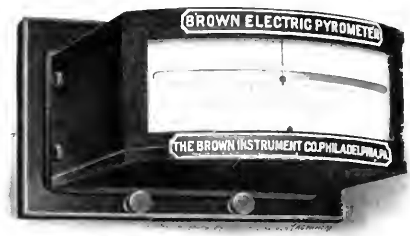


Fig. 1. High Resistance Type of Brown Electric Pyrometer

bearings and that the resistance of the instrument is made sufficiently high so that changes in the lengths of the leads running from the thermocouple to the instrument do not affect the accuracy of the indications.

The resistance of the instrument is about 100 ohms and changes of from 1 to 1000 feet in the lengths of the leads will not affect the indications as much as 5 degrees F. Changes in the temperature of the leads are also of no

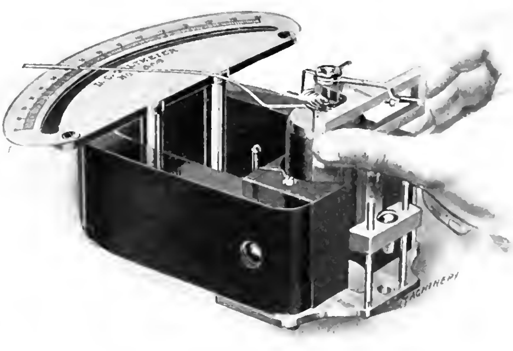

Fig. 2. Brown Pyrometer with Case removed to show the Mechanism

importance. This is due to the fact that the resistance of the instrument is very high as compared with the resistance of the leads. By having the moving element mounted in jeweled bearings, the instrument is also made more serviceable for shop use, as it is not easily damaged and does not have to be placed quite level in order to give accurate results. The scale is made of sufficient length to give the necessary interval between graduations and a mirror is provided under the scale in order to enable the needle to be lined up with its image. These two features facilitate making accurate readings.

OESTERLEIN UNIVERSAL AND PLAIN MILLING MACHINES

The universal and plain millers illustrated in Figs. 1 and 2 are representative members of a new line of milling machines which has been placed on the market by the Oesterlein Machine Co., Cincinnati, Ohio. They are known as "Ohio" milling machines and each style is built in five different sizes. One of the distinctive features of these machines lies in the fact that the heavy table and knee of the plain type of milling machine has been adapted for use on the universal machines. Practically the only difference between the plain and universal machines lies in the addition of the swivel saddle and table in the latter case. This arrangement has effected a great saving in the cost of production, as it is only necessary to provide jigs and fixtures for the manufacture of a single machine.

Universal milling machines are generally required to handle a variety of tool-room work. In order to adapt the present machines for this class of service, the construction has been worked out along lines which provide ample rigidity so that there is no vibration when taking heavy cuts on tool steel. As the ability to turn out work rapidly is proportional

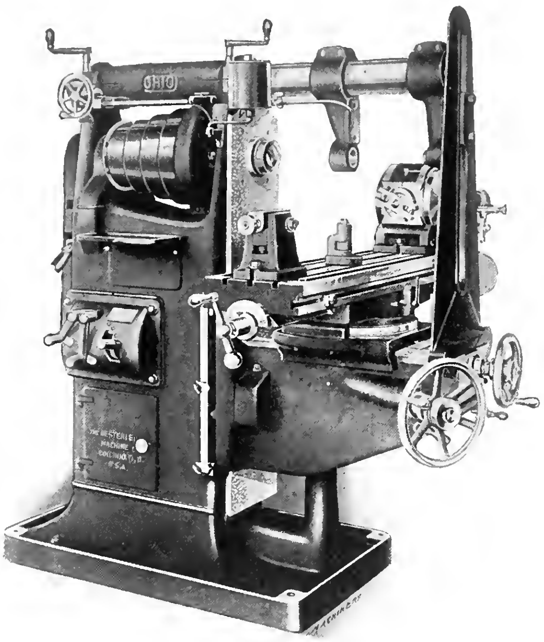

Fig. 1. Oesterlein Universal Milling Machine

to the amount of power delivered to the cutter, the provision of a cone with large belt contact, which is backed up by a construction of adequate rigidity, assures efficient operation and a high rate of output. In connection with the design of the universal machines, it may be mentioned that the swivel is clamped to the saddle in such a way that there is no possibility of movement. Oil pads and grooves are provided for lubricating the bearing surface of the swivel and table.

The plain milling machines of this line are essentially manufacturing machines. In order to make them well suited for this class of service, a number of features have been embodied in the design which add to the efficiency with which the machines operate. Among these, the belt shifting device which enables any speed to be instantly obtained is an important feature. The design of this belt shifting mechanism will be described in detail in a later paragraph, but it may be mentioned here that the method of operation is so simple that the workman will not hesitate to run his machine at the most suitable speed for the work upon which it is engaged.

Having touched upon the general characteristics of this line of milling machines and the distinctive features of the plain and universal types, a detailed description will now be given of different parts of the mechanism which are common to both the plain and universal machines. This can be conveniently done by following the course by which power is transmitted from the countershaft to the spindle and feed mechanism. Figs. 3 and 4 illustrate the arrangement of the cone-pulley and the countershaft, and clearly show the mechanism by which the belt is shifted. One complete turn of the handwheel on the machine shifts the belt from the center of one step on the cone-pulley to the center of the next step. A

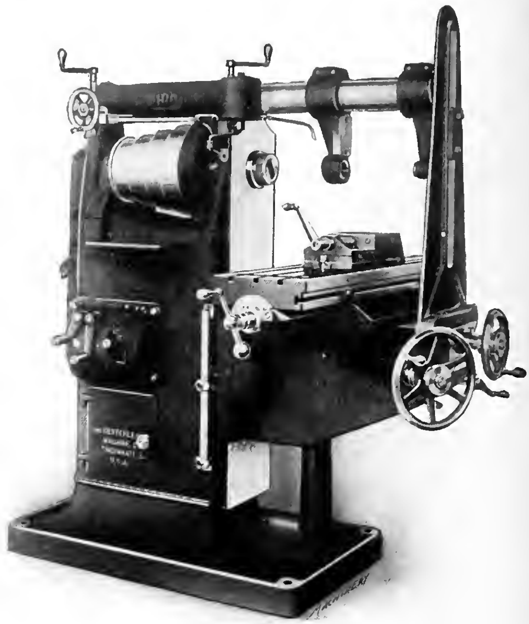

Fig. 2. Oesterlein Plain Milling Machine

simple lever equipped with a straight line motion shifts the belt to the desired position on the countershaft. By this means the required speed is obtained at once, without the necessity of making any intermediate changes. The operation of the mechanism is so simple that it is quite safe for an unskilled workman to make the change without any danger of damage to the machine. It will be noticed from the illustrations that there is but a slight difference in the diameter of adjacent steps on the cone pulley.

The spindle is made of special steel and runs in bronze journals which are lubricated by oil supplied from reservoirs

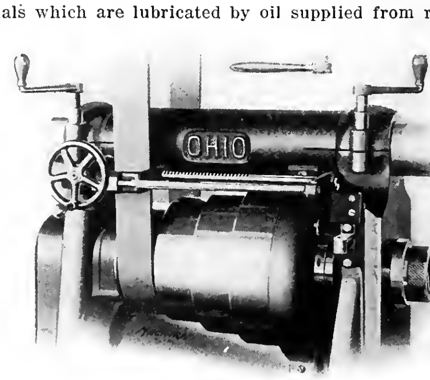

Fig. 3. Belt Shifting Mechanism on Oesterlein Millers

in the column. It will be noticed from the illustrations that the spindle nose is recessed, the purpose being to provide a positive drive for the cutter arbor. An adjustable bronze bearing 3 inches in length provides the front support for the arbor and an intermediate bracket is furnished for use when the machine is engaged upon extremely heavy cutting;

this bracket supports the arbor at a point close to the milling cutter. The back gear is mounted on a shaft inside the column of the machine. The gears are all cut with single-purpose, 14½-degree cutters which assures silent operation under all conditions.

The feed mechanism is driven from the spindle by means of a Diamond steel chain, the interior of the feed box being shown in Fig. 5. All gears and shafts in this box are of hardened steel and the shafts run in bronze bearings. The gears run in oil so that ample lubrication is assured. Two gears are keyed to the sprocket shaft and either of these gears can be engaged with the tumbler shaft. From this shaft, the drive is across the cone of gears to either sliding gear on the rear shaft, from which power is transmitted to the reverse gears in the knee by means of a universal joint. At this point, all of the feeds may be reversed by a lever on the front of the knee. The feed is carried from the knee through the saddle to the lead-screw.

A detailed view of the table and knee is shown in Fig. 6, from which it will be seen that the table has a bearing across

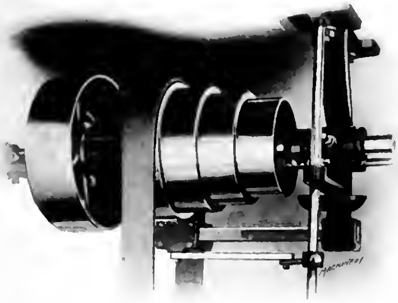

Fig. 4. Countershaft and Belt Shifter for Oesterlein Millers

its entire width. Ball bearings take the thrust of the table and means are provided for taking up any wear which may be developed in the table bearings. The table is supported by an exceptionally rigid saddle and knee, and as the construction is identical for both the plain and universal milling machines, the dividing head may be attached to either type of machine without disturbing the quick return mechanism.

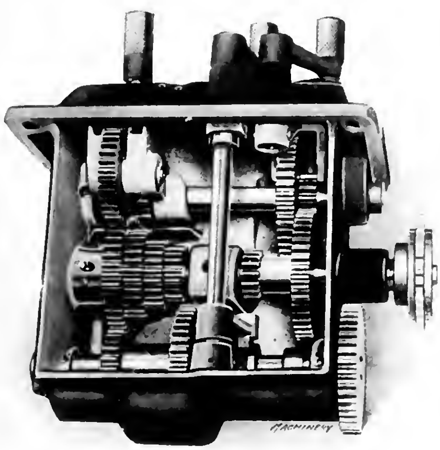

Fig. 5. Feed Box used on the Oesterlein Millers

Cross and vertical adjustments are made by means of handwheels that may be disengaged by means of clutch collars at the front of the wheels, so that the settings cannot be disturbed. Dials reading to 0.001 inch provide for accurate settings of the table and saddle. The knee is of heavy box section and stoutly ribbed to give adequate support to the table. When a setting is made, the knee may be locked to the column by means of a sliding taper gib which extends the entire length of the knee and is controlled from the front of the machine. The entire length and width of the table is used as a working surface.

The spiral dividing centers used on these machines are carefully tested before leaving the factory so that their accuracy is assured. The index crank is mounted directly on the worm-shaft instead of being connected by gearing. Without the use of tools, the spindle may be instantly freed so that it may be revolved by hand for direct indexing, the spacing being read by graduations on the flange of the spindle nose.

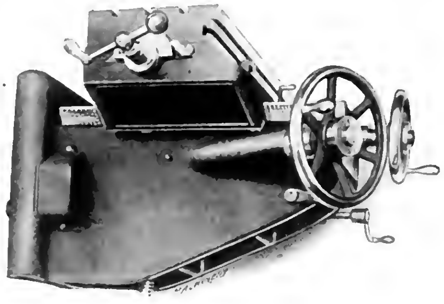

Fig. 6. Knee and Table of the Oesterlein Millers

PEDRICK PORTABLE TURNING MACHINE

The illustrations show several applications of a portable turning machine which has recently been placed on the market by the Pedrick Tool & Machine Co., 3639 Lawrence St., Philadelphia, Pa. This machine may be used for a variety of purposes, among which turning crankpins of locomotives and other side crank engines; turning center crankpins, journals, shafts and axles, and reboring crankpin holes may be mentioned. In most cases, it is not necessary to remove a crankshaft or other piece from its regular position on an engine, in order to true it up on this machine.

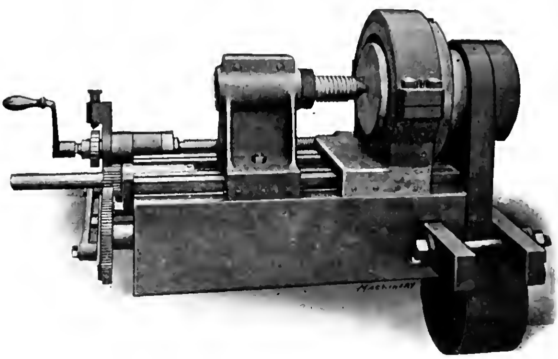

Fig. 1. Pedrick Machine set up for truing a Side Crankpin

Space is provided at the front end of the machine for clamping bars and other means of attachment to the work. The feed-screw is located at the back of the machine and is actuated by a ratchet and pawl mechanism of simple design. Variable and reversible automatic feeds are obtained. The crankshaft shown in the illustration provides for quick return of the cutter-slide and is also used for setting the tool against the work. The driving shaft is located beneath the cutter-head, where it is supported by bearings of ample dimensions. This position of the shaft permits a lighter construction to be used than would otherwise be possible and also adds to the convenience with which the drive may be taken from a motor mounted on a bracket attached to the frame of the machine.

The cutter-head is split to enable it to be put over the shaft or other member that is to be trued up while in position on a machine. The design of the cutter-head has been worked out in such a way that the split construction does not weaken it. The tailstock may be located at any point

along the bed to meet the requirements of different classes of work. When using the machine for reboring crankpin holes, the tailstock is placed in front of the cutter-head, in which position it affords a rigid guide for the boring-bar. The setting-heads are bored concentric with the center of the machine and are provided with set-screws by which the machine can be attached to an unworn part or set according to the center in the tailstock to secure the desired alignment. In cases where the work extends over the driving shaft so that a pulley cannot be used, the machine may be driven by a telescopic shaft with universal joints.

Five typical operations performed on this machine are shown in the accompanying illustrations. Fig. 1 shows the ordinary equipment used for truing up a side crankpin in its regular position. In this case, the movable tailstock with its adjustable center is placed in position, the adjustment of the tailstock adapting the machine for work of different lengths. Fig. 2 illustrates the machine set up for reboring crankpin holes after the crankpin has been removed. It will be seen that the tailstock is placed in front of the cutter-head. In this case, the cutter-head is only used to drive and feed the boring bar which is supported by the tailstock.

Fig. 3 shows the equipment used for truing up center crankpins. For this purpose, the mechanic lays off and drills centering holes for the pin on the outside of the cheeks of

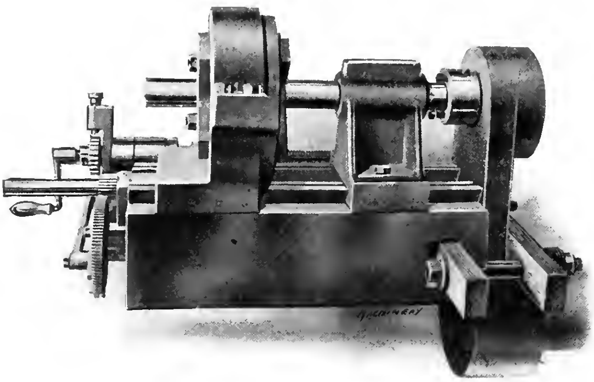

Fig. 2. Reboring Crankpin Hole on Pedrick Machine

the crank. The machine is then set up with two tailstocks which engage in these centering holes. Cutting tools can be used on either side of the cutter-head and where the distance between the cheeks is small, the cut may be started at the middle of the pin and run over to one side. The tools are then placed on the opposite side of the cutter-head and run across to the other cheek of the crankshaft.

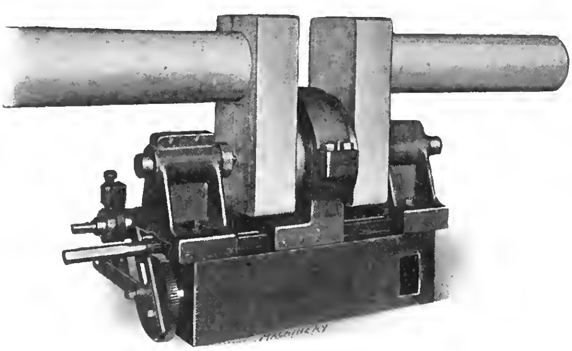

Fig. 3. Truing up a Center Crankpin

Fig. 4 shows the application of the machine for truing up large shafts, axles and similar parts. For this purpose, it will be seen that the machine is equipped with two setting-heads and a cutter-head. These three parts are all split so that they may be placed around the shaft regardless of any obstructions at either end. The machine may be fitted to the work by set-screws in the setting-heads or by making two sleeves with outside diameters the same as the diameter of the setting-heads and inside diameters the same as the shaft which is to be turned. In case the latter method is used, the sleeves are split and placed around the shaft, after which the machine is set up in the usual way. The setting-heads are bored concentric with the machine, thus providing the necessary alignment.

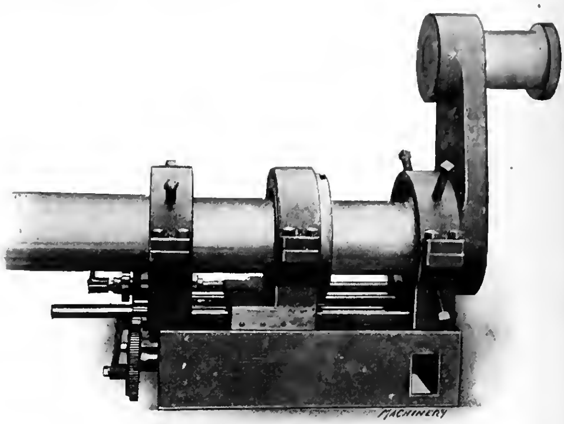

Fig. 4. Truing up a Large Shaft

Fig. 5 shows the arrangement employed for truing up the main bearing of an engine crankshaft or similar part. By referring to this illustration, it will be seen that the obstruction at either end of the shaft did not prevent the machine being used, due to the fact that setting- and cutter-heads are not slipped over the shaft, but placed around it. In some cases the machine will be worked upside down when there is not sufficient room for the bed of the machine between the pedestal and the crank-cheek or for similar reasons. This does not affect the accuracy of the work which is produced.

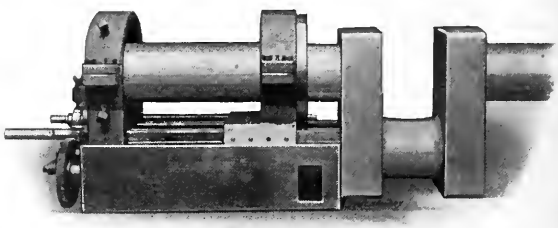

Fig. 5. Truing the Bearings of an Engine Crank

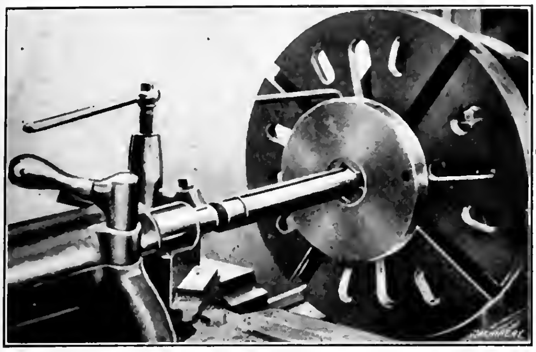
A study of the illustrations will doubtless suggest a variety of other purposes for which this machine is suitable, the illustrations merely showing a few typical operations for which it is adapted.

ONEIDA NATIONAL SAFETY LATHE DOG

The Oneida National Chuck Co., Oneida, N. Y., is now manufacturing the safety lathe dog illustrated herewith. This dog has been designed with the view of guarding all projecting parts, so that it is impossible for the operator's clothing to be caught or for him to be struck by set-screws, etc. This dog is made with hardened steel jaws which are tightened on the work by means of hardened steel adjusting screws. Two springs provide for opening the jaws when the screws are released.

The entire mechanism is enclosed in a pressed steel case, the construction being clearly shown in the illustration. This case is screwed onto the body of the dog and holes are provided through which the adjusting screws can be manipulated. These holes are large enough to admit the adjusting wrench but are not large enough to pass the screws, so that it is impossible for them to project through the cover. The driver is protected at the rear of the dog.

Two holes are provided through which the guard can be bolted to the lathe faceplate. This saves the time that would be lost in changing when duplicate parts are being machined, as the dog is held in a central position ready to receive successive pieces. This arrangement is the means of effecting

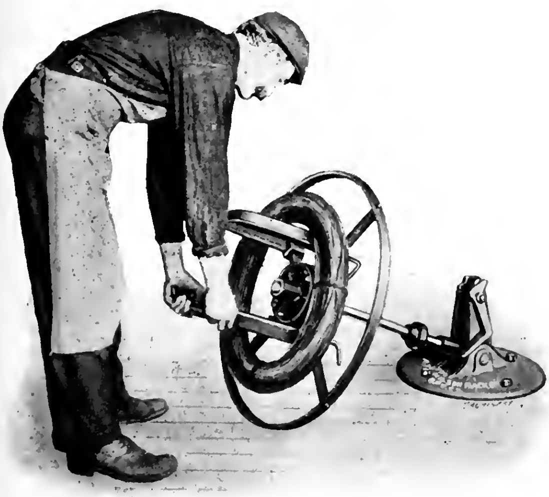


Oneida Safety Lathe Dog showing use of Wrench to tighten Jaws

a material saving of time in the production of repetition work. The assurance of safety afforded by this dog also adds to the normal rate of production of a workman as he is not kept on the "lookout" to prevent being injured.

NILSON TILTING WIRE REEL

In using the ordinary type of wire reel in connection with wire-forming machines and presses, it is difficult to place heavy coils of wire on the coil-holder. This is due to the fact that the coil-holder is fixed in a horizontal plane and at a distance of two or three feet from the floor. In order to place a heavy coil of wire on the reel two men are generally required to lift it into the required position.

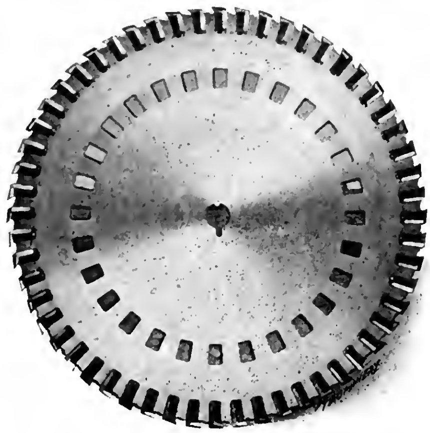


Nilson Wire Reel which facilitates placing Coils of Wire in Position

The A. H. Nilson Machine Co., Bridgeport, Conn., has brought out a reel which is designed to avoid these difficulties. Referring to the illustration, it will be seen that the standard which carries the reel is constructed in such a way that it can be tilted over to enable a coil of wire to be slipped onto the reel. When the reel is tilted over in this way, the coil can be rolled along the floor and put in place on the reel without requiring the services of more than one man. The illustration shows the reel on which a coil of wire has been mounted and the workman is about to lift it back into the operating position. When the reel is brought back to the vertical position it is automatically locked, and is thus ready for use. In order to tilt the reel over to put a new coil in place, the locking mechanism is released by means of a treadle which will be seen at the side of the machine close to the base.

HUNTER INSERTED TOOTH SAW BLADE

The Hunter Saw & Machine Co., Pittsburg, Pa., has recently brought out an inserted tooth saw blade suitable for use on sprocket-driven machines such as the Higley, Lea Simplex, and Lea-Courtenay machines. Heretofore this type of blade has not been adopted for use on sprocket-driven machines, owing to the fact that the teeth were so far apart that the operation of the machine was "jerky" when cutting the smaller sections. It was also considered impracticable to make a blade thick enough to withstand the strain at the sprocket holes and still operate without requiring the power of the machine to be increased. These objections have been overcome in the present design of blade, which has an ample number of teeth to insure smooth operation and is made



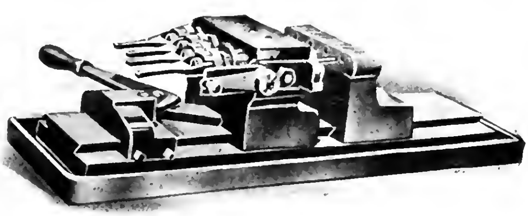
Hunter Inserted Tooth Saw Blade for Sprocket Drive Machines

thin enough so that the power required to drive the saw is not abnormal.

The body of the saw is made of heat-treated vanadium steel quenched in oil. This greatly reduces any chance of the tool pockets spreading or of the sprocket holes becoming distorted. The saw teeth are made of high-speed steel. A tool steel wedge is placed at the back of each tooth to hold it securely in place, and a brass screw is fitted in the body of the saw beneath each tooth to provide for regulating the height of the teeth. These saw blades are suitable for cutting structural steel, forgings, steel castings and a variety of other classes of work.

BICKFORD TAP FLUTING ATTACHMENT

The illustration shows a milling machine attachment for fluting machine screw taps which has been added to the line of the Bickford Machine Co., Greenfield, Mass. It will be seen that four taps are fluted simultaneously; the taps are



Bickford Milling Machine Attachment for fluting Machine Screw Taps

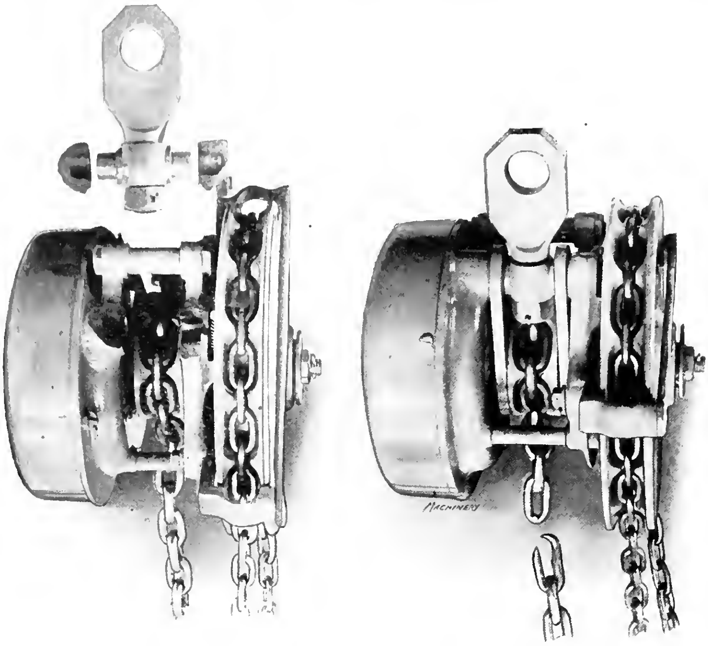
held in spring chucks with their point ends supported in bushings. The regular head center block is used and the indexing is accomplished by either a complete or a half turn of the crank.

The chucks are opened by raising the levers which are

seen projecting from the rear of the fixture. The head center block is operated by a lever after the taps are tightened in the chucks, thus bringing them into the bushings which are grooved to admit the fluting cutters. Small centers inside the spring chucks receive the end thrust. The attachment can be used on any milling machine.

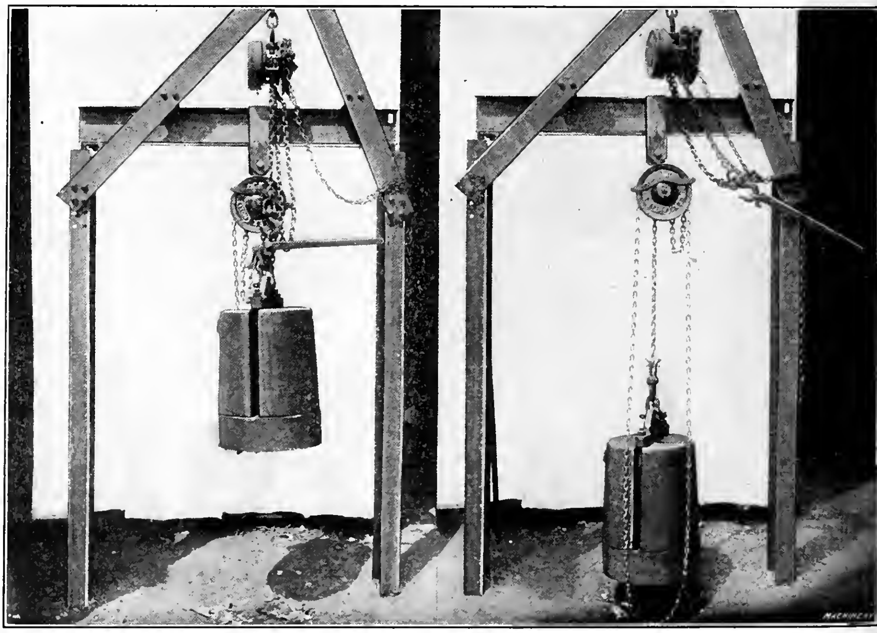
YALE TRIPLEX BLOCK

Owing to the constantly increasing tendency to speed-up the work in manufacturing plants, the need of equipment of greater strength becomes more and more urgent. When working fast, the operators are bound to exercise less care and provision must be made to avoid accidents due to the failure of the equipment.



Figs. 1 and 2. Shock Tests on Cast-iron and Steel Blocks showing Relative Strength

In order to obtain greater strength and safety in operation, the Yale & Towne Mfg. Co., 9 E. 40th St., New York City, has designed the Yale triplex hoist which is from hook to hook a line of steel. Fig. 1 shows a one-ton cast suspension block. This block was tested by raising a load of one ton on an auxiliary hoist and allowing it to drop in such a way that the shock came full upon the block. In the test illustrated, the load was dropped from a height of 16 inches and it will be seen that the cast-iron suspension member broke, although the chain is still intact. The Yale triplex block of steel construction is shown in Fig. 2. This block was tested in the manner previously described, and the one-ton load dropped from a height of 26 inches without injury to the gears and suspension plates. The only part affected was the load chain. This will withstand a drop test of 25 inches, however.



Figs. 3 and 4. Method of making the Shock Test

The method by which these tests are made is clearly illustrated in Figs. 3 and 4 where the arrangement of the auxiliary hoist and the location of the weight before and after the test are clearly shown. It will be seen that the top and bottom hooks were replaced by suspension eyes in making these tests. This is due to the fact that the hooks are designed in such a way that they start to open when subjected to a load of three times the rated capacity of the hoist. This arrangement has been adopted to constitute a safety device which will protect the equipment from damage that might be caused through careless operation.

The Yale & Towne Mfg. Co. has adopted the use of the long ton (2240 pounds) in rating hoisting equipment for two reasons. For equipment sold in the United States, ratings based upon the long ton are entirely satisfactory as such a rating merely affords a greater factor of safety. In England and several European countries, the long ton is in general use and consequently it is desirable to have equipment sold in such countries rated upon this basis. The mechanical efficiency of this hoist is such that a pull of 82 pounds by the workman is sufficient to lift 2000 pounds. In operating the hoist, 31 feet of chain are pulled through the block in order to lift the weight 1 foot.

NILSON FOUR-SLIDE WIRE FORMING MACHINE

In bringing out the new four-slide wire forming machine, the A. H. Nilson Machine Co. of Bridgeport, Conn., has incorporated a number of features new to this class of machinery. In general, the design of the machine is similar to that of other machines of this type, as will be noticed from the halftone illustration Fig. 1. By referring to Fig. 2, however, it will be seen that the distribution of the working members over the top of the frame is slightly different from the usual arrangement. The forming opening is at the center and

ll of the forming slides are of the same length or prac-
ically so. On most other machines the right-hand and ack slides are made considerably shorter owing to the act that the feed, grip and cut-off mechanisms require o much room that the slide space is thrown over to the ight and back of the machine. The slides are indicated t *A*, *B*, *C* and *D* in Fig. 2, and it will be seen that they ave long and equal bearing surfaces. They are supported ver their entire length by extensions from the bed. On each lide is cast an oil reservoir which furnishes a constant

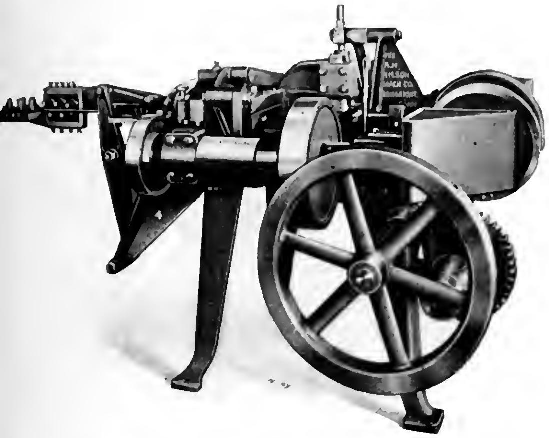


Fig. 1. Nilson Four-slide Wire Forming Machine

upply of lubricant for the cam roll studs. From Fig. 2 it vill also be seen that the forces which act upon the wire ine, namely, the feed, grip, etc., are as far as possible, n direct alignment; this is especially true of the feed it-elf. The wire line is indicated at *E*, and it will be seen hat none of the forces that act upon it are far removed from his line. The feed will be described in detail later on.

Referring to Fig. 3, which shows the plan view of this nachine, the idea of the central location of the four slides s clearly shown. As in other machines, the four cam-hafts are at the sides of the bed. The cams that operate

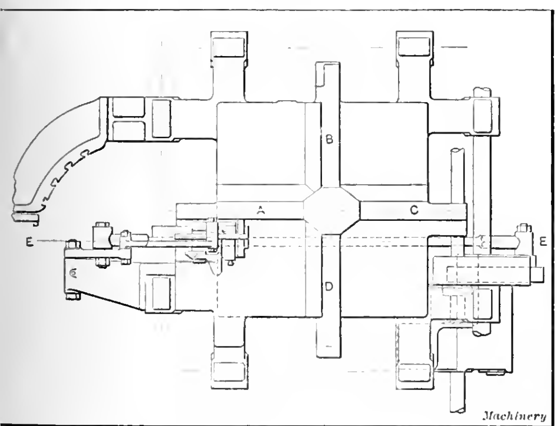

Fig. 2. Arrangement of Slides on Nilson Wire Forming Machine

the four slides of the Nilson machine are lined with tool steel plates, which give long wear and greater accuracy to the movements of the machine. The former bracket which is shown at the upper right-hand corner of the bed is particularly open in its design, being supported so that it overhangs the rear slides and does not in any way conflict with the adjustment or operation of the tools. The stripper lever, which is operated through the former, is carried on an independent bracket. Into this fits a block which holds the stripper pin. As the block is held in the yoke of the stripper lever, a better balance is secured, and the tools will operate with less vibration than with the old style of side connection. The stripper lever and bracket are illustrated in Fig. 5

The grip and feed may be seen in Fig. 3, but they are best illustrated in Fig. 4. Here the feed operating rod is shown at *A*; this is the same rod that may be seen directly beneath the wire line, extending over to the right-hand side of the machine in Fig. 2. It should be especially noticed that this rod is in direct line with the wire; the rod is operated through a geared connection with the driving wheel which is shown in Fig. 1 at the lower right-hand corner. Instead of the offset bracket which is usually employed for operating the feed on wire forming machines, the Nilson machine uses a practically straight line lever shown at *B* in Fig. 4, whereby all cramping action of the old-time feed movement is eliminated. From this lever the force is transmitted to the

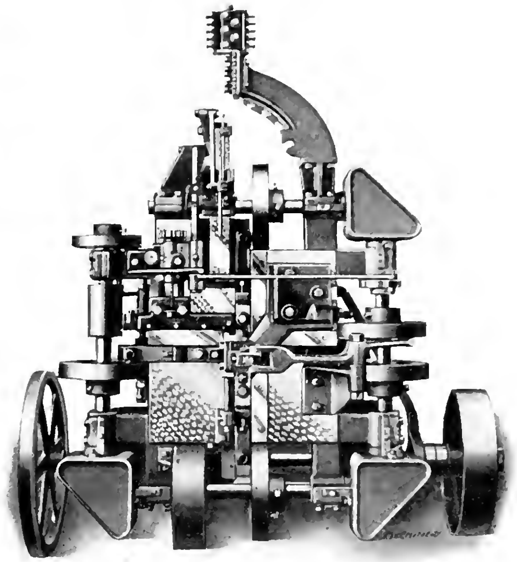

Fig. 3. Plan View of Wire Forming Machine

smaller lever *C*, which operates directly upon the wire-feeding mechanism. The feed finger *D* may be thrown out of engagement with the wire at any time by simply operating the spindle *E*, which is in an accessible position near the front of the machine. This feature of disengaging the wire feed with a plunger is quite novel. Upon the cut-off bracket is mounted the gripping lever that may be seen extending over to the rear cam-shaft of the machine. The cam on this shaft operates the gripping mechanism in the usual manner. The cut-off adjustment is secured in a very satisfactory way by means of a handwheel, which may be seen at the left of

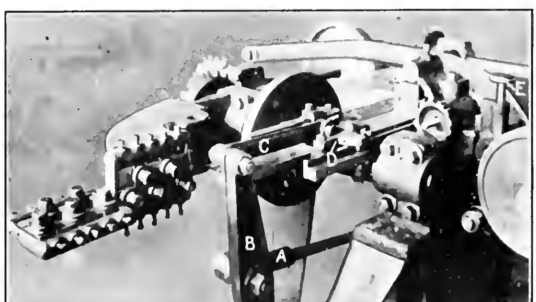

Fig. 4. View of Gripping and Feed Mechanism

the bracket. This handwheel operates the screw so that a very close adjustment of the feed may be obtained without resorting to guesswork.

Another interesting feature is the lever by which the cut-off blade is operated. Cut-off movements on wire forming machines have usually been unsatisfactory because the action

given to the cut-off blade has not been in line with the action of the tool. The cut-off must necessarily be above the line of the cam-shaft. This means that a bent cut-off slide and inefficient movement had to be used. The cut-off mechanism of the Nilson machine is clearly shown in Fig. 6. Here the cut-off slide is shown at *A*, and the operating cam at *B*. The operating cam, however, does not act directly on the cut-off slide, but its motion is transmitted to the arm *C*, which receives the motion at its lower end and transmits it from a point about half way up, to the end of the cut-off slide. The cut-off slide is brought back after its operation by means of the arm *D* which is operated from the opposite side of the cut-off cam. This arm serves as a confining member, making the lever *C* positive in its action. The cut-off slide is kept in contact with lever *C* by means of a stiff spiral spring. These machines are built in seven standard sizes, which form wire from 1/32 inch to ½ inch in diameter, and have a capacity for wire lengths from 4½ to 22 inches.

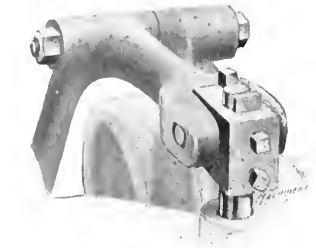

Fig. 5. Detail of Stripper Lever and Bracket

GARRIGUS NO. 2 HAND MILLING MACHINE

The illustrations show a machine known as the No. 2 Bristol miller which has recently been placed on the market by the C. G. Garrigus Machine Co., Bristol, Conn. This machine is adapted for a variety of milling operations on small work, among which may be mentioned: hobbing worm-wheels, profiling, cam cutting and keyseating. Such work is conveniently handled on a hand milling machine and the provision of both lever and crank feed on the present machine adds to its convenience of operation.

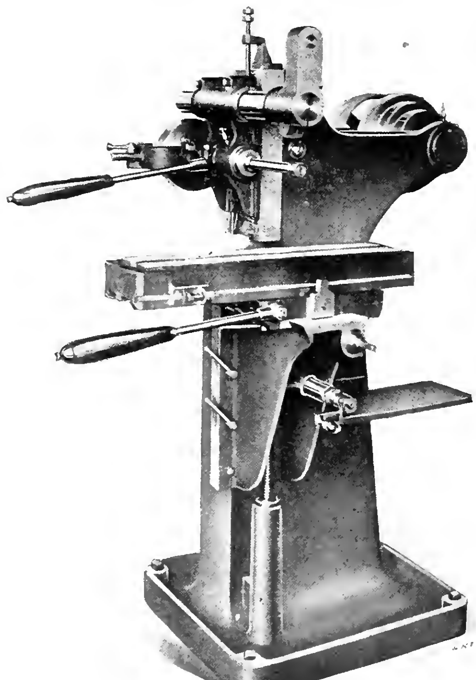

Fig. 1. Garrigus No. 2 Hand Milling Machine

The following gives a brief outline of the features of the design of this machine. The spindle has double tapers at each end, and adjustment for wear is made by means of check-nuts which are capable of compensating for any amount of wear which the machine may develop. The spindle bearing is bronze-bushed and a reservoir which holds one-half pint of oil is located at the center of the bushing, thus insuring adequate lubrication. The geared head on the spindle provides ample power for the heaviest cuts that a machine of this size will be called upon to handle. The cone pulley back-shaft is fitted with New Departure double-row combined radial and thrust bearings. The machine is furnished either with or without power feed.

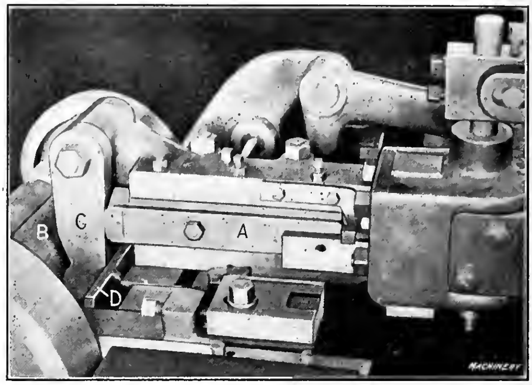

Fig. 6. Cut-off Mechanism of Nilson Wire Forming Machine

The distance from the center of the spindle to the under side of the arm is 3⅞ inches, and the distance from the end of the spindle to the center in the arm is 12 inches. The spindle has either No. 9 B. & S. taper or No. 3 Morse taper. There are six changes of spindle speed. The maximum lever feed is 6 inches and the maximum crank feed is 18 inches. The table is 7 by 25 inches in size and has one T-slot ⅝ inch wide. The maximum distance from the top of the table to the center of the spindle is 17 inches. The transverse movement of the table is 6½ inches. The machine

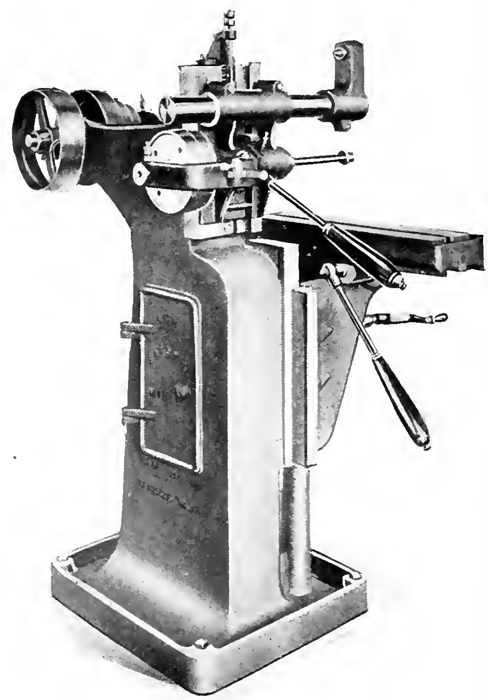

Fig. 2. Rear View of Garrigus Miller showing Arrangement of Drive

occupies a floor space of 30 by 46 inches and weighs 1112 pounds.

CINCINNATI GEAR CUTTER GRINDER

The illustrations show front and rear views of a gear cutter grinder for formed cutters which is a recent product of

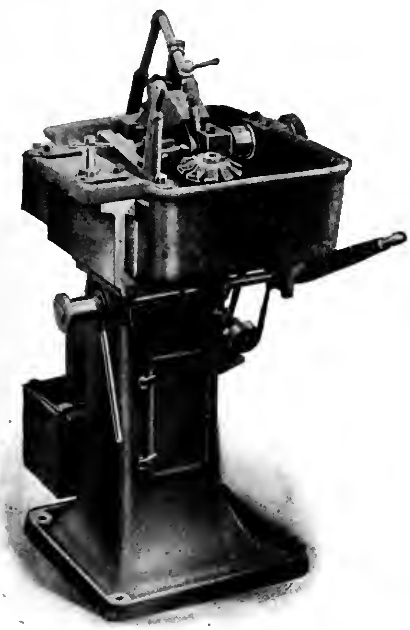

Fig. 1. Front View of Cincinnati Gear Cutter Grinder

the Cincinnati Gear Cutting Machine Co., Elam St. and Garrard Ave., Cincinnati, Ohio. It is a well-known fact that formed cutters for cutting gear teeth must be ground so that the axis of the cutter lies in the plane of each of the tooth faces, and it is to provide for grinding these radial faces of the teeth that this machine has been designed. The principal claims made for the construction are simplicity and the fact that the work-slide is located outside of the pan so that it is not exposed to damage from water and grit.

Adjustments are provided for centering the work with the wheel, and for regulating the position of the work-slide, cutter diameter, depth to which the tooth is ground, thickness of the cut, inclination of the cutter, and to provide for feeding the cutter to the grinding wheel. Indexing is done by means of a pawl which bears against the heel of the cutter. The following advantages are claimed for this method of indexing. It is not complicated, can be rapidly effected, it is not necessary to secure the cutter to its arbor by means of clamping nuts and consequently the cutter can be instantly removed for gaging or inspection, and inaccuracies in the cutters due to hardening or other causes may be corrected.

The work-spindle is hardened and ground and runs in bronze bushings that are carefully protected from grit and provided with means of adjusting for wear. The work-slide has a long bearing on the pan of the machine and is provided with a taper gib for taking up wear. The machine is equipped with a wheel truing device for keeping the grinding face of the wheel accurate. Water is supplied to the wheel by means of a centrifugal pump, which draws the water from a reservoir to which it is delivered from the settling tank, where emery dust and grindings are removed.

The machine is driven from a countershaft which has tight and loose pulleys 8 inches in diameter by 2¼ inches face, the countershaft being driven at 350 R. P. M. The machine occupies a floor space of 31 inches by 41 inches and the total weight of the machine and countershaft is 1200 pounds. The

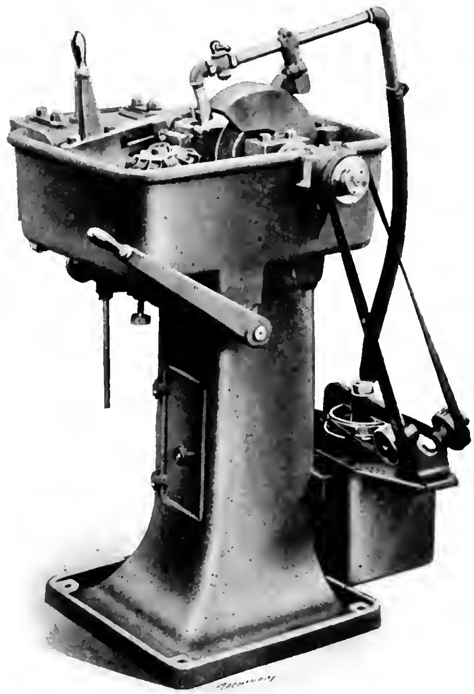

Fig. 2. Rear View of Cincinnati Gear Cutter Grinder

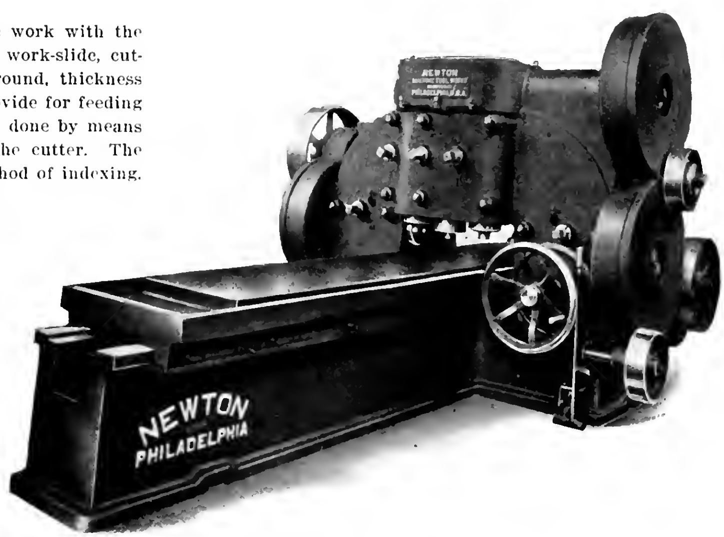
capacity is for cutters up to 10 inches in diameter and 1 diametral pitch.

NEWTON FIVE-SPINDLE MILLING MACHINE

The illustration shows a five-spindle milling machine which has been added to the line of the Newton Machine Tool



Newton Five-spindle Milling Machine

Works, Inc., Philadelphia, Pa. The machine is of simple design and has a powerful drive for the spindles which insures a high rate of output at a low maintenance cost. The drive for all of the spindles is taken from a single pulley

which is mounted on a shaft extending through the machine. The right- and left-hand spindles are driven from this shaft by means of spur gears, while the three vertical spindles are driven by spiral gears. Each of the spindles has a double taper bearing in its sleeve, and hand adjustments are provided for each of these sleeves which are held in position by means of binding bolts.

The work table is provided with an angular rack and spiral gear drive. Only one change of gear feed is available at any time, but additional changes can be made by using different gears. The table is 24 inches wide and long enough to provide for milling work 12 feet in length. The machine has a capacity for handling work 24 inches in width by 4½ inches high and uses milling cutters up to 5 inches in diameter. The feed is taken from the end of the main driving shaft and motion for the quick return is taken direct from the countershaft to the pulley which drives the quick-return mechanism. Hand adjustment of the table is provided and the engagement of the feed and fast power traverse is controlled by a single lever.

The weight of the machine is 22,000 pounds. While such a powerful machine may appear unnecessary for the light work for which it is intended, experience has shown that more accurate work and heavier feeds are possible on such a machine and that this justifies the additional expenditure for heavy equipment.

ROCKFORD TWENTY-INCH DRILL

The illustrations show the right- and left-hand sides of a new 20-inch vertical drill press which has been added to the line of the Rockford Drilling Machine Co., Rockford, Ill. The distinctive features of this machine are briefly described by the following: It will be seen that a star feed handle is used in place of the lever which was previously applied to the machines of this company's manufacture. This handle consists of a central clutch member, which, when thrown into the outer position, acts directly on the cross spindle to provide a quick approach or return of the tool. When thrown into the inner position, a gear is engaged which operates with a train of four reduction gears to provide a slow movement for heavy drilling or facing operations.

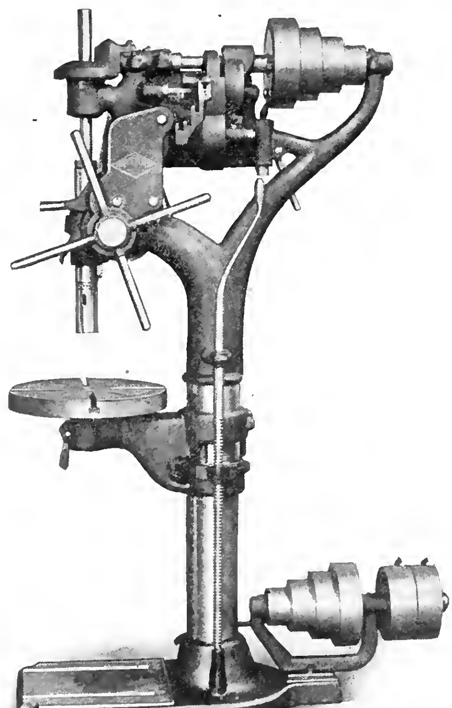


Fig. 1. Right-hand Side of Rockford Drill showing Star Feed Handle

Another distinctive feature consists of the dial which acts as a trip for the power feed. This dial is graduated to correspond with graduations on the sleeve and a small trip dog is mounted on it, which can be readily moved to any desired position, where it is secured by means of a thumbscrew. When the required depth of drilling is reached this trip engages a roll shown on the yoke casting in Fig. 2 and throws it upward, thereby disengaging the power feed. It will be seen that all gears are thoroughly incased. The worm-wheel is guarded from beneath and this guard forms a well for holding lubricating oil.

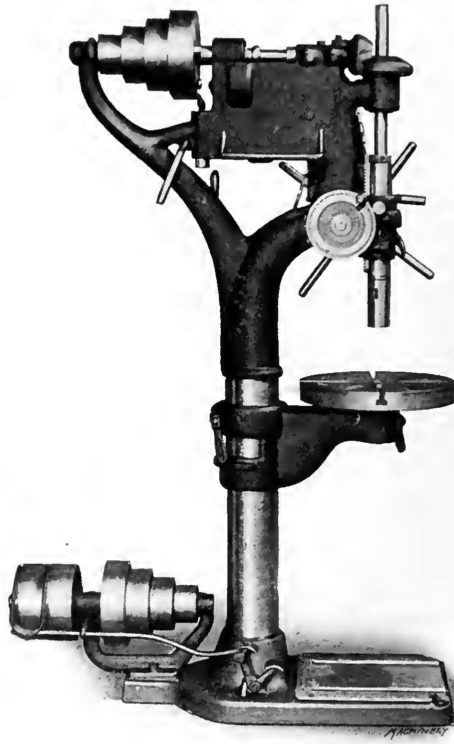

Fig. 2. Left-hand Side of Rockford Drill showing Dial Feed Trip

NEW MACHINERY AND TOOLS NOTES

Traveling Crane Trolley: Shaw Electric Crane Co., Muskegon, Mich. A traveling crane trolley particularly adapted for steel mill service. The trolley is constructed entirely of steel.

Releasing Chuck: Manufacturers' Equipment Co., Chicago, Ill. A releasing chuck designed to hold threaded pieces. This chuck eliminates the necessity of stopping or reversing the machine in chucking or removing the work.

Hand Drill: Millers Falls Mfg. Co., 28 Warren St., New York City. A two-speed hand drill with gear ratios of 1½ to 1 and 4 to 1. The change of speed is made instantaneously by means of a clutch mechanism on the drill.

Pillar Crane: Production Engineering Co., Philadelphia, Pa. A crane designed to be carried by one of the pillars in an industrial plant. The arm can be swung in a complete circle around the pillar. The crane is equipped with a chain-block hoist and is adapted for all classes of light lifting.

Center Grinder: Paul Spiegel, 234 E. 117th St., New York City. A lathe center grinder consisting of a swinging bracket attached to the front of the head. The grinder spindle is driven by a friction wheel engaging with one of the steps of the cone pulley, the speed being increased through suitable gearing.

Pneumatic Hammer: Chicago Pneumatic Tool Co., Chicago, Ill. A pneumatic riveting hammer equipped with a safety device. This device consists of a knurled nosepiece screwed over the end of the cylinder. The cup end of the rivet set projects through an opening in the nosepiece, which holds the rivet set in place.

Vertical Miller: Becker Milling Machine Co., Hyde Park, Mass. A vertical milling machine in which the movement of the head is controlled by a worm and worm-wheel, an automatic stop being provided for throwing out the feed. A quick hand return is also provided, and the depth of cut is accurately determined by means of a micrometer gage.

Boring Mill: H. Bickford & Co., Lakeport, N. H. A seven-foot motor-driven boring mill equipped with a ten-horsepower variable-speed motor. The machine is driven direct through a gear-box, which, in conjunction with the variable-speed motor, gives thirty-six table speeds. Work 84 inches in diameter by 48 inches high can be handled.

Forming Press: Hydraulic Press Mfg. Co., 84 Lincoln Ave., Mount Gilead, Ohio. A hydraulic press for forming articles out of sheet metal. This press has three cylinders, the middle cylinder operating the blank-holder while the cylinders at each side operate the forming platen. The press has a capacity for pressures up to 68 tons and will handle work up to 38 by 38 inches in size.

Coupler Shear and Riveter: Watson-Stillman Co., 192 Fulton St., New York City. A hydraulic car-coupler shear and riveter in which the cylinder is an integral part of the body of the machine. The main casting is pivoted to a stand on its back face, instead of being bolted to the stand from the bottom. This permits the casting to be swung around to meet the requirements of different classes of work.

Combination Lathe and Grinder: Cincinnati Precision Lathe Co., Cincinnati, Ohio. This company has modified the design of its friction head bench lathes to adapt them for cutter grinding. When engaged on cutter grinding operations, the tooth-rest bracket is bolted to the swivel head or to the bed of the machine, according to the requirements of different classes of work. The grinding wheel is mounted on the tool-slide in the usual way.

Horizontal Miller: Becker Milling Machine Co., Hyde Park, Mass. A horizontal milling machine driven by a constant-speed pulley which adapts the machine for belting direct to the lineshaft. The gear-box is placed between the constant-speed pulley and the pulley to which the spindle is belted. Twenty-one spindle speeds are available ranging from 8 to 375 revolutions per minute. The feeds are obtained through friction disks, feeds ranging from 0.003 to 0.600 inch per revolution being available.

* * *

BROACHING HEAVY BENCH VISE BODIES

The ordinary machinists' bench vise with front sliding jaw fixed on a rectangular section bar offers, in the back jaw, a first-class broaching job. A common practice has been to cast the back jaws with the rectangular opening cored as closely as possible to the required size and to fit the sliding jaw bar to it by filing. The result, of course, is considerable hand labor and more or less unsatisfactory work in many cases. The application of the broaching machine enables the vise manufacturer to cast the back jaws with smaller openings and to remove metal all around the inside of the hole with the broach. This insures perfect bearing and working surfaces free from hard scale.

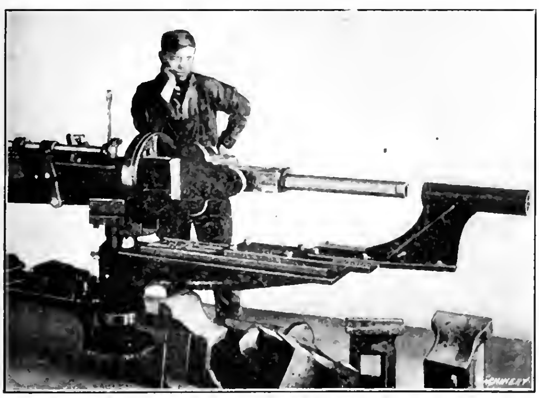

Fig. 1. J. N. Lapointe Machine broaching Heavy Vise Body

The accompanying illustration Fig. 1 shows an equipment recently furnished by the J. N. Lapointe Co., New London, Conn., to a vise manufacturer for broaching the holes in heavy vises. The chief feature of interest, aside from the general operation, is the means provided for supporting the heavy broach. The broach weighs 275 pounds and is, therefore, entirely too heavy and dangerous a tool to be lifted by hand. The necessity of handling the broach at each operation is neatly avoided. The broach is provided with a round shank at the rear, which telescopes into a supporting bracket. The bracket holds it up in line with the pulling shaft and thus eliminates the necessity of the operator's handling it. The round shank enables the broach to be turned readily to clean off the chips.

The jaw of the vise shown in the illustration weighs about 150 pounds. It is mounted for broaching with the broach in the position shown in Fig. 2, and the broach is then slipped up over the pulling shaft which projects out of the machine and is connected with the key shown lying on top. As soon as the machine begins to pull the broach through the vise jaw, the teeth come in contact with the metal all around and by the time the support shank of the broach leaves the support bracket at the rear the pressure developed is sufficient to hold the broach and vise jaw up in position. The bracket for supporting the broach is pivoted on the round column beneath the end of the machine bed, and can be swung around beside the bed out of the way when the machine is being used on lighter broaching work.

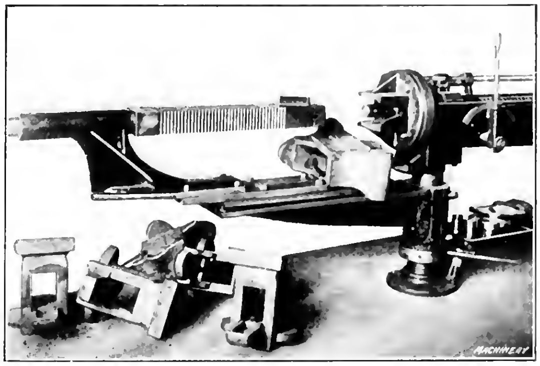

Fig. 2. Showing Heavy Broach supported on Bracket ready for placing Work in Position

This broach is believed by the makers to be the heaviest ever made and used. The time required for broaching a jaw depends, of course, on the activity of the operator, being perhaps from four to five minutes apiece.

EIGHTH ANNUAL CONVENTION OF TRADE PRESS ASSOCIATION

The eighth annual convention of the Federation of Trade Press Associations was held at the Hotel Astor, New York City, September 18-20. The program included a large number of short papers and addresses on advertising, editorial policy, circulation, publishing, etc. The object of the Federation is to bring about better business methods and a higher conception of ideals in trade paper publishing, to increase the efficiency of trade papers as advertising mediums and to raise the standards of the business generally. Friday evening, September 19, was given over to the annual banquet at the Hotel Astor which was attended by several hundred men, many of whom are prominently connected with trade paper publication.

* * *

The report of the Interstate Commerce Commission for the year ending June 30, 1912, states that the aggregate mileage of railway tracks of all kinds was 360,714.24 miles. This mileage was classified: Single track, 240,238.81; second track, 21,929.51; third track, 2511.76; fourth, fifth and sixth tracks, 1783.97; odd tracks and sidings, 91,250.19 miles. The number of locomotives in service was 61,250 of which 14,206 were classified as passenger, 36,600 as freight, 9475 as switching and 969 were unclassified.

MACHINE FOR MAKING "WELDED SEAMLESS" TUBING

Mr. Marshall B. Lloyd of the Lloyd Mfg. Co., Menominee, Mich., is the inventor of a new process for manufacturing "seamless welded" metal tubing. Front and rear views of the machine used for this purpose are shown in the accompanying illustrations; the machine is of a very compact design, only occupying a floor space of 3 by 20 feet. Double machines for producing two tubes simultaneously are also built, such machines requiring the attention of two operators.

The method by which stock is fed to the machine is clearly illustrated in Fig. 1. Either hot- or cold-rolled steel is used; the material is fed into one end of the machine and the finished tubing comes out at the other end. The operation of the machine is entirely automatic, the operations of forming, welding, straightening, sizing, polishing and cutting off being performed without any attention from the operator. The capacity of a single machine is for 4000 feet of tubing per day, regardless of the size of the tubing which is produced.

The machine is very economical in the use of stock, the only waste consisting of about 1/16 of an inch of material at

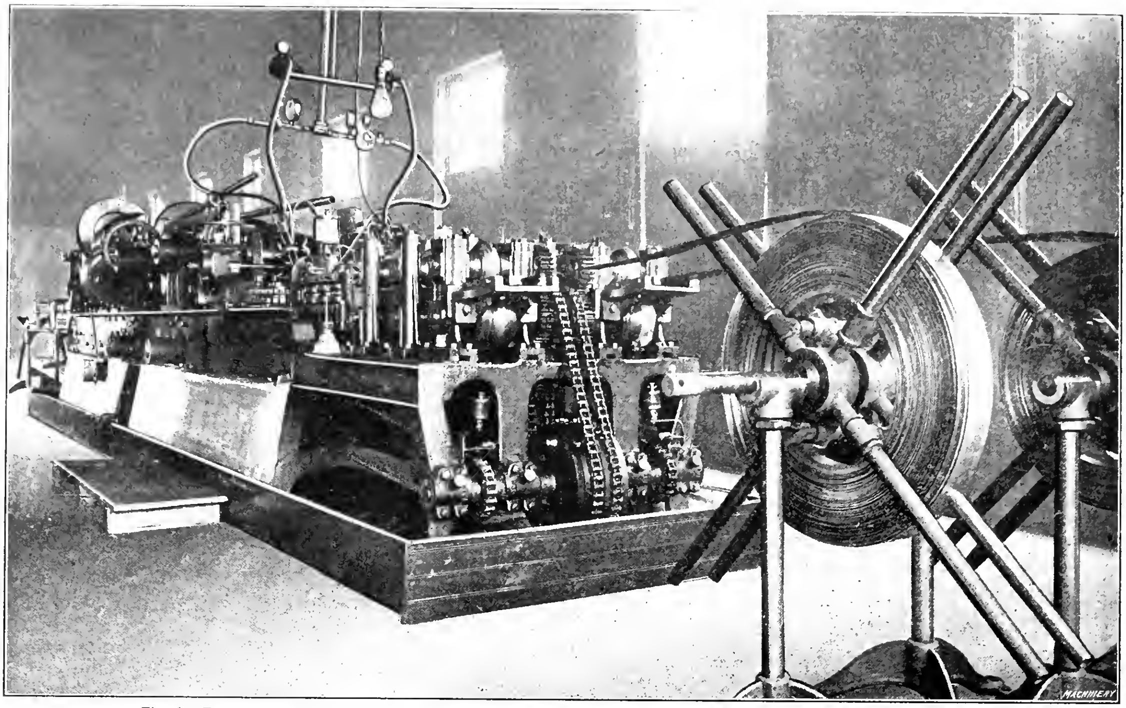

Fig. 1. Front View of Lloyd Machine for making "Welded Seamless" Tubing showing Delivery of Stock to the Machine

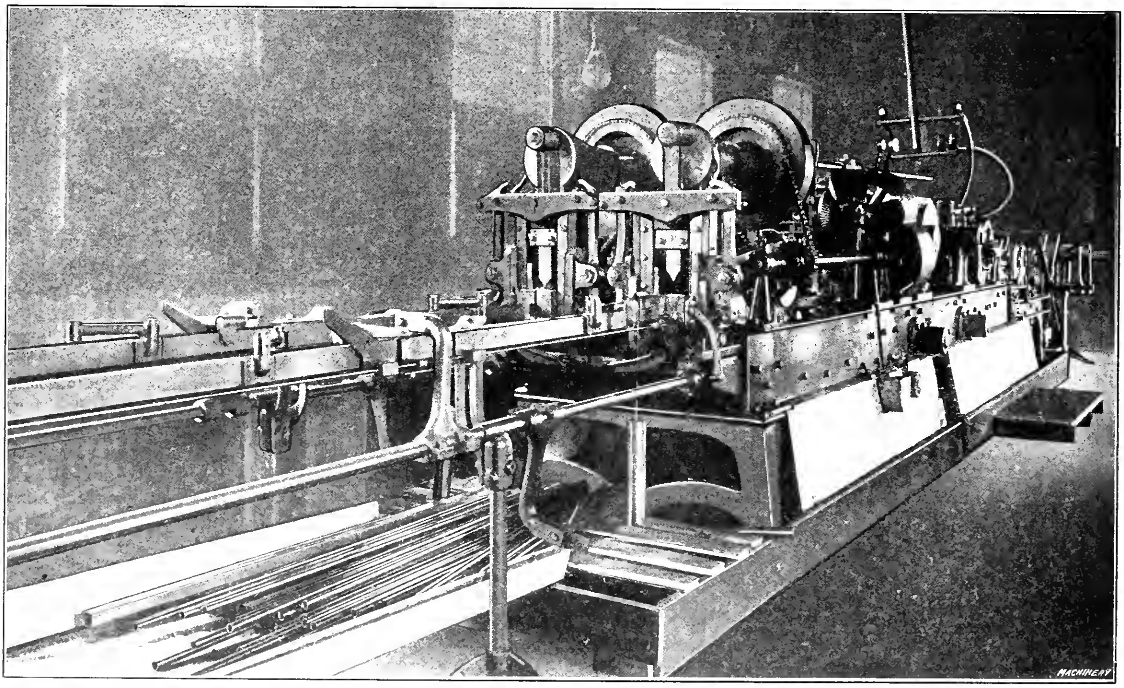

Fig. 2. Rear View of Machine for making "Welded Seamless" Tubing, showing Finished Tubes made in the Machine

each point where a finished tube is cut off. Anyone familiar with the process of manufacturing tubing will appreciate the fact that this is far more economical than other methods which are in common use. In producing drawn tubing, the thinner that the walls of the tube are required to be, the greater the expense of production, owing to the increased amount of power that is necessary during the drawing operation. With the Lloyd process, walls of a given thickness are obtained by using the proper gage of metal so that the cost of production is not affected. Practically any desired shape of tube can be made, among which may be mentioned such standard forms as oval, round, square or hexagonal. No additional expense is involved in the production of irregular shapes.

The machine has a capacity for producing tubing from one to seven inches in diameter and special machines could be built for producing larger sizes. The method of operating the machine is quite simple and consequently no extended experience in tube making is necessary in order to produce satisfactory work. The method of threading the ends of tubing produced on this machine is to build them onto the ends of the tube rather than to cut threads in the walls of the tubing. By this means, the threaded section can be made of any desired strength.

The operation of the machine may be briefly outlined as follows: The flat metal strip is drawn through a series of small rolls which form it to the required shape around a suitable mandrel of special construction. After passing through this process, the edges of the tube are close together ready for the welding operation. An autogenous welding torch is used for this purpose which joins the seam of the tube by the familiar process of fusion welding. A thin burr shows on the metal at the point where the weld was made but this defect is removed by a knife on the machine. The tube is next smoothed down with a fine emery wheel.

After these operations have been completed, the tube passes on to a powerful vise equipped with semicircular jaws. This vise has a reciprocating movement through a distance of two feet and draws the tubing through the machine at each forward movement. When the tube leaves the vise, it is sized and polished by a process of cold rolling with water. After this operation has been completed, the tube goes through the straightening device and is then cut off and dropped into a receptacle at the end of the machine. This end of the machine is clearly illustrated in Fig. 2. It is stated that the tubing produced in this way is so smooth and bright that it has the appearance of having been electroplated.

* * *

LARGEST PRECISION TESTING MACHINE

The U. S. Bureau of Standards, Washington, D. C., lately installed a testing machine for testing columns, blocks, beams, girders and other shapes of steel, iron, wood, concrete, reinforced concrete, etc. The machine measures the breaking strength, spring under load, etc. It has a capacity for specimens of any length up to 34 feet and is capable of exerting a pull of 1,150,000 pounds and a compression of 2,300,000 pounds. Although of such great capacity, the claim is made that the mechanism is so delicate that the pressure of a finger on the ram will be registered.

* * *

PERSONALS

Forrest R. Jones, formerly head of the department of machine design at the University of Wisconsin and later with Cornell University, has taken charge of the editing of data sheets known as "Lefax" published by the Standard Corporation, Philadelphia.

Otto E. Kleinert, for the past twenty-five years general foreman of the automatic and tool departments of the Waterbury Farrel Foundry & Machine Co., Waterbury, Conn., has resigned to become superintendent of the King Machine Co.'s works in Bridgeport, Conn.

Col. George W. Goethals, chairman of the Isthmian Canal Commission and chief engineer of the Panama Canal, has accepted the honorary presidency of the International Engineering Congress, and will preside in person over the general sessions to be held in San Francisco September 20-25, 1915.

Lawrence W. Cady, formerly electrical engineer for the Browning Engineering Co., of Cleveland, Ohio, is now engaged in consulting and designing work. Mr. Cady is a specialist on the design and application of electrically-operated machines. His address is 1557 Robinwood Ave., Lakewood, Ohio.

George L. Colburn, for the past three years assistant to Frank Burgess, proprietor and general manager of the Boston Gear Works, Norfolk Downs, Mass., is now mechanical engineer with the Holmes & Blanchard Co., builders and dealers in crushing, grinding, sifting and mixing machinery. Mr. Colburn is also associated with George Vincent Rogers, president of the company, who conducts a large factory appraisal business, established in 1893.

Axel F. Backlin, mechanical engineer with the American Steel & Wire Co., Worcester, Mass., and assistant to the late Fred H. Daniels, was tendered a farewell dinner by the Swedish Engineers' Society of which he is president, at the Bancroft Hotel, Worcester, September 26. Mr. Backlin has been transferred to the Pittsburg office of the American Steel & Wire Co., as assistant superintendent. He will act, in a sense, as master mechanic for the company.

D. De Vries, a well-known machine tool specialist, employed by R. S. Stokvis & Zonen, Ltd., Rotterdam, Holland, will visit the United States in October in the interest of his concern, which is actively engaged in selling American machine tools. Mr. De Vries has just returned from a trip to the far East, where he spent four months in Java, establishing agencies for the sale of American machine tools, and making demonstrations, etc. His work attracted favorable attention from government and railway officials. Mr. De Vries will visit the United States especially in the interest of his firm's Eastern machine tool business.

Prof. A. Riebe, director of the Riebe Kugellager und Werkzeug Fabrik, Berlin, Germany, arrived in New York, September 18, on the steamer *Imperator* to visit his American agents, Olin, Giberson & Lowy, 30 Church St. Prof. Riebe, who in conjunction with Prof. Stribeck made many original investigations into the design of radial ball bearings, will deliver several illustrated lectures while in America before the various sections of the Society of Automobile Engineers. The lecture before the metropolitan section was given on September 25, the subject being "A Review of the Inception of the Ball Bearing and Roller Bearing and their Application in the Automobile Industry."

* * *

OBITUARIES

Thurston M. Phetteplace, professor of mechanical engineering of Brown University, Providence, died at the Maine General Hospital September 7, aged thirty-six years, following an operation for carbuncle. Prof. Phetteplace was a member of the A. S. M. E. and had contributed valuable papers to its proceedings. His untimely death will be mourned by all knowing his abilities.

Howard F. Martin, general sales manager of the Eveland Engineering & Mfg. Co., Philadelphia, Pa., was killed in a railroad accident near North Haven, Conn., September 2. Mr. Martin was returning with his wife, from a vacation in Maine and she, too, was killed. Mr. Martin was forty-five years old and had been connected with the Pennsylvania Steel Co., for about fifteen years as purchasing agent and sales manager. After resigning his position as sales manager with the Pennsylvania Steel Co., which he had held for about ten years, he went with the Eveland Engineering & Mfg. Co. in a similar capacity. He was a member of several leading clubs and other organizations of Philadelphia, and was also a member of a number of steel trade organizations.

George W. Bennett, vice-president and general manager of the Willys-Overland Co., Toledo, Ohio, died September 19, aged forty-nine years. He was born in Worthing, England, and came to America at an early age. He was assistant manager of Gormully & Jeffrey Mfg. Co., of Chicago, from 1885 to 1892. In 1892 he became branch manager of the company at Washington, D. C., remaining there until 1895. From Washington he went to Brooklyn, N. Y., for the same company, leaving in 1899 to become Eastern representative of the American Bicycle Co. of New York. From 1900 to 1906 he was sales manager for the Thomas B. Jeffrey Co. of Kenosha, Wis., and in 1906 manager of the Knox Automobile Co. of Springfield, Mass. He then became Eastern representative of the White Co., remaining in this position until 1910, when he went to Toledo to join the Overland forces. Mr. Bennett was a member of many national and international organizations connected with the automobile trade, including the Automobile Board of Trade. He is survived by a widow and two sons.

Fred H. Daniels, chief engineer of the American Steel & Wire Co., Worcester, Mass., died at his home in Worcester August 31, aged sixty years. Mr. Daniels was a well-known mechanical engineer and was chairman of the board of engi-

FOR HEAVY SERVICE

What do you expect in any machine designed for heavy manufacturing service?

Above all, ample power and a consistently rigid design.

Note how well these points have been taken care of in the No. 5-B Heavy Plain Milling Machine.

Large diameter constant speed drive pulley running at high speed carries an extra wide belt. The overhead pulley is also of large diameter giving wide belt contact and powerful driving leverage. The variable feed, by means of hardened spur gears, is driven by chain direct, mounted on large diameter hardened steel shafts, firmly supported. Result—elimination of vibration, and maximum efficiency.

The knee slide extends to the top of the frame, stiffening the column and forming a massive housing for the spindle. Notice the long bearing of the knee on the column. Stout transverse ribs give rigidity for heavy service.

The table is heavy and has a vertical depth that gives the necessary stiffness to prevent springing under deep cuts. The depth of the saddle and extra long bearings in proportion to the length of the table are clearly shown.

Stout, easily adjustable braces serve to firmly lock the knee and overhanging arm together, resisting the stresses that tend to produce vibration.

If you have heavy milling, these features should interest you.

Better ask us now for full particulars.

neers of the United States Steel Corporation. He was a graduate of Worcester Polytechnic Institute, and entered the employ of the Washburn & Moen Co. immediately after graduation as a draftsman. His skill and ability as a draftsman and designer soon won recognition and he was sent abroad several times to obtain plans and data for the development of the plant. When Charles H. Morgan retired from the company in 1887, Mr. Philip W. Moen was made superintendent and Mr. Daniels, assistant superintendent. Mr. Daniels became general superintendent after a year's service as assistant general superintendent. When the thirty big steel and wire manufacturing plants of the country were consolidated by John W. Gates in 1896 under the name of the American Steel & Wire Co., he was given the responsibility of putting a number of run-down plants in first-class condition. Mr. Daniels was the inventor of about 150 improvements in wire drawing machinery, etc.

Frank B. Rutter, second vice-president and sales manager of the Scranton Bolt & Nut Co., Scranton, Pa., was killed in a railroad wreck near North Haven, Conn., September 2, while a passenger on the Bar Harbor express which was telescoped by the White Mountain express. Mr. Rutter was forty-one years old. He was born in Lykens, Dauphin Co., Pa., and was educated in the public schools of Lebanon, Pa., from which he entered the employ of the Pennsylvania Bolt & Nut Co., now the American Iron & Steel Mfg. Co. He started as an office boy and served for a time as clerk in the rolling mills and from there was transferred to the estimating department of the general offices of the company. After working several years in that department he was chosen teller of the First National Bank of Lebanon, in which capacity he served for four years with marked ability. He left this position in 1903 to take a position as chief clerk of the accounting department of the Scranton Bolt & Nut Co., and in 1905 was promoted to president in the sales department. In 1906 he was made sales manager and in 1910 was chosen a director of the company, which position he filled with ability until his death. Mr. Rutter was a man of unusual character and ideals. He was a member of the Manufacturers' Club of New York City, the Pennsylvania Society of New York, Engineers' Society of Northeastern Pennsylvania, the Scranton Club and the Country Club of Scranton. In 1908 he married Miss Grace B. Law, daughter of A. F. Law, president of the Temple Iron Co. Mrs. Rutter also lost her life in the wreck.

SOCIETIES, SCHOOLS AND COLLEGES

University of Manchester, Manchester, England. Prospectus of University courses, session 1913-14; also illustrations of the school, laboratories, workshops, and departments for bleaching, dyeing, printing and finishing textile goods and manufacturing paper.

American Museum of Safety, 29 W. 39th St., New York City, has made a special report on lead poisoning and the report is considered of so much value by Dr. C. F. Stokes, surgeon-general of the U. S. Navy, that a lengthy abstract with illustrations will be published in the "U. S. Medical Bulletin."

Pratt Institute, Brooklyn, N. Y., will begin evening courses in mechanical drawing and machine design, October 1. Other courses offered are technical chemistry, industrial electricity, practical electricity, steam engines, strength of materials, practical mathematics, trade teaching, machine work, toolmaking, carpentry and building, patternmaking, and sheet metal work.

COMING EVENTS

October 7-10.—Convention of American Society of Municipal Improvements in Wilmington, Del. George H. McGovern, secretary, Chambers of Commerce, Wilmington, Del.

October 10-17.—Eighth annual foundry and machine exhibition in the International Amphitheater Bldg., Chicago, Ill. This exhibit, which was started eight years ago to show foundry equipment only, has broadened out considerably in the past few years and now includes all classes of machine tools and shop equipment as well as foundry equipment and supplies. One hundred and eight concerns were represented in the exhibition held in Buffalo, N. Y., last year and over one hundred and twenty-five concerns have taken space for this year and two hundred are expected. C. E. Hoyt, secretary, Lewis Institute Bldg., Chicago, Ill.

October 13-17.—Annual convention of the American Institute of Metals at Chicago, Ill. W. M. Corse, secretary, Lumen Bearing Co., Buffalo, N. Y.

October 14-16.—Annual convention of the Allied Foundrymen's Association. Hotel La Salle, headquarters. Richard Moldenke, Watchung, N. J., secretary.

October 19-25.—Seventh annual convention of the National Society for the Promotion of Industrial Education, in Grand Rapids, Mich. The convention promises to be the greatest yet held by the society in point of attendance, importance of questions to be discussed and interest in the work. C. A. Prosser, secretary, 105 East 22nd St., New York City.

October 20-26.—Convention of the American Mining Congress in Horticultural Hall, Philadelphia, Pa. James F. Callbreath, secretary, Munsey Bldg., Washington, D. C.

October 22-24.—Twelfth annual convention of the National Machine Tool Builders' Association, New York City. Hotel Astor, headquarters. James H. Herron, general manager, Cleveland, Ohio.

October 28-30.—Pennsylvania Industrial Welfare and Efficiency conference in the Capitol Bldg., Harrisburg, Pa., under the auspices of the Engineers' Society of Pennsylvania, Harrisburg, Pa. In connection with the convention an engineering exhibit will be held October 27-31 in the concrete building of the Harrisburg Railway Co. containing 26,000 square feet floor space. Paul Gendell, director of exhibits, Harrisburg, Pa.

December 3-6.—Annual meeting of the American Society of Mechanical Engineers. Headquarters Engineers Bldg., 29 W. 39th St., New York City. Calvin W. Rice, secretary.

December 11-20.—First International Exposition of Safety and Sanitation under the auspices of the American Museum of Safety, 29 W. 39th St., New York City. Dr. William H. Tolman, director. Safety and health in every branch of American industrial life—manufacturing, trade, transportation on land and sea, business and engineering, in all of their subdivisions, will be represented at this exposition. Exhibits from Europe and other foreign countries will be admitted free of duty by special act of Congress. European employers have cut their accident and death rate in half by a persistent campaign of safety. There are twenty one museums of safety in Europe, and all these will contribute to the American Exposition.

NEW BOOKS AND PAMPHLETS

Metallographic Testing. 16 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Circular No. 42 of the Bureau of Standards.

Standard Analyzed Samples—General Information. 12 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Circular No. 25 of the Bureau of Standards.

Analyzed Irons and Steels—Methods of Analysis. 15 pages, 7 by 10 inches. Published by the Department of Commerce, Bureau of Standards, Washington, D. C., as Circular No. 14.

Analyzed Iron and Manganese Ores—Methods of Analysis. 27 pages, 7 by 10 inches. Published by the Department of Commerce, Bureau of Standards, Washington, D. C., as Circular No. 26.

United States Government Specification for Portland Cement. 28 pages, 7 by 10 inches. Illustrated. Published by the Department of Commerce, Bureau of Standards, Washington, D. C., as Circular No. 33.

Dehydration of Clays. By G. H. Brown and E. T. Montgomery. 23 pages, 7 by 10 inches. Diagrams. Published by Department of Commerce, Bureau of Standards, Washington, D. C., as Technologic Paper No. 21.

Vitrified Brick as a Paving Material for Country Roads. By Vernon M. Peirce and Charles H. Moorefield. 34 pages, 6 by 9 inches. Illustrated. Published by the U. S. Department of Agriculture, Washington, D. C., as Bulletin No. 23.

Determination of Sulphur in Illuminating Gas. By R. S. McBride and E. R. Weaver. 46 pages, 7 by 10 inches. Illustrated. Published by Department of Commerce, Bureau of Standards, Washington, D. C., as Technologic Paper No. 20.

Typical Specifications for the Fabrication and Erection of Steel Highway Bridges. By the Office of Public Roads. 25 pages, 6 by 9 inches. Published by the U. S. Department of Agriculture, Office of Public Roads, Washington, D. C., as Circular No. 100.

New Calorimetric Resistance Thermometers. By H. C. Dickinson and E. F. Mueller. 12 pages, 7 by 10 inches. Illustrated. Published by the Department of Commerce, Bureau of Standards, Washington, D. C., as reprint No. 200 from the Bulletin of the Bureau of Standards, Vol. 9.

Note on Cold-Junction Corrections for Thermocouples. By Paul D. Foote. 13 pages, 7 by 10 inches. Diagrams. Published by the Department of Commerce, Bureau of Standards, Washington, D. C., as reprint No. 202 from the Bulletin of the Bureau of Standards, Vol. 9.

Proceedings of the First Cooperative Safety Congress. 336 pages, 6 by 9 inches. Published by the National Congress for Industrial Safety, 2135 Green St., Harrisburg, Pa. The first Safety Congress was held under the auspices of the Association of Iron and Steel Electrical Engineers in Milwaukee, Wis., September 30-October 5, 1912.

Boiler Construction. By Frank B. Kleinhans. 462 pages, 5½ by 7¾ inches. 334 illustrations and five folding plates. Published by Norman W. Henley & Son, New York City. Price $3.

The first edition of this work was published several years ago; the second revised and enlarged edition has just been published. It undoubtedly is one of the best books of the kind in print, starting with the laying out of the sheets and concluding with the completed boiler. The contents comprise laying out work, flanging and forging, punching, shearing, plate planing, bending, machining parts, boiler details, assembling and calking, finishing parts, boiler shop machinery, general tables, plates showing types of modern locomotive boilers, locomotive boiler inspection and questions and answers on boiler inspection.

The Polytechnic Engineer. Vol. XIII. 138 pages, 6 by 9 inches. Published annually by the students of the Polytechnic Institute of Brooklyn, Brooklyn, N. Y.

The 1913 volume of this interesting annual contains the following articles: An Historical Sketch of the Early Development of Bridge Building, by Clarence W. Hudson; Thickness of Films of Silver Upon Glass, by Irving W. Fay and Arthur C. Rauchfuss; Lattice Bars, by George W. Oxley and Edward J. Squire; The Vector Diagrams of Electric Discharges, by Monroe George Woolfson; Senior Inspection Trip, by John H. Hnsing; The Diffusion of Light by Mechanical Means, by Louis A. Rosett; The Pitot Tube, by H. P. Hammond; Chinese Wood Oil, by Everitt J. Cole; Engineering Education Today in America and the Place of the Polytechnic among Colleges of Engineering, by William D. Ennis; A Resume of the Lectures of Sir William Ramsay, by Henry W. Sheff; The Predetermination of the Voltage—Regulation of Alternators, by Sampson K. Barrett.

Shop Mathematics. Part II. By Earle B. Norris and Ralph T. Craigo. 214 pages, 6 by 9 inches. Published by McGraw-Hill Book Co., New York City. Price $1.50 net.

This work on advanced shop mathematics is a second half of the instruction papers developed and used in the University of Wisconsin. It presents the principles of algebra, geometry, trigonometry and logarithms with the intention of making them of practical value in shop work. The contents by chapter heads are: Formulas; Explanation of Terms—Algebraic Addition; Algebraic Subtraction; Transformation of Formulas; Algebraic Multiplication and Division; Solution of Simple Equations; Simultaneous Equations—Quadratic Equations; Tables and Curves; Equations of Curves; Geometric Constructions; Construction and Properties of Geometric Figures; Areas of Geometric Figures; Volumes and Surfaces of Solids; Trigonometry—the Tangent and Cotangent; Some Uses of the Tangent and Cotangent; the Sine, Cosine, Secant and Cosecant; Screw Threads and Spirals; Solution of Triangles; Logarithms; Logarithms of Decimals, Powers and Roots. The work is gotten up in excellent typographical style. The principles and problems are illustrated with good drawings, and the work as a whole is one that can be recommended to ambitious practical men generally, bent on improving their condition by home study.

Dyke's Automobile Encyclopedia. By A. L. Dyke. 557 pages, 6½ by 10 inches. Illustrated. Published by A. L. Dyke, St. Louis, Mo. Price $3.

This work is in forty parts and contains 239 charts with a dictionary and index. It treats of the construction, operation and repair of automobiles and gasoline engines in a very thorough and effective manner, covering the subjects more thoroughly probably than any other published work at the price. The titles of the subjects treated are: The Car Complete; Drives; Steering, Springs, Brakes; Axles, Differential; Clutches; Transmissions or Change Speed Gears; Gasoline Engine; Engine Parts; Valve Timing; Engine Balance, How Cylinders Fire; Explanation of the Two "Cycle" Principle; Carburetion; Self Starters; Electric Ignition—Low Tension Coil; High Tension Coil Systems; Wiring and Connections; Ignition Timing; Various Ignition Systems; Low Tension Magnetos; High Tension Magnetos; Principle and Construction of Magnetos; Magneto Wiring Diagrams; Magneto Setting and Troubles; Storage Batteries and Power Lighting; Cooling; Lubrication; Car Operation; Rules of the Road; Care of Cars; Tires; Vulcanizing; Garages and Repair Shops; Equipment, Tools and Use of Tools; Repairs and Adjustments; Digest of Troubles, Diagnosis and Remedy; Insurance, Laws; Horsepower, Tables, Measurements; Steam Cars, Air Craft; Pointers for Automobile Salesmen; Dictionary, Index.

Rules of Management. By William Lodge. 130 pages, 5 by 7½ inches. Published by McGraw-Hill Book Co., New York City. Price $2 net.

The principles of management laid down in this book are exemplified in the management of the Lodge & Shipley Machine Tool Co., of Cincinnati, Ohio, of which Mr. Lodge is president. The book is unique, being virtually a compilation of the rules and practice of the company, which is a well-known manufacturer of lathes. The contents by chapter heads are: The Exceptional Employe, The General Manager, Chief Engineer and Designer, Drawing-room, Purchasing Agent, Incoming Material and Stores Department, Superintendent of Manufacture, Routing Department, Chief Clerk, Cost and Time-keeping Department, Operation of Premium Plan, Superintendent of Assembly, Handling Complaints, Pattern Shop, Tool-making Room, Forge Department, Lathe Department, Grinding Department, Drilling Department, Planer Department, Milling Department, Gear Cutting Department, Special Manufacturing Department, Inspecting Department, Specific Instructions for Painting Lathes, Sales Manager, Shipping Clerk, Boss Laborer and Express Truckman, Millwright and Belt Man, Engineer, Electrician and Oiler, Janitors and Watchman, A Proposed Pension Plan and Basis on which a Fund can be Started. The work is one that should interest and instruct all concerned in any way with the superintendence or management of manufacturing plants and especially those connected with the building of machine tools.

NEW CATALOGUES AND CIRCULARS

Standard Tool Co., Cleveland, Ohio. Catalogue No. 21 on drill chucks.

S. E. Parker, Chicago, Ill. Catalogue No. 26 on hoisting machinery.

Yale & Towne Mfg. Co., 9 E. 40th St., New York City. Leaflet on the Yale all-steel triplex block.

Asbestos Protected Metal Co., Beaver Falls, Pa. Bulletin No. 53 on asbestos steel for roofs and walls.

Whitman & Barnes Mfg. Co., Akron, Ohio. Folder on "W. & B" screw and drop-forged wrenches.

Chicago Pneumatic Tool Co., Fisher Bldg., Chicago, Ill. Bulletin No. 148 on hand drills and portable air compressors.

Cling Surface Co., 1018 Niagara St. Buffalo, N. Y. Report of comparative tests of belts with and without "Cling Surface."

Brown Instrument Co., Philadelphia, Pa. Bulletin containing a large number of testimonial letters received from users of Brown electric pyrometers.

George G. Dana, 2311 Washington Ave., Racine, Wis. Circular of the Dana duplex spring clips for holding drawings, tracings, blueprints and similar materials.

American Museum of Safety, 29 W. 39th St., New York City. Pamphlet on safety including the conditions of competition for the E. H. Harriman memorial gold medal, etc.

Millers Falls Co., 28 Warren St., New York City and Millers Falls, Mass. Circulars of "Star" hacksaw frames, sill borer or joist tools, hand and breast drills, chain drills, etc.

Kennicott Co., Chicago Heights, Ill. Little Journey to the Kennicott Co., by Elbert Hubbard, describing the ideals, aims and business of the concern, and written in characteristic Hubbard style.

Green, Tweed & Co., 109 Duane St., New York City. Booklet illustrating a number of large, well-known buildings in New York City whose engine rooms are fitted with "Rochester" automatic lubricators.

Quigley Furnace & Foundry Co., 25 Church St., New York City. Bulletin No. 2 on the continuous revolving shelf or reel type core ovens, burning coal, coke, oil or gas fuel, for baking small and medium size cores.

C. G. Garrigus Machine Co., Bristol, Conn. Circular of No. 2 Bristol hand milling machines, a machine especially adapted for keyseating, hobbing worm gears, profiling, cam cutting, and other characteristic hand milling machine work.

F. W. King Optical Co., Cleveland, Ohio. Circular on the King "I-Safe" goggle for workmen in shops, mills and factories. Special forms with colored glass are offered for open-hearth steel workers, oxy-acetylene welders, etc.

Skinner Chuck Co., New Britain, Conn. Catalogue and price list of independent, universal and combination lathe chucks, drill chucks, planer chucks, faceplate jaws, drill press vises, reamer stands, precision drawing-in chucks, etc.

Edge Moor Iron Co., Edge Moor, Del. Bulletin 51, entitled "Tests of a Steam Boiler at High Rates of Evaporation," describing tests made at the Westport generating station of the Consolidated Gas Electric Light & Power Co., of Baltimore.

Fosdick Machine Tool Co., Cincinnati, Ohio. Circular illustrating and describing heavy-duty type of round column radial drill, being the first of a complete line of round column radial drills which will be added to the company's regular line of box column radials.

Standard Electric Tool Co., Cincinnati, Ohio. Bulletin D-9 and DA-10, superseding D-8 and D-9, respectively on "Standard" high-power direct-current portable electric drills and "Standard" high-power two- and three-phase alternating-current portable electric drills.

Diamond Machine Co., Providence, R. I. Catalogue of the "Diamond" heavy face and guide bar grinding machine, illustrating details of construction fully. The machine embodies some interesting features of design, especially in table tripping and reversing mechanism.

Oneida National Chuck Co., Oneida, N. Y. Circular on the "National" safety lathe dog having no projections, driving arms or exposed set-screws to injure workmen or tear clothing. This safety lathe dog is offered in response to the demand for a greater safety in engine lathe operations.

De Laval Steam Turbine Co., Trenton, N. J. Booklet entitled "Improved Methods of Connecting Small Turbines in Steam Power Plants and Exhaust Heating and Drying Systems," describing several methods of connecting small turbines for driving auxiliaries in large steam power plants, etc.

Racine Electric Co., corner Prospect and Superior Sts., Racine, Wis. Catalogue A of "Racine" universal motor specialties, including high-speed electric grinders, driving grinding wheels at 14,000 R. P. M., high-speed lathe center grinders, universal electric portable grinder, desk and table fans, etc.

Rice Gasoline Rock Drill Co., 1510 Land Title Bldg., Philadelphia, Pa. Bulletin on the Rice gasoline rock drill, which is said to be the only free piston gasoline rock drill. The machine is entirely self-contained, consisting of gasoline drill, tripod, fuel and lubricant container, ignition battery and water tank.

Welles Caliper Co. (associated with A. J. Machek & Co.), 305 Twenty-fourth St., Milwaukee, Wis. Catalogue of Welles calipers and machinists' tools, comprising firm joint calipers, hermaphrodite calipers, adjustable calipers, hermaphrodite calipers and dividers with inserted points, steel rules, precision bench shears, tubular micrometer frames, etc.

Ingersoll Milling Machine Co., Rockford, Ill. Bulletin No. 34 R. F. on fixed-rail milling machines for manufacturing purposes. The bulletin illustrates a variety of designs of fixed-rail milling machines built by the company for various manufacturing establishments; it also shows illustrations of work in process of being machined.

Titanium Alloy Mfg. Co., Niagara Falls, N. Y. Rail Reports Bulletin No. 2 on rails made of open-hearth steel, giving physical tests and chemical analysis of standard open-hearth rails and titanium open-hearth rails, photographs of sections, sulphur prints, etc. These rail reports contain valuable data for railway officials and all concerned with maintenance-of-way.

Sprague Electric Works of the General Electric Co., 527-531 W. 34th St., New York City. Bulletin No. 850 on industrial ozonators for ventilation and air purification and water purification. The effect of the industrial ozonators on industries such as fertilizer work, slaughter houses, etc., probably will be revolutionary. Such industries apparently can be made as innoxious as any other enterprise.

Skinner Chuck Co., New Britain, Conn. Circular of the Jarvis precision draw-in chuck for straight, concentric and eccentric work. The chuck is made in three sizes ranging in capacity up to 1½ inch. When used as an eccentric chuck it can be thrown 0.250 inch off center. Any degree of eccentricity between 0 and 0.250 inch can be obtained without measurement by using the dial adjustment.

Toledo Electric Welder Co., Langland and Knowlton Sts., Cincinnati, Ohio. Bulletins Nos. 13 and 14 on electric welder data and electric butt welders. These bulletins illustrate a variety of electric welding machines and examples of electric welding. They give elementary welding information, instructions for operating welding data and other useful data for users of welding machines.

Canton Foundry & Machine Co., Canton, Ohio. Catalogue of Canton alligator shears, illustrating five sizes having capacity from 1½ inch square in machinery steel or iron to 3 inches square, inclusive. These alligator shears are built with either motor or belt drive. Besides the regular styles, the company builds high-knife and stop motion alligator shears of various sizes; also portable motor driven shears in the No. 1 size only.

Hess-Bright Mfg. Co., 17 E. Erie Ave., Philadelphia, Pa. Data sheets on adjustable mounting for automobile bevel driving pinion and gear and ball bearing on vertical spindle of matching machine. These data sheets illustrate the recommended mounting practice for Hess-Bright annular ball bearings in the designs mentioned and are uniform in style and size with data sheets previously published, illustrating a great variety of ball bearing designs.

Philadelphia Steel & Forge Co., 50 Church St., New York City. Circular on the products manufactured, including automobile steel, alloy steel, axe and hatchet steel, ball bearing steel, bit and jar steel, bevel shapes, car axles, cutlery steel, connecting rods, clover brand tool steel, crankshafts, die blocks, drill steel, forged bars and shapes, file and rasp steel, gear blanks, locomotive forgings, magnet steel, nickel steel, rings, spring steel, spindles, shafts, etc.

Superior Tap Co., Charlestown, N. H. Catalogue of taps, dies and screw plates, including machinists' screw plates, machine screw taps, machinists' hand taps, machine or nut taps, pulley taps, tapper taps, patch bolt taps, blacksmiths' taper taps, straight and taper boiler taps, Beaman & Smith taps, stove bolt taps, long hobs or master taps, short hob taps, Sellers' hob taps, staybolt taps, pipe taps, hobs and reamers, combined pipe tap and drill, mud plug taps, round and adjustable dies, machine or solid bolt dies, solid square pipe dies, "Superior" screw plates, blacksmiths' stocks and dies, etc.

Engrenages Citroen Societe Anonyme, 31 Quai de Grenelle, Paris, France. Catalogue of Citroen gears, containing a history of the development of the system, illustrations of large spur and bevel types, rolling mill pinions, etc. The Citroen gear is of the herringbone form but the right- and left-hand helical teeth are integral, being cut on one solid rim; the junctures between the right- and left-hand helices are effected in curves of short radii. In wide-face large gears there is a double reversal of helix, making in substance, two herringbone gears in one. The result is very smooth tooth action. Also pamphlet of testimonial letters from users of Citroen gears illustrated with notable examples of gears furnished.

Baldwin Locomotive Works, Philadelphia, Pa. Baldwin booklet issued in commemoration of the completion of the forty thousandth locomotive built by the company. The Baldwin Locomotive Works has been in continuous operation for eighty-two years. The first locomotive was completed in 1832. The forty thousandth locomotive is one of thirty similar engines built for the Pennsylvania Lines West of Pittsburg and designated as class K-3-S. It is of the "Pacific" type, having three pairs of driving wheels, a four-wheeled leading truck, and a two-wheeled trailing truck. The cylinders are 26 by 26 inches; steam pressure, 205 pounds per square inch; grate area, 55.4 square feet; water-heating surface 3680 square feet; weight on driving wheels, 189,500 pounds; total weight of locomotive, 293,200 pounds; tractive force, 38,300 pounds. The booklet contains a number of illustrations showing the development of American locomotives.

National-Acme Mfg. Co., Cleveland, Ohio. Catalogue of the "Acme" automatic multiple-spindle screw machines. This catalogue, which is of the standard letter size, 8½ by 11 inches, is the most comprehensive and complete that has ever been issued by this company, and is a beautiful example of typographical work. The catalogue is divided into several sections, such as construction and operation of the machine, different sizes and styles of machines, attachments for saving time or doing extraordinary operations, chucks, cams, tools and product. It is replete with halftone illustrations and contains a large number of small line illustrations showing the operating mechanism in detail. The supplementary text describes the chief mechanical features. Superintendents, foremen and operators interested in screw machines and screw machine practice generally should possess a copy of this latest catalogue, as it contains the very latest developments in this type of multiple-spindle screw machine.

TRADE NOTES

King Machine Tool Co., Cincinnati, Ohio, manufacturer of boring mills, has just completed a large addition to its plant. The company reports a rapidly increasing business.

Hoefer Mfg. Co., Freeport, Ill., has appointed the J. R. Stone Tool & Supply Co., 24 Goebel Bldg., Detroit, Mich., agent for the Hoefer line of auxiliary heads in Michigan territory.

Bury Compressor Co., Erie, Pa., has begun the erection of an addition to its plant extending the main building 100 feet. The addition is necessary to take care of the company's increasing business.

Metal Treating and Equipment Co., Inc., 1784 Broadway, New York City, has opened a plant at 834 Humboldt St., Brooklyn, N. Y., to do job galvanizing work by an improved process of electro-galvanizing.

H. W. Johns-Manville Co., Madison Ave. and 41st St., New York City, has opened a new office and warehouse in Galveston, Tex. The company now has three offices in the state of Texas, at Houston, Dallas and Galveston.

Ready Tool Co., 654 Main St. Bridgeport, Conn., has appointed the J. R. Stone Tool & Supply Co., direct manufacturers, representative of "Red-E" tools and "Red-E Hill" line of machine dogs for the state of Michigan and the northwestern part of Ohio.

Philadelphia Steel & Forge Co., Tacony, Philadelphia, Pa., has installed a new power plant in its rolling mill department which will increase its tonnage of finished bars 2000 tons per month. The company has also installed a heat-treating plant, and is specializing on high-grade steels for automobiles, locomotives, machine tools, etc.

Beaudry & Co., Inc., Boston, Mass., has perfected a direct-connected motor drive for the "Beaudry Champion" and "Peerless" power hammers, and descriptive circular matter will soon be ready for distribution. The company has arranged to carry a complete stock of motor-driven hammers in addition to the belt-driven hammers which they have marketed for years.

W. H. Leland & Co., Worcester, Mass., has appointed Mr. Stanley B. Dowd, formerly manager of the machinery and supply department of the Fairbanks Co., Boston, as its exclusive selling

MACHINERY

NOVEMBER, 1913

MAKING THE PHILIPS PRESSED STEEL PULLEY

OUT-OF-THE-ORDINARY SHEET-METAL FORMING OPERATIONS USED IN STEEL PULLEY MANUFACTURE

BY CHESTER L. LUCAS*

THE advance that has been made in producing good pressed steel pulleys has been largely responsible for their popularity. The earlier types were crude, but the modern pulley is light, strong and has excellent gripping qualities. Through the courtesy of Mr. J. J. Monday, president of the Philips Pressed Steel Pulley Works, Philadelphia, Pa., we are enabled to present the principal steps in the making of a modern pressed steel pulley. There are several types of steel pulleys but the Philips pulley is the only one in which the cross-section of the entire rim and supporting flange is made from a single sheet of metal. This pulley is illustrated in Fig. 1 and the steps in the formation of the rim and flange are indicated in the line illustration Fig. 2. From this it will be seen that the rim is one continuous surface of metal, properly crowned and integral with the inner part of the flange which is attached to the spider. This point should be firmly borne in mind throughout the article, as the manufacture of a pulley of this character presents unusual difficulties on account of this feature.

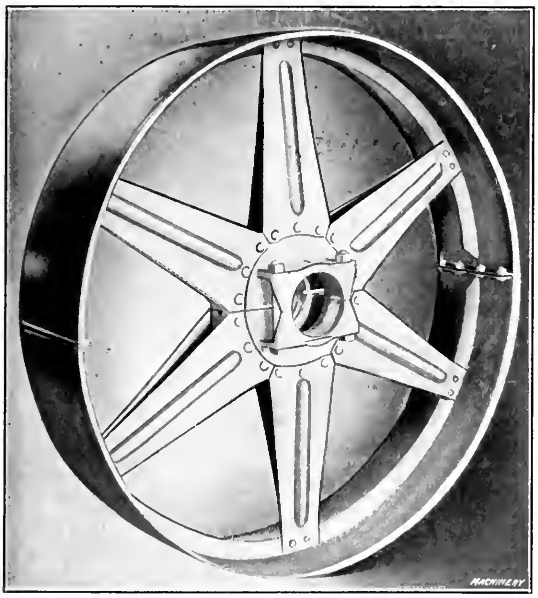

Fig. 1. Philips Pressed Steel Pulley—60-inch Size

These pulleys are made in diameters ranging from 12 inches to 60 inches, and with faces from 2 inches to 16 inches wide. For these varying sizes, different thicknesses of stock are employed, the thinnest being 17 gage and the thickest 12 gage. The first step in making the rim, aside from the shearing of the strips of steel, is the notching of the four corners as shown at *A* in Fig. 3. The purpose of this notching is to clear the metal from the section where the right angle bend must be made at each end to provide flanges for joining the two halves of the rim. This notching is a simple punch press operation and needs no further description. Next, the edges of the sheet are folded at right angles, as shown at *B*, so that they may later become the section which may be seen projecting from the center of the rim at *D*. Fig. 3, forming means for attaching to the spider. Two operations are required in doing this, the results being indicated at *C* and *D*. The folding over of these edges, as well as the subsequent bending of the rim-strip to the forms shown at *C* and *D*, requires a special type of machine, for to be successful as a manufacturing proposition it is essential that a quick and easily performed method of bending be employed.

Rolling the Rim Sections

For doing this work the rolling method has been found to be the most satisfactory, and Fig. 4 illustrates the details of the working parts of one of these machines. The principal parts of this type of machine are the long body *A* upon which a carriage *B* is traversed by a rack and pinion drive. The sheet of stock is laid upon this table and a plate *C* is clamped upon it by two clamps *D*. When locating the strip upon the table of the rolling machine, the edges overhang at each side just enough to make the two folded edges. Thus the blank is supported from above and below at the center section, leaving the edges unsupported so that they may be readily bent. As the clamping plate is a heavy casting to handle, a lifting toggle *J* is provided to assist in adjusting the strip before the rolling operation commences, and it also serves to return the plate after the strip has been removed at the end of the rolling stroke. While firmly clamped upon the table, the table, stock and plate traverse between the uprights *E*, the top of the clamping plate passing under the rolls *F*, which insures a continuous pressure

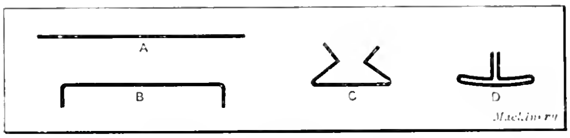

Fig. 2. Sectional Development of the Rim

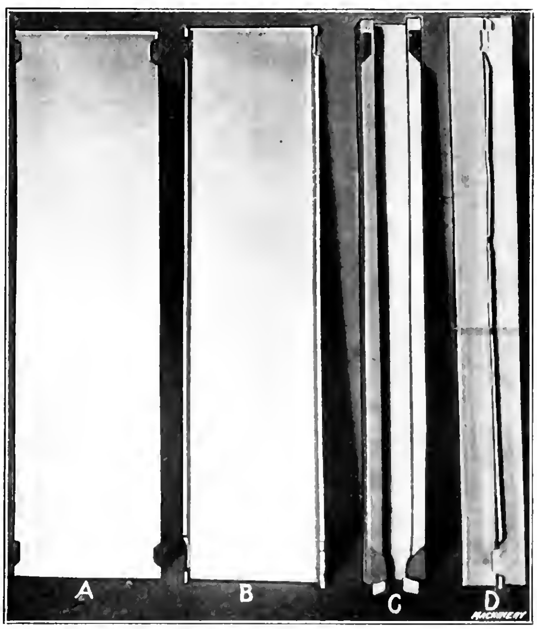

Fig. 3. The First Four Steps—accomplished in the Machines shown in Figs. 4 and 5

* Associate Editor of MACHINERY.

being placed downward upon the sheet. While this downward pressure is being applied the edges are passing by two cam-strips *G*, only one of which may be seen in Fig. 4. These cam-strips are so bent that the edge of the metal is gradually twisted from the horizontal plane down to the vertical plane by reason of its contact with the cam-strip. At the end it passes under a roller *H* which "sets" it against the edge of the carriage, leaving it in a perfectly square

Fig. 4. Rolling Machine for turning the Edges

bent condition, as shown at *I*. This operation leaves the rim-strip in the condition shown at *B* in Fig. 3. Subsequent bending operations which bring the rim-strip into the condition shown at *C* and *D* in Fig. 3 are performed upon another machine. This machine is illustrated in Fig. 5 and it works upon the same principle as that previously described in bringing the strip from the state shown at *B* to that shown at *D*, Figs. 2 and 3. For this purpose the strip in the condition at *B* is placed upon the carriage *A* of the rolling machine illustrated in Fig. 5, and a plate *B* is clamped upon it.

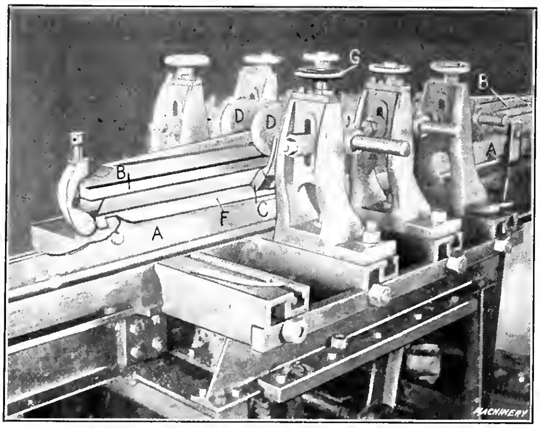

Fig. 5. The Second Bend—Reversing the Strip

It should be noted that in locating the strip, the turned edges are placed upward. As in the machine previously described there is a pair of cam-plates, one of which is shown at *C*, and as the carriage and clamping strip pass under rolls *D*, of which there are six, the edge of the strip comes in contact with the beginning of the cam-strips. At the start these strips simply bear on the top of the rim blank, and as the work follows the cam-piece down, it gradually takes on the finished shape, so that when it emerges at the end of the cam-strip, as shown at section *F*, that part of the work is completed. The cam-strips are adjustable, and the rolls which bear upon the clamping plate may be adjusted through hand screws *G*. The machine in Fig. 5 is used for rolling the strips to the condition shown at *C* in Figs. 2 and 3, and by inserting a new pair of cam-strips and holding block this piece is brought to the condition shown at *D*, Figs. 2 and 3, leaving it ready to be curved into the final rim shape.

Curving the Rim

One of the most important operations in the making of the Philips pulley is the curving of the rim-strips to form the two sections of the pulley. This operation presents difficulties in that it is very important that the central rib formed by the two edges of the strip be kept perfectly straight and free from buckling. This rolling is performed in the machine shown in Fig. 6 which at the same time crowns the rim face and leaves it curved properly for assembling. By referring to Fig. 7, the details of the working parts of this machine may be more clearly seen. The roll over which the strip is formed must, of course, be the exact diameter of the finished pulley. This means that sets of rolls must be provided for the different diameters of pulleys. As the pulleys are made in various widths of face as well as diameters it will be seen that the number of rolls required for rolling a complete line of pulleys would be very great

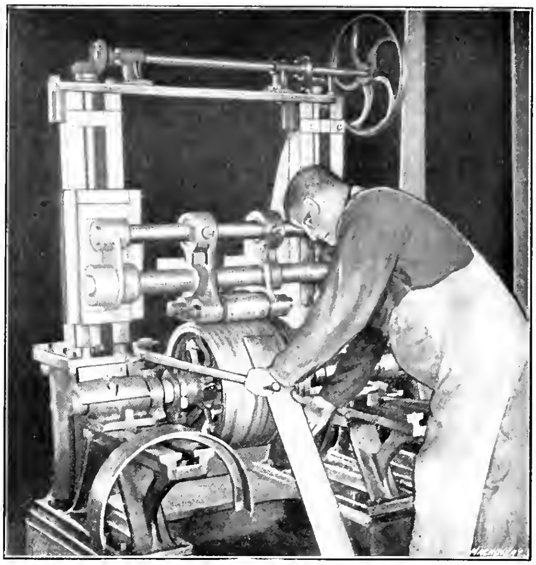

Fig. 6. Starting the Rim-forming Operation

were it not for the fact that each size of roll is arranged so that the various widths of pulleys may be formed upon it, although the upper rolls which support the face of the rim-strip must be changed to suit every width of face. Before the straight rim-strips come to this machine, iron stiffening rods are slid into the outer edges of the bends so that they may be rolled in place and thus reinforce the edges of the rim. To accommodate the various widths of pulley faces, the forming rolls over which the strips are curved are cut

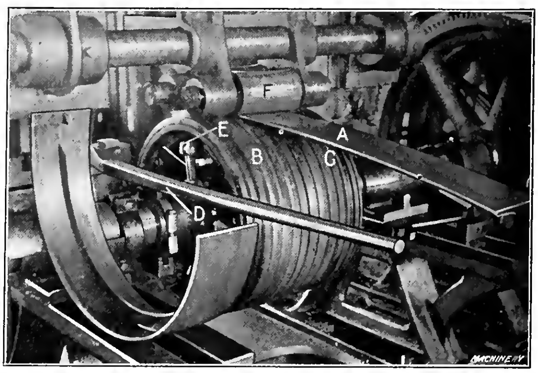

Fig. 7. Details of the Rim-forming Operation

with depressions corresponding with each width of pulley face which that diameter of roll will be called upon to form. These depressions are to allow the reinforced edges of the rim to drop beneath the surface while being rolled. One of the completely rolled strips is shown at the left-hand side of the machine in Fig. 7, and from this it will be seen that the central rim is preserved very straight and smooth, being in fact, in better condition than it was in the straight form.

This is accomplished by having the lower forming roll in two sections *B* and *C*, of which *C* is stationary and *B* capable of being set up against *C* by means of lever *D* and toggles *E*. It has already been stated that the object of cutting out notches at the corners of the sheet shown at *A* in Fig. 3 was to provide clearance for the right-angle bending of the end to secure flanges for bolting the two halves of the rim

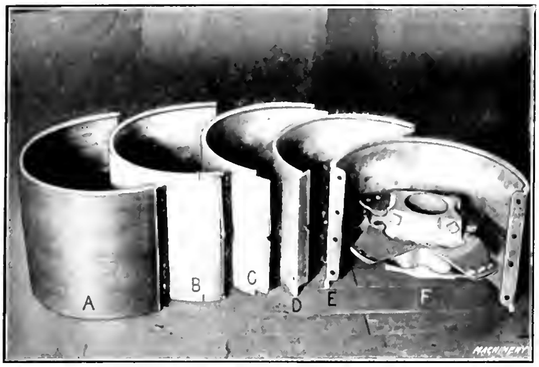

Fig. 8. The Evolution of the Rim Lug

together. The purpose of the short section of tongue remaining beyond the notch was not stated, however, and the object of this is to secure a gripping surface for starting the rolling operation. As shown in Fig. 6, the operator starts the piece by separating the two halves *B* and *C* of the roll and inserting the extreme end of the tongue in the gripping section of the rolls where the inner faces are knurled. Clamping the knurled section against the tongue he starts the rolling operation, allowing the strip to feed in under the pressure rolls *F* which press the strip into shape against the forming rolls *B* and *C*, at the same time squeezing the flanges down between the rolls. After running under the pressure rolls for two revolutions the piece is formed and ready to be taken from the machine. The point that should not be overlooked in this rolling operation is that the central

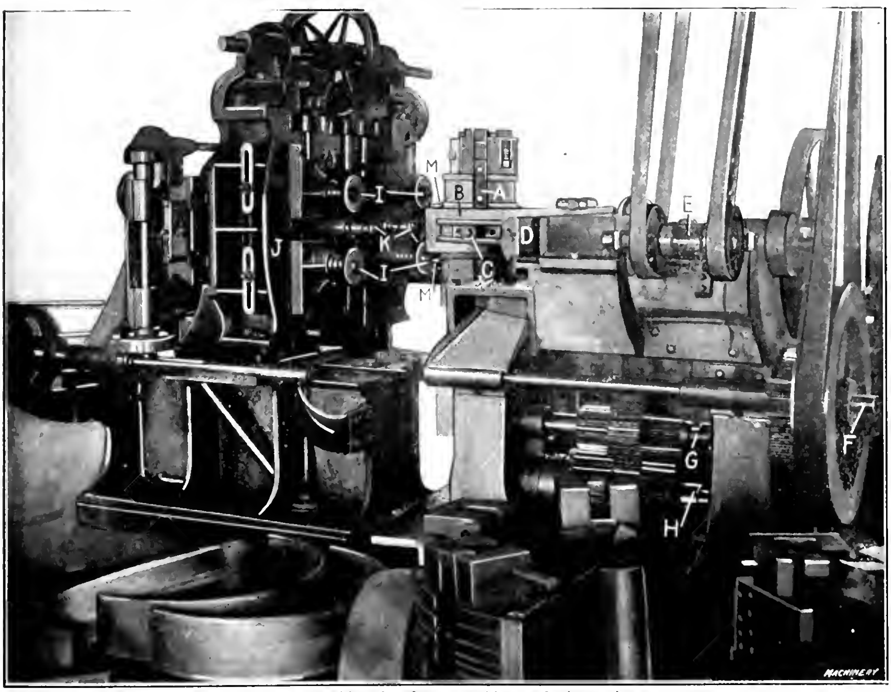

Fig. 9. Machine for flange-punching and rim-sawing

rib or flange is kept from buckling by reason of the side pressure exerted between halves *B* and *C* of the forming rolls, so that when the upper rolls *F* force this web between the two halves it is confined so that it cannot buckle or distort in any way.

Operations on the Rolled Rim-strip

The operations performed on the rolled rim-strip are four in number and the rim-strip and the four operations are shown at *A*, *B*, *C*, *D* and *E* in Fig. 8. The first of these operations consists of sawing the edges of the rim, thus sizing them to the semicircular dimension, and at the same time punching the holes in the flange to provide for the riveting of the spider in place. The function of these rivet holes is more clearly illustrated by observing the spider shown at *F* in connection with the rib or flange of rim *E*.

This combined shearing and sawing machine is interesting in its operation, and is shown as a whole in Fig. 9. Referring to this illustration the machine may properly be said to consist of two working members on opposite sides of a stationary arbor *A*. The rim is placed upon this arbor as

Fig. 10. Punching the Rivet Holes in the Arms

indicated at *B* and is firmly clamped in position by clamping strap *C* which is semicircular in form and held against the rim face, pressing it to the arbor by means of a traveling carriage *D*, which is advanced by power from driving shaft *E*. Through another driving shaft *F* at this end of the machine power is transmitted by means of a small pinion to an intermediate shaft *G* and thence to a pinion sleeve *H*, rotating upon a shaft, on the end of which there is a large eccentric. Now, by referring to Fig. 11, which shows the arbor and part of the eccentric on a larger scale, the method of punching the holes in the rim flange may be followed. Here again we have the central arbor and the clamping strap shown at *C*, and lower down may be seen the intermediate shaft *G* and the pinion sleeve *H* on the eccentric shaft. It will be noticed that in the center of the form where the rim is held, is a deep depression *B*. This is for the reception of the central rib of the rim through which the holes must be punched. For the purpose of punching these holes, a pair of punches is located at *P*, and the dies are, of course, directly beneath, allowing the punchings to drop out through the recess *Q*. These punches are held in a slide *R* which is reciprocated by a lever *S*, pivoted at *T* near the top of the arbor. The opposite end of the pivoted lever is held in the vertical shaft *U* and reciprocated by the eccentric motion previously referred to in connection with

Fig. 9. Some of the punchings from the central ribs may be seen in this illustration and even more clearly in Fig. 12 where they have dropped out from the dies. In Fig. 12, however, the work is shown in place; therefore the punches and dies are concealed.

This feature of the machine takes care of the punching only, the sawing being performed at the opposite side of the arbor. Referring back to Fig. 9, the arrangement of the sawing mechanism is adequately shown. There are four sawing spindles *I*, each fitted with circular saws and rotating at correct cutting speeds for steel. These are all mounted upon the traveling head *J* which is advanced by a hand

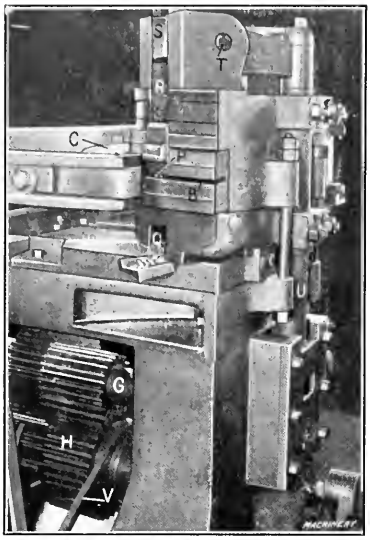

Fig. 11. Close View of the Arbor and Punches

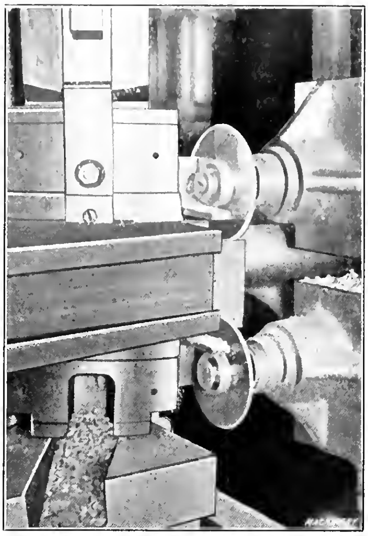

Fig. 12. The Sawing Operation

Fig. 13. Assembling the Pulleys

lever on the opposite side of the machine until stop *K* strikes against the work-arbor *A*. The feeding forward of the head brings the saws into the cutting position, but in order to take up any little differences in the saw locations or end play of the spindles, the saws are flexibly mounted. They are held in forward positions on the arbors by stiff spiral springs. The feeding forward of the head causes the sides of the saws to bear against gages *M* and any differences in position are taken up by the spring pressure. Gages *M* are, of course, set so that the sawing will be done at

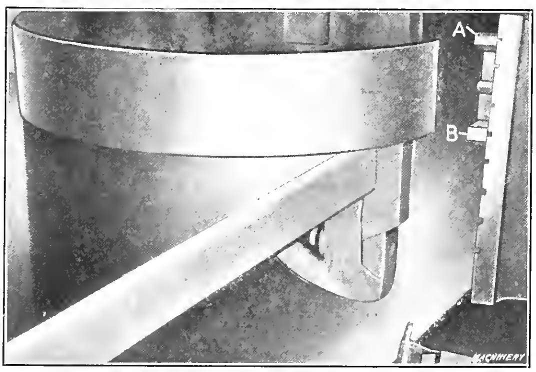

Fig. 14. Rough-trimming the Ends of the Rim

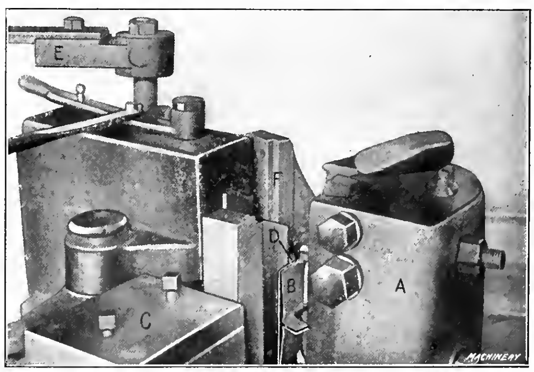

Fig. 15. Bending the Rim-lug

exactly opposite points on the rim. At this point the saws are above and below the edges of the pulley rim, and by throwing in the vertical feed the operator causes the two lower saws to come up and the two upper saws to feed down into the rim, sawing until the feed is automatically tripped. This, of course, takes place after the rims have been sawed to the required depth. Sawing rather than slotting is necessary for this operation on account of the heavy steel wire reinforcement which is within the rim on each edge. The result of this operation leaves the rim in the condition shown at *B* in Fig. 8. In operation, the rim is clamped around the arbor by running carriage *D* up to the arbor so as to bring clamping strip *C* into action. Shaft *F* is transmitting rotation continuously to auxiliary shaft *G*, and thus to the pinion sleeve *H* on the eccentric shaft. This sleeve rotates loosely upon the shaft except when keyed to it by a clutch that is controlled by lever *V* shown in Fig. 11. Throwing over this lever, therefore, causes the eccentric to operate the set of punches, pushing them downward through the rim flange. The smaller rim halves have four punched holes, while the larger ones have six holes. The rim punching is followed closely by the sawing operation on the same machine as has been described.

Preparing the Rim Halves for Joining

A series of three punching and forming operations follow the sawing and they are all done on similar machines, *viz.*, a type of horizontal punch. The first of these operations consists of cutting out the square section that has been sawed and rough-trimming the end of the rim section to approximately the finished length, leaving it in the condition shown at *C* in Fig. 8. The rough-trimming operation appears in Fig. 14. An adjustable table is provided upon which the rim is supported, its end being inserted between the punch and die of the horizontal punching machine. The work is located by means of the previously made saw cuts, and adjustable punches *A* and *B* cut out the two sections beyond the saw cuts, the punches being in line with the dies on the opposite side of the work. The object of having these punches and dies adjustable is to provide for trimming the different widths of rims which must be handled in the machine. Tongues on the punches fit into corresponding grooves in the punch-holder and make the changing over of the machine for another size of pulley a comparatively simple matter.

Following this operation comes the bending of the flanges to the condition shown at *D*, Fig. 8, on a machine similar to that illustrated in Fig. 15. While the machine on which this bending operation is done is similar to the horizontal punch, the movements of the tools are more interesting and may be best understood by the line illustration Fig. 16. In order to bend this end of the rim properly it must be supported while the right-angle bend is made, and then an additional "setting" bend from the front is necessary to give it the proper angle to make a good tight joint when bolted to the mating-rim half. Referring to the line engraving which shows a plan view of the working parts of the horizontal punch, the anvil is shown at *A* and the work encircling it at *B*. The ram or head of the punch appears at *C* and the side bending punch at *D*. After the work has been placed in position the operator swings hand lever *E* over, causing rocker arm *F* to bear against the work thus holding it firmly for the bending. Tripping the clutch of

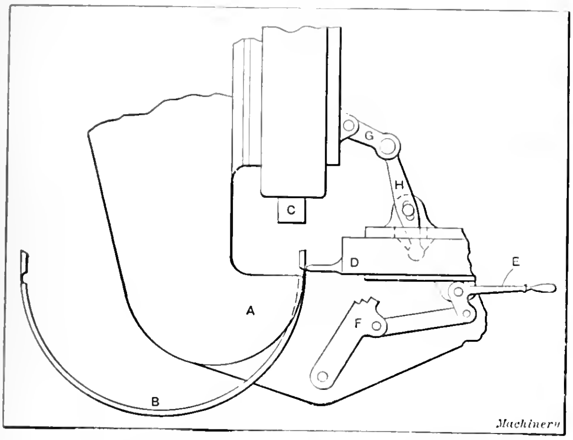

Fig. 16. The Mechanism of the Rim-lug Bending Machine

the punch the ram advances and through link *G* and toggle *H* the side bending slide *D* is caused to advance and make the first part of the bend, producing the approximate shape. As the ram continues to advance, the side bending slide draws back, after which the heading punch strikes the partly bent work and "sets" it against the form on the anvil. The operation of the cross bending slide by means of the heading punch is quite novel.

The third rim-finishing operation is along the same general lines, and comprises the final punching of the joining flange, trimming the lug to its finished shape and punching the

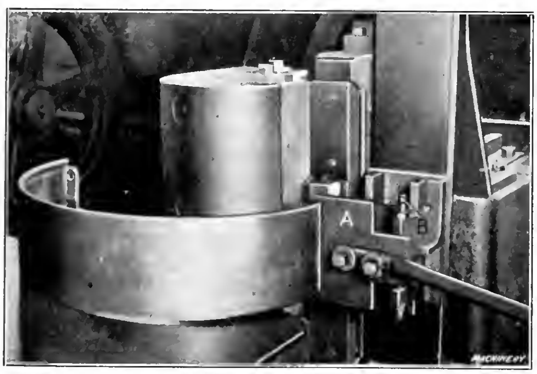

Fig. 17. The Final trimming of the Rim-lug

rivet holes for the attaching bolts. This operation is shown in Fig. 17, and with the exception of gate *A* which is hinged at *B* and serves to hold the work firmly while being punched this comparatively simple operation has no unusual features. This operation leaves the rim section in the finished condition shown at *E* in Fig. 8.

Making and Assembling the Spider

The spider or central structure from which the rim is supported is built up around a split cast-iron bushing. The two halves are bolted together and sheet metal arms riveted on each side to form connections with the central flange of the pulley rim. After these arms have been riveted in place, the ends are punched for assembling with the rim. It is very necessary that these rivet holes be equidistantly spaced from the hub of the spider so that the rim will be riveted

Fig. 18. Riveting the Arms to the Rim-flange

true with the bore in the hub, and thus produce a true running pulley. The punching fixture is shown in Fig. 10. This fixture has a pivot over which the spider may be slipped, and provision is made for indexing the spider for four or six arms, as the case may be. There is a certain amount of spring to the arms of the assembled spider, and in order to punch the holes accurately they must be held close together, while the punches are passing through the stock. For this purpose a stripper *A* is fitted over the die, being hinged at *B*, and extending out around the punches. Before punching,

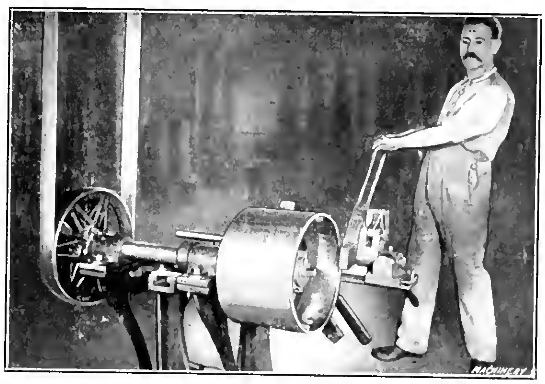

Fig. 19. Truing the Edge of the Pulley Rim

hand lever *C* is depressed, causing the stripper to be pressed against the stock, and while the two spiders are thus held close together, they are punched clean and accurate.

Two of the pulley assemblers are shown in Fig. 13. Their part of the work is to assemble the two halves of the rim about the spider and to insert the rivets ready for riveting. The spider is first mounted on a pivot stud and the two halves of the rim bolted over it. These operators handle S-wrenches continuously, and the speed which they develop in manipulating them while putting the bolts through the rim-lugs is remarkable, considering that the bolt locations are not very accessible.

In Fig. 18 may be seen one of the hydraulic riveters for upsetting the rivets when attaching the spiders to the rims. The riveter is fitted with a stationary anvil and a hydraulically operated punch directly over it. A traveling carriage is mounted on the frame of the machine, on which is supported a pivot stud which may be moved in or out according to the diameter of the pulley being riveted. The riveting operation is simplicity itself, for after the work is located, it is only

necessary to pull over the operating lever which hydraulically applies pressure to the riveting punch.

Truing the Pulleys

The final operation, exclusive of painting, on the Philips pressed steel pulley, is truing. This is an operation which requires considerable skill and no little manual strength. The pulley is mounted on the truing stand as shown in Fig. 19, and the operator revolves it by power and observes the way the rim runs, locating the high points by holding a piece of chalk stationary against the revolving rim. His first operation consists in throwing the edges of the rim into their respective vertical planes. This is done by pressing in the high points with a wooden lever applied as shown in Fig. 19. Two or three pulls by an experienced operator will usually put the edges into alignment. This part of the work being done, the face receives attention, and with the two

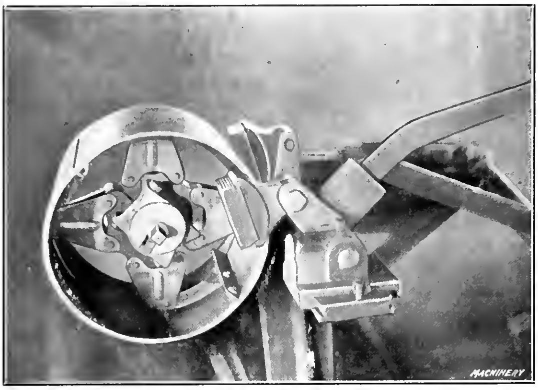

Fig. 20. Method of truing the Pulley Face

levers with which the truing stand is equipped, shown on a larger scale in Fig. 20, the rim may be trued. This is done by pressing down the high points by pulling up on the levers when their wooden faces are against the outside of the rim or by depressing the levers with the edge of the block caught inside the rim as shown by the forward lever in Fig. 20. It will be seen that four different combinations of the two levers may be secured; both inside, both outside, one inside and one outside in both directions, thus providing for restoring any distorted rim. Care has to be taken not to throw the edge out of true when working on the face and *vice versa*. In spite of the seeming difficulties of the pulley truing operation an experienced operator will true 200 finished pulleys in a day of 10 hours.

* * *

The cartoonists' idea of illustrating motor car troubles still seems to be to show the driver underneath, lying on his back or stomach, with his feet sticking out, working himself into a frenzy under the mysterious and diabolical mechanism. The cartoonists are not up to date. They have not found out, apparently, that very little of modern motor car machinery needs tinkering from beneath. It is true that the first cars were so built that the prostrate position of the luckless driver was necessary to effect many repairs, but the modern car is quite a different sort of machine. With the engine in front, the gear-box and clutch beneath the floor in front of the front seat, and the differential in the rear axle, there is very little indeed to call for taking a mud or dust bath underneath. But we suppose that comic pictures of automobile troubles will be shown in the conventional way for another ten years at least.

* * *

Wireless telephony continues to make progress. Wireless communications have been established between Berlin and Vienna, a distance of 355 miles. A Japanese telephone official is credited with having invented a wireless telephone apparatus different from those used in Europe, which has been successfully tested between Yokohama and steamships 60 miles at sea.

DON'TS FOR DRILLING MACHINE OPERATORS*

BY JAMES E. COOLEY†

Don't use a loose feed belt.
Don't use the shank of a file for a drift.
Don't spot holes in the table with the drill.
Don't use a wrench or a file to throw off a belt.
Don't use a wrench or a collet to drive a drift with.
Don't forget to use oil when drilling malleable iron.
Don't drum on the table with the ball-end of a hammer.
Don't forget to fasten the spindle-head and table-slide.
Don't leave chips in the drilled hole; empty them out.
Don't try to drill tough steel with oil; use turpentine.
Don't run a twist drill in a cored hole; use a butt-mill.
Don't use a jack having a top as large or larger than its base.
Don't run a body-counterbore down too far in a tap size hole.
Don't use a reamed stud-hole in a knee to drill work through.
Don't put drills or reamers in collets having different tapers.

Don't let the lip of the drill strike on the edge of the bushing.

Don't let the drift and wrench get lost each time after using it.

Don't get in the habit of slapping a belt each time you adjust it.

Don't try to get along by using one jack; use two if necessary.

Don't leave the machine with a drill running idly in a bushing.

Don't slide a jig across the table and bang it against the drill.

Don't try to grind a reamer if it does not cut; take it to the foreman.

Don't forget the value of a long leverage as a stop when drilling.

Don't forget that a piece of hard wood is handy to drill sheet metal on.

Don't fail to clean and oil the threads in the clamp screws occasionally.

Don't have a foot on a jig extend over the edge of a hole in the table.

Don't be afraid to own up that you have broken a drill or counterbore.

Don't throw or toss drilled work in a box; lay it down carefully.

Don't be above sweeping the dirt around your machine into a neat pile.

Don't fail to lower the spindle-head as close to the work as possible.

Don't bear down too hard when drilling a hole through the rim of a pulley.

Don't forget to chalk over the spot you are laying out on a rough casting.

Don't think that it is necessary to sit down for every drilling operation.

Don't let oil drip off the table onto your overalls, shoes, or the floor.

Don't let the drill cut on the edge of the holes or slots in the table.

Don't fail to look and see if every hole has been drilled in the piece.

Don't drive a drill out of a sleeve collet by striking the end on the table.

Don't be too slow in putting in and taking out a quick-change drill collet.

Don't use your fist to drive a heavy casting under the drill; use a babbitt hammer.

Don't use machine oil to drill with; use lard oil or a drilling compound.

Don't forget to fasten every screw in the jig and lock the work in securely

Don't place the fingers under the work to feel if the drill is coming through.

* For "Don'ts" previously published in MACHINERY, see "Don'ts for Drill Grinders," July, 1913, engineering edition, and "Don'ts" there referred to.
† Address: 46 Wyllys St., Hartford, Conn.

Don't put a jack directly under the point where the drill comes through the work.

Don't put on the feed until the point of the drill is down against the work.

Don't forget to have another piece ready to put in the jig when one is taken out.

Don't kill time by letting the drill run deeper in the work than is necessary.

Don't use too much oil when tapping holes in cast iron with the tapping fixture.

Don't forget to take out the scratches and dents in the table with a smooth file.

Don't throw clamps and bolts around on the floor and jam the threads in the screws.

Don't drill aluminum without using kerosene oil; it makes a very smooth hole.

Don't forget that brass, aluminum and wood should be drilled at a high speed.

Don't forget to use the try-square against the spindle to see if the work is true.

Don't forget to spot a hole with a full-size drill, before using a tap size drill.

Don't use a center-punch made out of a round file; it is too brittle and dangerous.

Don't forget to fasten the tap securely in the tapping fixture before tapping a hole.

Don't keep the jacks where you have to stretch over to reach them; have them near you.

Don't fail to rub oil on the pilot of counterbores each time they are placed in a hole.

Don't use extension collets to lengthen the spindle unless absolutely necessary.

Don't use a large drill press to drill a small hole, when a smaller one can be used.

Don't start to drill a hole unless you are sure you are using the right size drill.

Don't let the spindle-sleeve get gummed up; wipe it clean and oil the entire length.

Don't forget to put a piece of sheet brass between the end of the clamp screw and the work.

Don't stand on the table or belt-shipper to adjust a belt while the machine is running.

Don't forget to clean off all taper shank tools before "socking" them up in the spindle hole.

Don't think a piece of work will hold itself while it is being drilled, but fasten it down.

Don't yank the belt-shipper forward to start the machine, but draw it over carefully.

Don't take a drill out of a spindle by clamping a monkey wrench across the flute and twisting it.

Don't forget to look at the outer end of the work that is being drilled to see if it tips up.

Don't push a drill down in a bushing without first oiling the drill or inside of the bushing.

Don't put the spanner wrench in your pocket or in a place where someone will have to hunt for it.

Don't strap work on the outside of a knee or angle plate when it can be placed on the inside.

Don't drive out an Almond chuck from the spindle by hitting it on the back end; use a drift.

Don't forget that a dull tap in a tapping fixture breaks the fixture quicker than the tap.

Don't forget that a reamer should be drawn up from a hole, nearly as slowly as it was run down.

Don't forget to wipe the oil and chips from the table each time before laying the jig down under the drill.

Don't forget that a box is a handy thing for holding a pulley to drill an oil-hole in it on an angle.

Don't run a head counterbore into cast iron scale, but gouge out the hole first with an old drill.

Don't brush chips toward the column, as they will get in on the ways of the table slide.

Don't set a screw too tight against the piece in the jig; it will spring the piece or spread the jig.

Don't push a tap against a hole when it is running in the reverse direction in the tapping fixture; raise it up first.

Don't forget when drilling pin holes to try a pin in the hole occasionally to see if it will drive.

Don't forget to try the reamer in a hole after the drill is ground to see if the drill cuts small enough.

Don't try to hold work with the hand while drilling because it is too much trouble to rise and get a wrench.

Don't leave drills and reamers lying around after you are through with them; return them to the tool-room.

Don't use waste to wipe the chips off the tap while it is running in the tapping fixture; use a stiff brush.

Don't waste time by running a nut too far on the thread of a bolt when bolting down work; use plenty of washers.

Don't hasten the spindle stoppage after the machine is shut off by trying to insert the drift in the spindle broach.

Don't, when the drill runs off the center of a scribed circle use a center-punch to draw it back; use a draw-chisel.

Don't forget that the very first rudiment in running a drilling machine is to have the work square with the spindle.

Don't force out a collet from the spindle by placing the drift through the broach in the collet and twisting it.

Don't put the spout of the oil can down in a jig-bushing while the drill is in motion; the end will be chewed off.

Don't drill a heavy casting on a sensitive drilling machine as the weight of it will spring the table out of true.

Don't leave an Almond chuck with a drill in it lying lengthwise on the table; it will roll off and break the drill.

Don't forget when drilling a deep hole in cast iron that a little oil rubbed on the drill will prevent it from squealing.

Don't use a collet for a stop by driving the taper end down in a hole in the table, but bolt down a knee for this purpose.

Don't forget that if a small drill is run down into the mark made with a center punch, it will guide a large drill central.

Don't let a tap strike the bottom of a hole when using a tapping fixture, but be sure to set the stop to limit the depth

Don't drive out a stud from an angle plate when it is strapped down; the hammering is likely to break or spring the plate.

Don't lay anything on the table too near a jig; in case it gets caught and whirls around it will sweep everything in range.

Don't forget when fastening a clamp over the table to have the head of the screw point downward; it is then out of the way.

Don't tighten the table slide or spindle head by hitting on the wrench with a babbitt block or hammer; the hand pressure is sufficient.

Don't, when the jig has been raised or tipped up, put it down again and continue drilling, because chips are likely to be under it.

Don't forget that the bottom end of a hole is smaller than the top and a hole should always be reamed from the drilled side.

Don't twist a drill with a wrench when it gets stuck in a jig; squirt a little turpentine in the bushing and it will come out easily.

Don't fail to examine the point of the drill after it has had a fit of sputtering in the hole; it has struck hard sand and needs grinding.

Don't have washers, nuts or clamps, etc., scattered around you; keep them in a box or, better still, drive nails in a bench and hang them up.

Don't forget that if you drill a hole in a separate piece and then strap it down over the piece you want to drill, you will get a true hole.

Don't leave the machine while it is running and think it will take care of itself; something is likely to get stuck and it is best to shut it off.

Don't fail to listen for the noise made by the drill when it is coming through the work, as it requires less pressure if there is backlash in the spindle.

Don't try to tighten up the drill chuck while it is running with the hand. When the drill slips stop the machine and use the spanner wrench.

Don't under any circumstances draw up a drill from a jig too quickly, as it will bind in the bushing and whirl the jig around.

DRAWING AND FORMING AN AUTOMOBILE CLUTCH CONE*

A GOOD EXAMPLE OF HEAVY SHEET-METAL FORMING IN THE PUNCH PRESS

BY DOUGLAS T. HAMILTON†

The automobile clutch cone shown in Fig. 1 illustrates one of the many interesting examples of sheet-metal work turned out by the Acklin Stamping Co., 1645-1653 Dorr St., Toledo, Ohio. This clutch cone is made from 1/8 inch cold-rolled sheet steel and is completed in the punch press, with the exception of a light cut taken from the bearing of the cone in

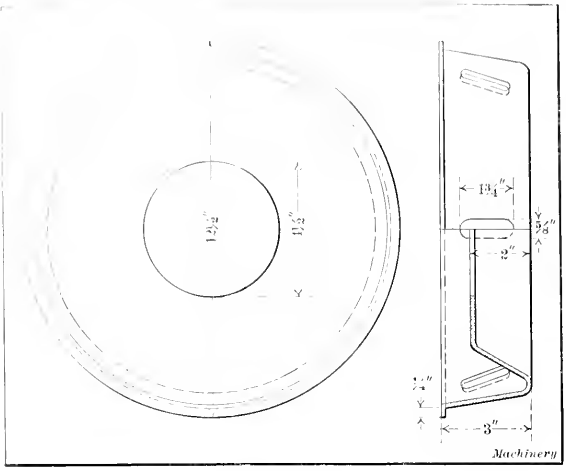

Fig. 1. Automobile Clutch Cone completed in the Punch Press in Six Operations

a grinding machine. The grinding is done in order to obtain a perfect frictional bearing surface. Some of the most important punch press operations on this clutch cone are illustrated in Fig. 2, where the nature of the work accomplished is evident. The cone is completed in the punch press in six operations, the completed part being shown at *D*.

Blanking and Drawing the Clutch Cone

In the half-tone Fig. 3 is shown the first drawing die and the result of the operation performed by it, the latter being indicated at *B* in the illustration. The blank *A*, which is 17

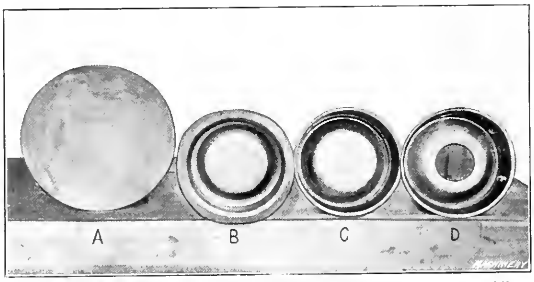

Fig. 2. Sequence of Important Operations performed on the Automobile Clutch Cone shown in Fig. 1

inches diameter by 1/8 inch thick, is cut out by a simple blanking die. Punch *H* is fastened to the base *I*, which is attached in the usual way to the bolster of a No. 78½ Bliss press shown in Fig. 4; draw ring *C* moves freely around punch *H*. The holder *D*, carrying the inserted die ring *E* and reversing pad *F* is held to the ram of the press. These dies are used in a single-action press and are given the double-action movement by means of a rubber compression pad under the bolster which operates the draw ring *C* through the medium of the six pins *G*. The pressure exerted by the rubber pad prevents the blank from buckling when being

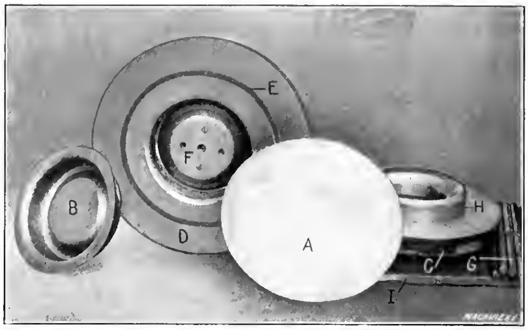

Fig. 3. Combination Blanking and Forming Dies for making an Automobile Clutch Cone

drawn. The reversing and drawing of the cup is accomplished by the punch *H* in combination with the reversing pad *F*. The result of this operation is shown at *B* in Figs. 2 and 3.

Redrawing and Tapering Dies

The dies used for redrawing the cup and bringing it to practically its final shape are shown in Fig. 5. These are held in the same manner as those shown in Fig. 3 and are

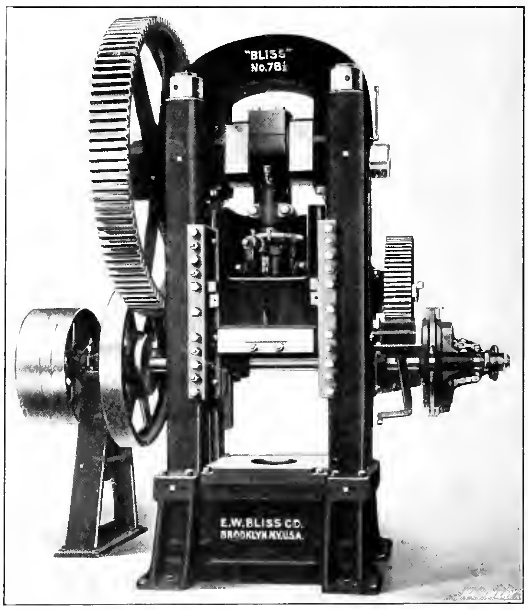

Fig. 4. Bliss No. 78½ Press used in making Automobile Clutch Cone

somewhat similar in design, with the exception that the exterior drawing surface of the punch *C* is tapered instead of straight like the punch used for the previous operation. These dies are also held in a single-action No. 78½ Bliss press. The pins *D* operate on the drawing ring *E* and prevent the blank from buckling when being drawn down into the die *F* by punch *C*. The condition of the cup before and after this operation is shown at *A* and *B* in the illustration, and at *B* and *C* in Fig. 2. The finishing operation requires a

* For additional information on punch and die work, see the following articles previously published in MACHINERY: "Blanking, Forming and Cutting Die," September, 1913; "Sectional Punch and Die Construction," July, 1913; "Blanking and Drawing a Large Steel Cup in One Operation," "A Problem in Press Work," July, 1913; "Blanking, Forming and Piercing Die," June, 1913; "Combination Punching, Cutting and Forming Die," "Punch and Die for Forming Electric Terminals," May, 1913; "Punch and Die made in Sections," "Punch and Die for Bending past the Vertical Line," March, 1913; "Standards in Die Work," "Locating Punches in Tandem Dies," "Tools for Multiple Plunger Presses, (engineering edition), February, 1913; "Some Interesting Drawing and Curling Dies," "A Bending Die," January, 1913; "Modern Methods of a Press Working Plant" (engineering edition), December, 1912; "Producing Drawn Steel Rollers in a Gang Die," "Drawing a Small Shell from Thick Brass," "Punch and Die for Forming Electric Terminals," "Combination Folding and Curling Die," November, 1912; "Method of Making Watch Case Pendants" (engineering edition), October, 1912; "Prevention of Wrinkles in Drawn Work," "Closing and Curling Die," September, 1912; "Tools for Perforating Lamp Burner Parts," "Watch Case Manufacture—," "Sub-press Die for Making a Cleat," August, 1912; "The Drawing of an Odd Shaped Cup," "A Piercing and Cutting Off Punch and Die," April, 1912; "Drawing a Flange and Tapered Cylindrical Shell," March, 1912; and other articles there referred to.

† Associate Editor of MACHINERY.

pressure of approximately 500 tons. After the redrawing and tapering operation the flange is trimmed and finished to size. Following this, the center hole is cut out.

Cutting the Elongated Slots in the Rim

Undoubtedly the most interesting operation in connection with the manufacture of this clutch cone is the cutting of the elongated slots in the rim. From an inspection of Fig. 1, it will be seen that the cutting of these slots presents a difficult problem, owing to the "returned" shape of the lower portion of the cone. This not only makes it hard to get at, but also makes it a difficult matter to get rid of the scrap if the punches are presented from the sides. The gang method of punching would be impossible owing to the slender construction of the dies which would be required for the space allowed. The tools used to accomplish this interesting operation are shown in Figs. 6, 7 and 8. Fig. 6 shows the work in position in the slotting die, while Fig. 7 shows the work removed and the die opened up and thrown back.

The manner in which this slotting die is used is as follows: The base *A*, Fig. 8, is held in the usual manner to the bolster of the punch press, while the two studs *B* are held by nuts

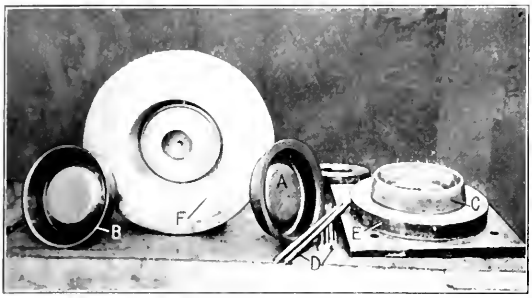

Fig. 5. Redrawing and Finish-forming Dies for Automobile Clutch Cone

in lugs cast integral with the ram of the press, and are used to return the punch-block *C* after the punch *E*, Fig. 7, has passed through the work. This, of course, is accomplished on the return stroke of the ram. The cutting die *D*, as shown in Fig. 7, is inserted in the base *A*, whereas the punch *E* is held in the block *C*, which is acted upon to punch the slot by a punch-holder *F*, held in the ram of the press.

In operation, the clutch cone is clamped to the circular holder *G* which is attached to the arm *H* by a block *I*, acted upon by a cap-screw *J*. This circular holder is revolved by hand and carries an indexing plate *K*, as shown in Fig. 8. This index plate is made of steel and is located for the different indexings by a hardened tool-steel dog controlled by the handle *L*. At the beginning of each indexing the moving

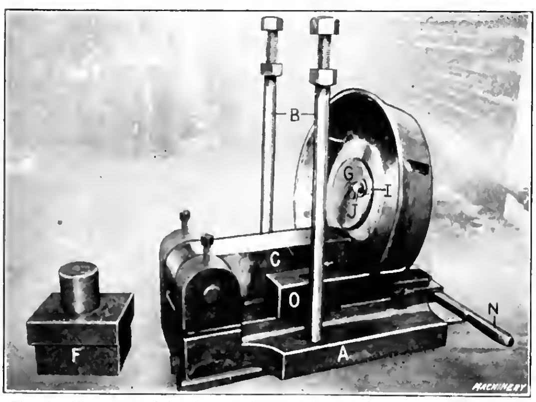

Fig. 6. Fixture used in the Punch Press for cutting the Six Elongated Slots in the Rim of the Clutch Cone

parts are securely clamped by means of the wedge *M* operated by handle *N* and the adjustable blocks *O* against which the rim of the cone is held. While these three members are not essential parts of the apparatus, they serve to render the gaging much more accurate. Handle *P* is attached to these blocks and is located in a recess provided in the base of the die shoe.

The ingenuity displayed in the solving of this difficult slotting problem speaks well for the ability of the Acklin Stamping Co. to handle sheet-metal stampings of unusual and complicated shapes.

* * *

FOOL-PROOF AUTOMOBILES

Some time ago a local paper published an item stating that a Norwich, N. Y., man drove his automobile ten miles with the emergency brake set, and humorously added, "It is

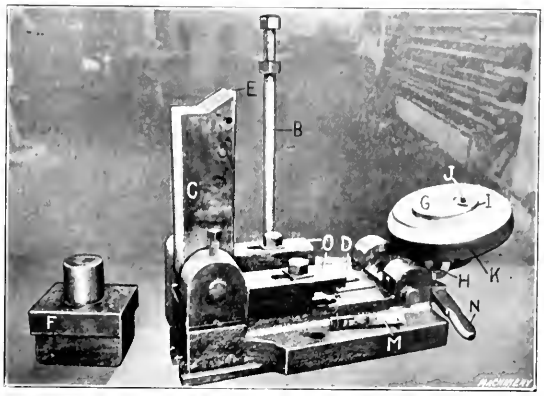

Fig. 7. Fixture shown in Fig. 6 with Work removed and opened up to show Construction

a pretty good car yet." This and other accidents that often happen indicate the need of better control apparatus on motor cars. Gears are often stripped by putting on the emergency brake with the clutch engaged, and other interferences contribute not a little to the rapid deterioration of the motive mechanism and tires.

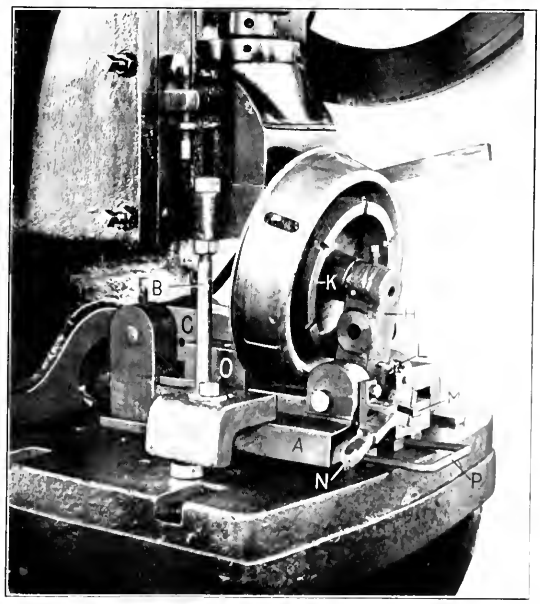

Fig. 8. Slotting Fixture shown in Fig. 6 set up in a Punch Press ready for Action

Automobiles, motor trucks and other power-driven vehicles should be provided with strictly interlocking gears which would prevent interferences of this character, and until that sort of control apparatus is achieved the motor car will not be a strictly practicable vehicle for all sorts of users. The tendency in all modern design is to simplify and make operation easy. Such improvements popularize machinery and materially reduce the cost of operation, to say nothing of making it safer for the average user. Safety is a prime requirement for all automobile driving, but so long as the driver can make serious blunders while driving they will continue to be made.

EXAMPLES OF SCREW MACHINE "SET-UPS"*

VARIOUS "SET-UPS" USED IN MAKING PARTS ON THE "ACME" MULTIPLE-SPINDLE AUTOMATIC SCREW MACHINE

BY DOUGLAS T. HAMILTON†

As one of the first considerations in laying out a job on the Acme multiple-spindle screw machine is to determine the best method of applying the tools, etc., a few examples of representative "set-ups" will be given. Of course many jobs could be handled in several different ways; but as a rule there is

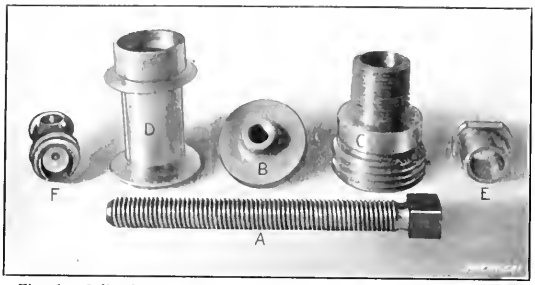

Fig. 1. Collection of Pieces economically produced on the "Acme" Multiple-spindle Automatic Screw Machine

always some governing feature that makes it possible to produce the part much more quickly and accurately in some specific way. Fig. 1 shows a number of parts produced on the "Acme" automatic by methods which are commendable, and in the following a description will be given of the tool equipments and "set-ups" used. The examples shown in Fig. 1 have been chosen because they represent several of the most common tooling methods employed in producing the general run of work.

"Set-up" in which the Longest Operation is performed from the End-working Tool-slide

The long set-screw shown at A in Fig. 1, and also in Figs. 2 and 4, is a common piece of work produced on the "Acme"

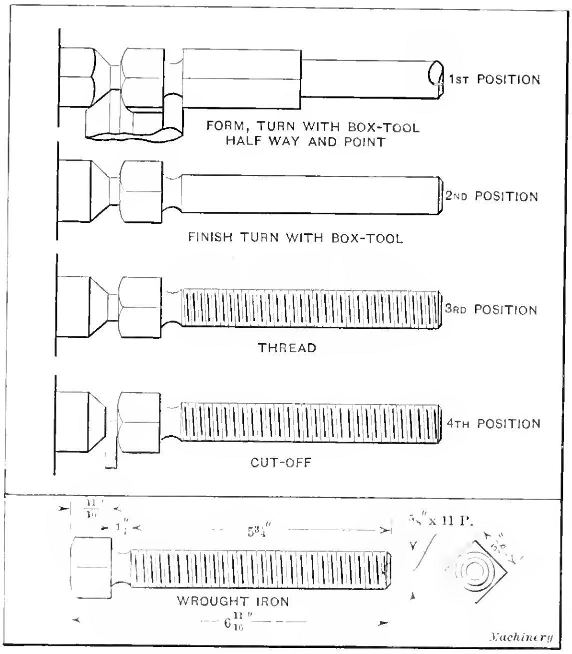

Fig. 2. Order of Operations used in making a Long Square-headed Set-screw

multiple-spindle automatic. By referring to the lower section of Fig. 2, it will be seen that this set-screw is made from a square wrought-iron bar, and that the threaded portion is 5¾ inches long, the length over all being 6 11/16 inches. The longest single operation, as can be seen at a glance, consists in turning down the body diameter to the required size. We first decide on the machine to use for this piece, endeavoring where possible to use the size of machine that will handle

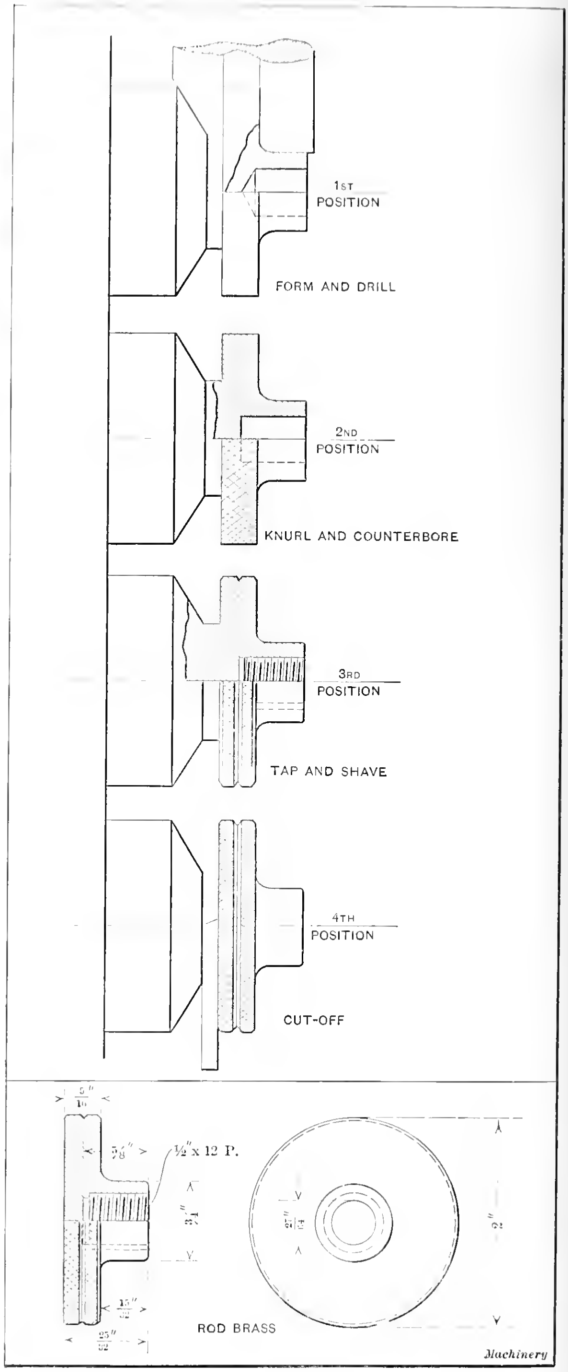

Fig. 3. Order of Operations used in producing a Brass Thumb-nut

the work most economically. Of course where only a few sizes are in use it is not always possible to select the machine best suited to every job. It is advisable, however, to have the work approach, as closely as possible, the rated capacity of the machine that is to produce it.

The distance across the corners of this set-screw is 0.880

* For material previously published on the "Acme" multiple-spindle screw machine, see "Setting Up and Operating Screw Machines" and articles there referred to in the October, 1913, number of MACHINERY.
†Associate Editor of MACHINERY.

inch, so we will select a No. 53 machine—this being the nearest size. The next step is to determine the spindle speed at which to rotate the work. Taking the diameter of the stock across the flats as the basis of our calculations and deciding on a surface speed of 100 feet per minute, we find that the desired spindle speed would be 611 R.P.M. Upon referring to Table VIII in the January, 1913, number of MACHINERY, we find that the nearest spindle speed is 635 R.P.M.; this gives a surface

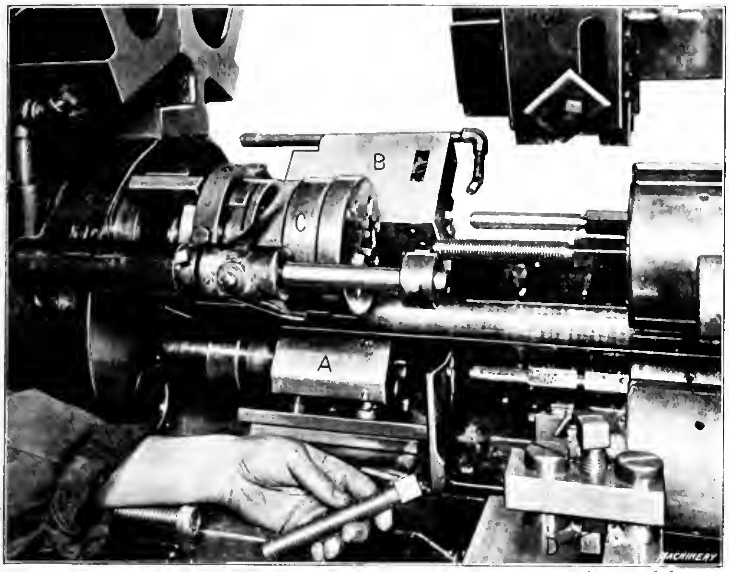

Fig. 4. Tooling "Set-up" used in producing the Set-screw shown in Figs. 1 and 2

speed of about 104 surface feet per minute, which will not be too high.

The next step is to determine the number of revolutions necessary for the box-tool to travel up half the length of the screw—$2\frac{7}{8}$ inches. Deciding on a feed of 0.0045 inch per revolution of the work, the number of revolutions required to make this cut is found to be 640. As the spindle makes 635 revolutions per minute, the time, in seconds, to turn half the body is $\frac{60}{635} \times \frac{640}{1} = 60.47$ seconds. Adding to this the time for the idle movements of the machine we get $60.47 + 2.4 = 62.87$, or approximately 63 seconds. This gives us a product of 57 pieces per hour, but upon referring to the table of change gears we find that gears to give this product are not obtainable. Therefore it is necessary to do either one of two things—increase the product to 59 and increase the feed of the tools accordingly, or else decrease the product to 51 pieces per hour with a corresponding decrease in feed.

The "set-up" used in making this set-screw is illustrated in Fig. 4. The operations start in the "first" position, where the first box-tool *A* comes into position, turns up half the length of the body—$2\frac{7}{8}$ inches—and points the end of the screw. At the same time that the box-tool is in operation on the work, the form tool comes in from the side and turns down the neck—also rough-forming the top of the head. As the cylinder is indexed into the "second" position, the second box-tool *B* comes into operation and finish-turns the body. The cylinder is again indexed into the "third" position, where a self-opening die *C* cuts the thread. For a clear description of the operation and application of this die, reference should be made to the article which appeared in the February, 1913, number of MACHINERY. After threading, the cylinder is again indexed and the piece cut off with a straight-blade cut-off tool *D*. These various operations have been described separately, but in actual performance all tools are at work on different bars at the same time.

"Set-up" in which Forming Operation is the Time to Complete One Piece

The knurled head nut shown at *B* in Fig. 1, and in Figs. 3 and 5, represents an example in which the forming is the longest single operation, and is the time to make one piece. This is evident from a glance at Fig. 3 where the dimensions of the piece are given. This knurled nut is made from a 2-inch bar of round brass rod in a No. 56 "Acme" multiple-spindle automatic screw machine.

The first step in determining the time to make this piece is to obtain the correct speed at which to rotate the work. Rod brass can be worked at 150 to 200 surface feet per minute, and by calculation we find that a spindle speed of 290 R.P.M. will give 150 feet surface speed. The next step is to determine the proper feed at which to operate the form tool. Now the conditions under which this thumb-nut is made are ideal as far as a heavy feed is concerned, so the form tool can easily be operated at 0.005 inch per revolution. By dividing this into the travel of the form tool, which is 0.635 inch (allowing 0.010 inch to approach the work) we find that it will require 127 revolutions of the spindle to complete the forming operation.

As this is a case where the longest single operation is performed from the form tool-slide, it will be necessary to calculate the time required in seconds to complete the idle movements of the machine. We find, however, by referring to Fig. 10, in the October number of MACHINERY, that the form cam occupies exactly the same circumferential space as the lead cam; thus we can utilize the same time as that given in the article previously mentioned, which is 4.6 seconds. Then

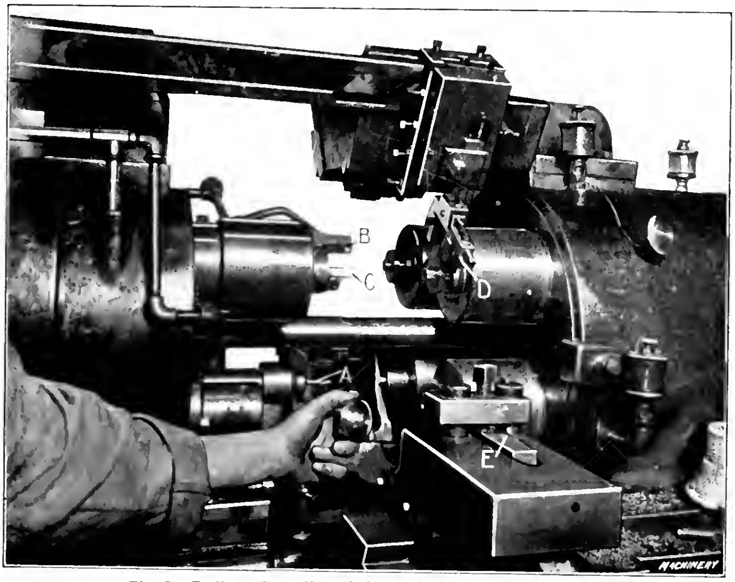

Fig. 5. Tooling "Set-up" used for producing a Brass Thumb-nut

the time in seconds to complete the forming operation equals 26.27 seconds. Adding the time for the idle movements we get $26.27 + 4.6 = 30.87$ seconds. Say that it takes 30 seconds to make one piece, then we get a product of 120 per hour. The nearest production to this for which change gears are obtainable is 122 pieces, and by using the change gears to get this production, we increase the feed of the tools slightly, which in this case could be done with satisfactory results.

In making this thumb-nut, the rough-forming is accom-

plished in the "first" position and the hole drilled to the proper depth with drill *A*, see Fig. 5. In the "second" position the head of the nut is knurled with knurl *B*, and the hole counterbored to a square bottom, both operations being handled by tools held in the end-working tool-slide. The hole is tapped with tap *C* and the head beveled and notched in the "third" position, the latter operation being accomplished with a shaving tool *D*. In the "fourth" position the completed nut is cut off from the bar with cut-off tool *E*.

An example of work whose operation is difficult to determine at a glance is shown in Figs. 6 and 8. This piece, which is also shown at *C* in Fig. 1, is made from cold-rolled steel bar, 2 3/16 inches diameter, and is 2¾ inches long. The forming cut is rather heavy, so the production on this piece can be considerably increased by dividing the forming cut between two forming tools. The first forming tool is used for breaking down only, as indicated at *A* in Fig. 6, while the second forming tool is used to bring the piece to the desired shape, as at *B*. The greatest reduction in diameter on this piece is 15/16 inch, making a rough-forming travel of 0.440 inch necessary. Now the finish-forming tool has to travel practically the same distance as the rough-forming tool, but while it does not remove as much material, it is operated by the same slide as the roughing tool; hence both roughing and finishing cuts consume the same amount of time and are the longest operations.

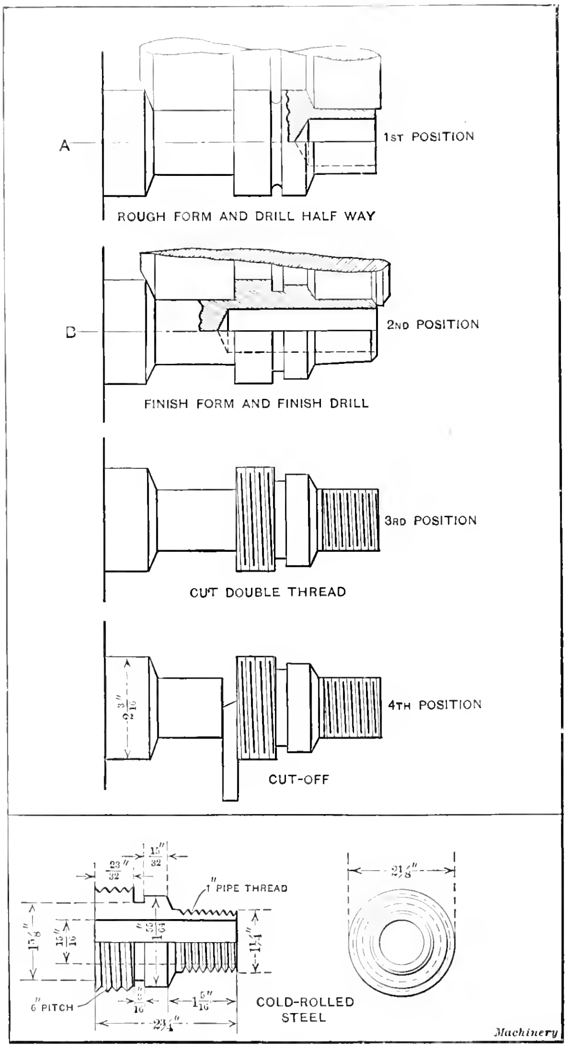

Fig. 6. An Example of Work on which it is Difficult to figure the Longest Single Operation

Turning our attention now to the drilling operation, we find that a hole 15/16 inch in diameter and 2¾ inches deep has to be produced. This can be divided between two drills, as indicated at *A* and *B* in Fig. 6, so that the travel of the main tool-slide for drilling will be 1⅜ + 1/32 inch, or a total of 1.406 inch. The drills can be operated successfully in this material at a feed of 0.010 inch per revolution. This will give 140 revolutions to complete the drilling operation. Figuring on a feed of 0.0015 inch for the rough-forming operation, and a rise of 0.445 inch (0.005 inch being allowed to approach the work), we find that it requires 296 revolutions of the spindle. As the method of calculating the time required to complete a piece of work when the forming cut is the longest single operation has been previously described, it will not be necessary to go into detail here.

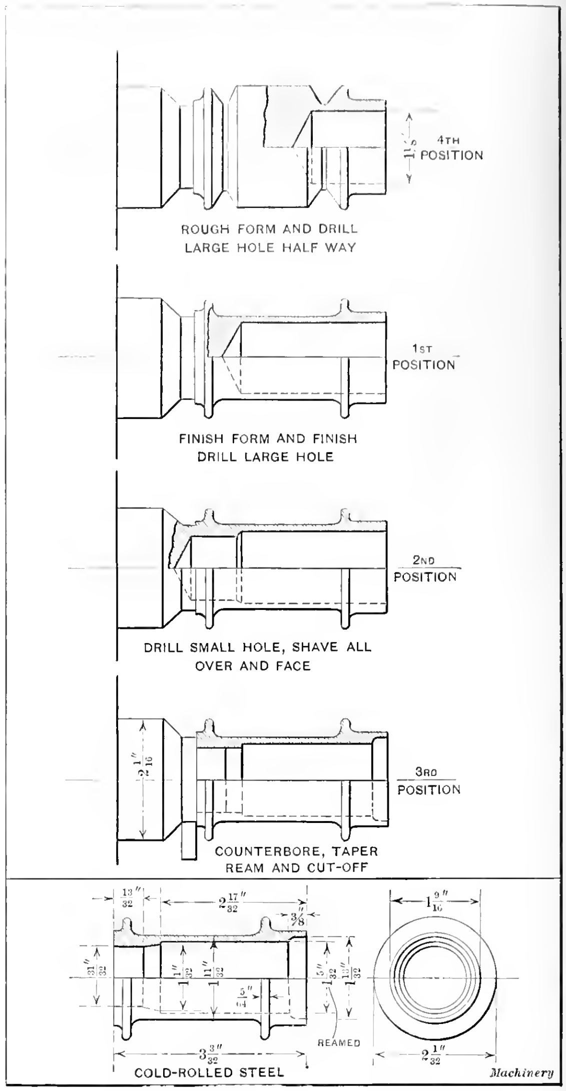

Fig. 7. Order of Operations on the Motorcycle Hub shown in Fig. 9

The tool "set-up" used for making the piece shown in Fig. 6 is shown in Fig. 8. It will be noticed by referring to this illustration that two circular forming tools *A* and *B* are used. The first forming tool *A* is held in the regular tool-holder, working in the "first" position, while the second or finish-forming tool *B* is held in a special holder, attached to the top face of the forming slide. This holder is provided with an overhanging arm in which a set-screw *C* is located, to enable the forming tool to be held rigidly in place. In making a double tool-holder of the type illustrated, it is essential that it be rigidly clamped to the tool-slide and have as much bearing surface as is consistent with the space available. As a general rule, it is advisable when a holder is of the built-up type, to have the stock rotating toward the form tool instead of away from

it. This enables a much heavier cut to be taken without chatter, as the thrust is directed against the tool-slide instead of from it, the latter action tending to lift the tool up. In this case, however, the holder is supported by the top bracket, thus overcoming the tendency of the tool to rise. This job also presents another interesting feature in the double or telescopic die-holder *D*. This die-holder, which was described in the February, 1913, number of MACHINERY, can be used for cutting two diameters of threads of unequal pitches, owing to its construction and operation. The outer member of the die-holder is spring controlled in its action, so that it can lead out in advance of the other part of the holder, thus enabling threads of different pitches to be cut.

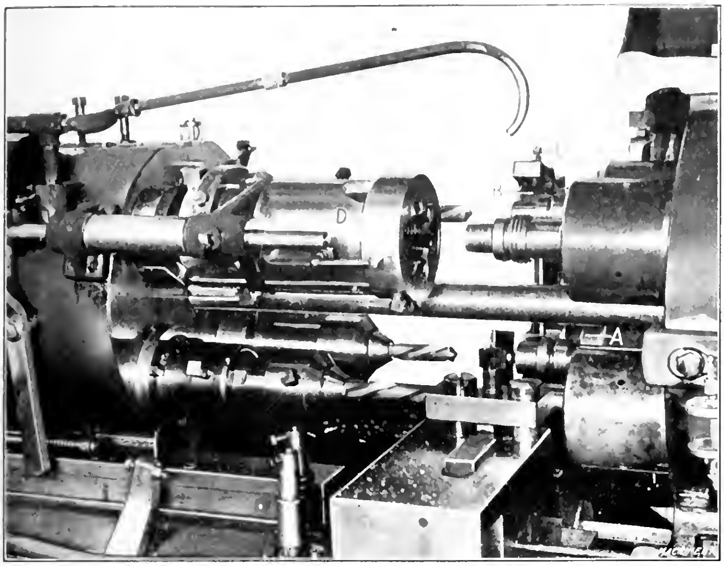

Fig. 8. Tooling "Set-up" used in producing the Steel Part shown in Fig. 6

The motorcycle hub shown in Figs. 7 and 9, and at *D* in Fig. 1, presents a good example of how production can be greatly increased by using the most efficient tooling method. It will be seen by referring to Fig. 7 that this motorcycle hub is made from a cold-rolled steel bar $2\frac{1}{16}$ inches in diameter and $3\frac{3}{16}$ inches long. Considering the length of form and the large amount of material to be removed in this manner, the work can be handled much more expeditiously by dividing the forming cuts between two or more tools. Both forming tools are required to take long, heavy cuts, so that rigidity is absolutely necessary.

In order to keep the feed up to a point where a good production is possible, the arrangement shown in Fig. 9 is adopted. This, as can be seen, consists in placing the first forming tool in the "fourth" position instead of in the "first," as is the usual manner, and cutting off the completed piece in the "third" position. It is evident that the cut-off tool does not need to be held nearly so rigidly as a form tool, and hence can be successfully handled on an extension bracket, as illustrated. This arrangement allows the rough-forming to be done in the "fourth" position (where the stock is fed out) and the finish-forming to be accomplished in the "first" position. Suppose, for instance, that the stock were fed out in the "first" position —the rough-forming would have to start at this point. This would hardly be advisable, as the wide amount of form necessary could not be handled with an extension tool. It is therefore evident that the tool "set-up" shown in Fig. 9 is commendable, in that it obviates all flimsy construction, and enables the work to be produced much more rapidly.

The operations handled in this "set-up" are as follows: In the "fourth" position the diameter is rough-formed, and the large hole drilled part way with drill *A*; in the "first" position the forming cut is finished, and the large hole drilled to the required depth with drill *B*; then in the "second" position the small hole is drilled with drill *C* and the diameter finished all over by a shaving tool *D*, the end also being faced with a cutter held in the holder *E* which is attached to the holder *G* carrying the smallest drill *F*. In the "third" position the hole is counterbored and taper-reamed, and the work cut off. Inasmuch as this job is handled in a manner out of the ordinary, it may be advisable to go through the calculations and see what product can be obtained by applying the "set-up" illustrated in Fig. 9.

Cold-rolled steel, as a rule, can be worked at from 90 to 110 surface feet per minute. We find by calculation that a spindle speed of 100 revolutions will be about the desired speed at which to rotate the work. The rough-forming tool will stand a very much heavier feed than the finish-forming tool, and as both tools have to travel the same distance, it is evident that the finish-forming operation will be the one on which it will be necessary to base our calculations. The width of the form tool is made up of two sections about $1\frac{1}{4}$ inch long, does not bear in the center, and the smallest diameter formed is $1\frac{11}{32}$ inch. Considering this, it would be inadvisable to use a feed exceeding 0.0015 inch per revolution of the work. Figuring on a travel of 0.350 inch for the finish-forming tool, at the rate of 0.0015 inch feed per revolution, we get 233 revolutions to complete this operation. As the forming cut is the longest single operation, we find from this the time to make one piece. The spindle speed used is 100 R.P.M. and the revolutions required for forming are 233, which is equivalent to 2 minutes and 18 seconds; adding the time required for the idle movements—4.6 seconds—we get a total of 2 minutes and 23 seconds, approximately, to complete one piece, or 26 pieces per hour.

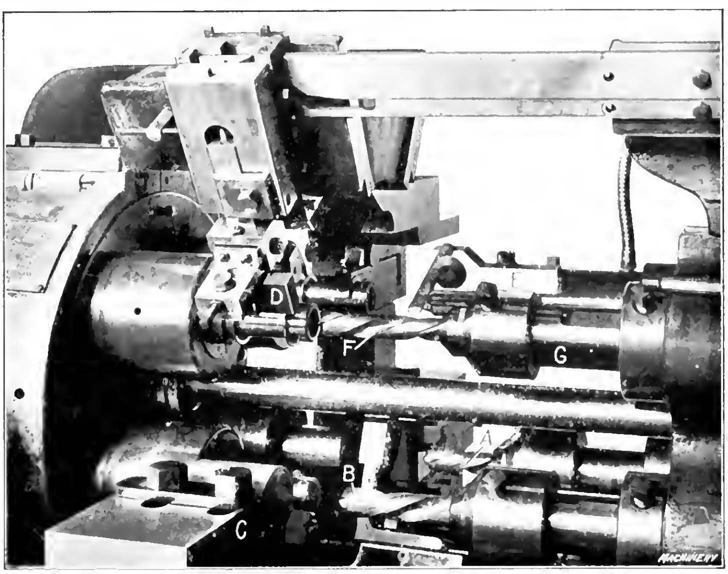

Fig. 9. A Motorcycle Hub which is produced economically on the "Acme" Multiple-spindle Machine by means of a Commendable Tooling "Set-up"

"Set-up" in which Longest Operation is performed from Cut-off Tool-slide

A sample of work which differs considerably from those previously described is shown in Figs. 10 and 12, and at *E* in Fig. 1. This piece is a cold-rolled steel bushing, which is slab milled on its largest diameter. The slab milling opera-

tion, in this case, can be most conveniently handled from the cut-off tool-slide, a fixture of the type shown in Fig. 11 in the April, 1913, number of MACHINERY being used and carrying two cutters. These end milling cutters are brought in at the same time as the cut-off tool and work in the "third" position, the cut-off tool severing the completed piece from the bar in the "fourth" position. Now it is evident from a close study of this piece that the longest single cut lies between the milling and forming operations. Taking the forming cut first, we find that the distance the forming tool must travel is 3/16 inch. No allowance need be made for the tool to approach the work, as the diameter is finished by a shaving tool. The length of the form tool is about 1 1/4 inch, and the smallest diameter 1 inch, so that the feed should not exceed 0.002 inch. Working the form tool at this rate of feed will require 93 revolutions. As the slab milling attachment is carried on the top face of the cut-off tool-slide, it can easily be seen that the feed given to the milling cutters will be governed by the feed used for cutting off. Now as the distance that the milling cutters must travel is greatly in excess of the travel of the cut-off tool, an accelerating device is used on the milling attachment. This increases the travel of the milling slide over the travel of the cut-off slide in a ratio of 1¾ to 1. Deciding on a feed for the cut-off tool of 0.0025 inch per revolution, the feed or rate of advance of the milling cutters in relation to the revolutions

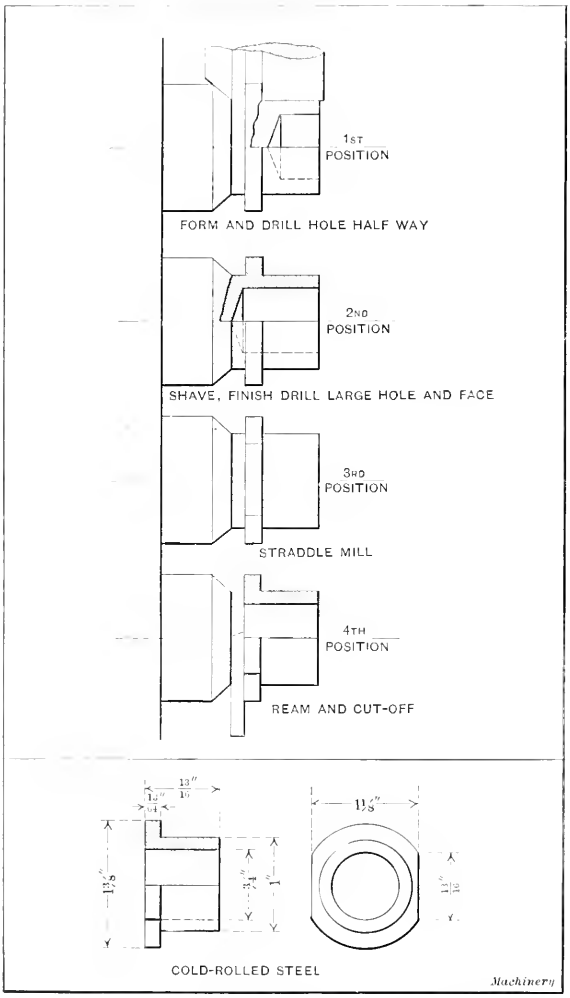

Fig. 10. Order of Operations on a Steel Job that is slab-milled

of the spindle will be $0.0025 \times 1.75 = 0.00438$ inch. Then dividing this into the travel of the slide—13/16 plus radius of the milling cutters, which are 1/2 inch diameter, plus 0.020 inch for clearance—gives us 1.082 inch travel. This is equivalent to 247 revolutions of the spindle.

This piece can be most economically produced on a No. 54 machine, and deciding on a surface speed of about 95 feet per minute, we get a spindle speed of 260 R.P.M. The time required to complete the milling operation was found to be equivalent to 247 revolutions of the spindle or 57 seconds.

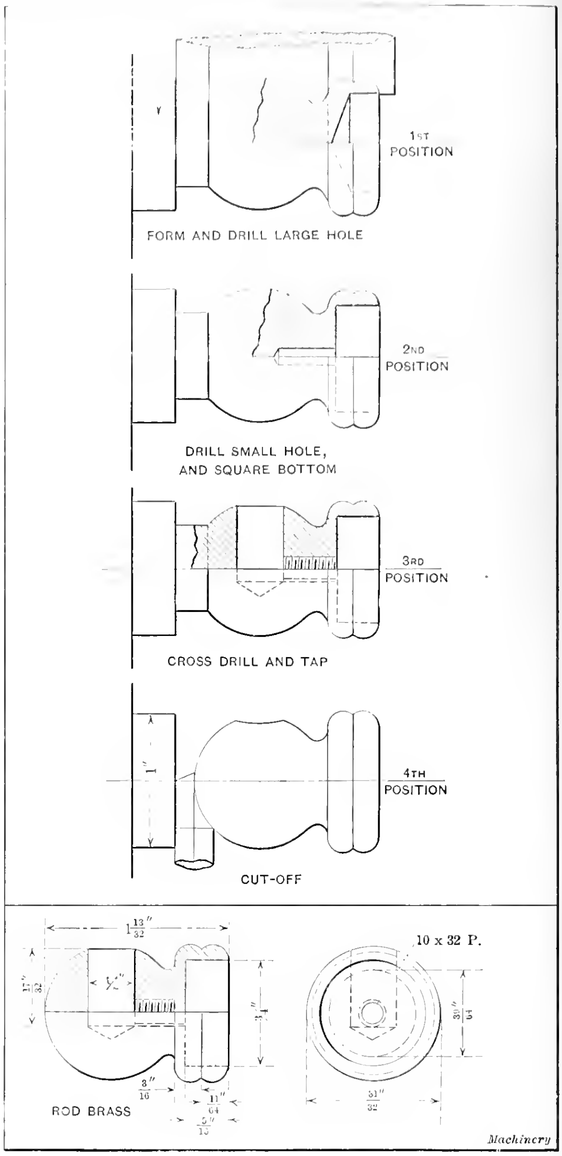

Fig. 11. Order of Operations for producing a Cross-drilled Brass Knob

Adding the time for the idle movements—1.88—(see Table IV in the October number of MACHINERY) gives us 58.88 or approximately 59 seconds to complete one piece, which is equivalent to a product of 61 pieces per hour. The nearest gears to the product required are those for 58.5 pieces, so we will drop down to this product.

The brass knob shown at *F* in Fig. 1, and in Figs. 11 and 13, is a difficult piece on which to determine the longest operation at a glance. It is evident, however, that the drilling of the large hole in the end will not require much time, so that the longest operation lies between the forming and cross-drilling cuts. Referring to Fig. 11, we find that the depth of form cut is 0.195 inch. Then deciding on a feed of 0.002 inch per revolution, we find that it will require 98 revolutions of the spindle to complete this operation.

The cross-drilling attachment is held on the cut-off tool-slide, and as was previously stated is governed in its travel by the feed given to the cut-off tool. As the cross-hole is deeper than half the diameter of the stock to be severed by the cut-off tool, it is necessary to use an accelerating cross-drilling

attachment. This will increase the rate of travel of the attachment in relation to the cut-off tool-slide in a ratio of 1¾ to 1. The travel of the cross-drill is equal to the depth of the hole—$\frac{15}{32}$ inch—plus the length of point on the drill and the height of the arc removed from the ball by drilling a hole in it. This we find is equal to 0.750 inch.

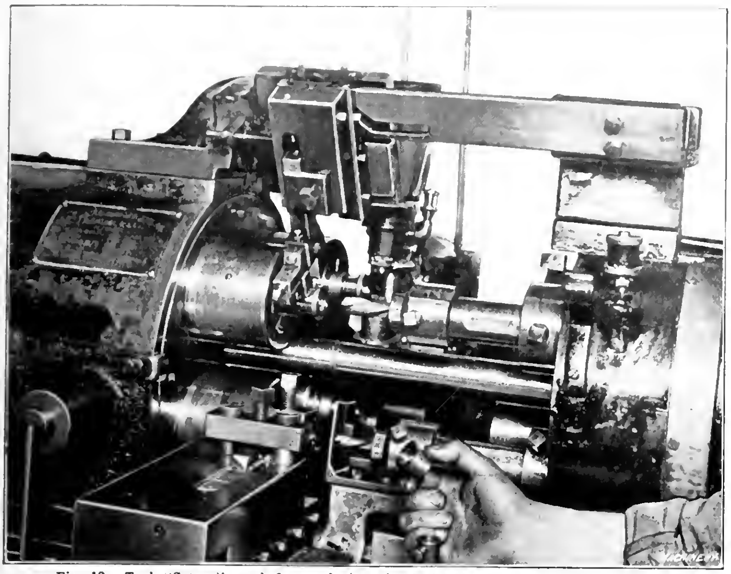

Fig. 12. Tool "Set-up" used for producing the Slab-milled Piece shown in Fig. 10

Deciding on a feed for the cut-off tool of 0.003 inch per revolution, the feed of the drill in relation to the rotation of the spindle is $0.003 \times 1.75 = 0.00525$ inch. Then the number of revolutions of the spindle equivalent to the time required to drill the cross-hole is 143. Putting this job on a No. 54 machine and using a speed of 520 R.P.M., it will require 16.5 seconds to drill the cross-hole. Adding the time for the idle movements—1.88—gives us a product of one piece in 18.38 seconds or 195 pieces per hour. We find upon referring to the product that the nearest production to this for which gears are provided is 199.5 pieces.

CAPITALIZING CHARACTER IN ITALY

Wherever one travels through the north of Italy he sees large or small groups of workingmen, skilled or unskilled, with no padrone to drive them, making roads, carting the gravel from beds of torrents, constructing steam railways for the government, erecting big apartment-houses for the working people to live in, extending their operations to every sort of trade by organizing themselves into cooperative societies to undertake big contracts. Binding themselves together to work for themselves and for one another, paying their own wages, carrying the responsibility of properly fulfilling their contract, and depositing a fund to guarantee its completion, they eliminate the intervening contractors entirely, saving the middleman's profit to divide among themselves in proportion to the amount of work which each man has contributed and to the existing wage scale for his trade. Having now become their own employers, they have in their own work eliminated the strike. The labor cooperative society is the latest and farthest advance of collectivism today, and some forms of it in Italy are unique. Ask these laborers about their work, how they are holding together, how they secured the contract and the necessary guarantee to obtain it, how they have been able to purchase all the machinery required to carry it out, and they will tell you that there is a cooperative bank in the neighboring city to which they belong, with which their contract is deposited, and which advances them from month to month the necessary funds for equipment, supplies and wages. Based on assets which have previously been of negligible value to the laborer in the securing of credit namely, character, thrift, the ambition of every man to get on, his normal impulse to produce the greatest within him, mere numbers which, joined together with their small mites of money, are no more to be despised than a Rothschild singly—there have arisen in Italy a host of Banks of the People—*Banche Poplari*—a veritable army of cooperative savings and loan societies which have given to individual members a credit service previously inaccessible if not impossible, and which now are extending their operations to reliable cooperative groups of workmen. Owned and operated by the people themselves on the most democratic lines, the power is diffused by the single vote which each member wields, irrespective of the number of shares he holds.—*Harper's Magazine.*

* * *

Electro-chemistry is likely to work a marvelous change in certain industries that are now generally regarded as nuisances by their neighbors if not actually detrimental to general health. Soap works, glue works, slaughter houses, fertilizer plants, tanneries and similar factories are the pariahs of industry condemned to locate in out-of-the-way and desolate parts where no one cares to live. Their odors advertise but do not recommend them. All this is likely to be changed by the ozonator, an electrical device that liberates free ozone, by electric discharge. Ozone has wonderful power to destroy bacteria and disagreeable smells. One part of free ozone in a million parts of air will dispel odors that resist all ordinary cleansing agents. Warehouses that reek with the smell of smoked fish can be made fit for storing meat, coffee or dress fabrics in a few hours Ozonators connected to the stacks of a meat packing-house completely eliminate the bad smells. To change thus the character of many disagreeable industries will mean an uplift in the state of employes, and other improvements in social and physical ways that can hardly be overestimated

REMOVAL OF MACHINERY'S OFFICES

The offices of MACHINERY will be removed this month to 140-148 Lafayette St., corner of Howard, five blocks north of the present location, where a twenty-one year lease has been taken of the four upper floors of the Bradstreet building, comprising about 40,000 square feet. The business offices will occupy the top floor, and the mechanical departments two other floors, the remaining floor being reserved for future requirements.

DESIGNING SPECIAL MACHINERY

The draftsman or mechanic who wishes to design special machinery, develop inventions or produce any mechanism out of the general run has few precedents to guide him. There are no schools nor textbooks that teach invention; the way to learn to design new combinations of mechanical elements is to go ahead and do it. This paradox has parallels in other walks of life. The way to accomplish the apparently impossible is simply to try.

However, the would-be designer can get much help from books and a general training in mechanical engineering. Books that illustrate many mechanical movements are useful. Treatises which explain the principles of mechanics, the laws of friction, motion, inertia, falling bodies, velocity ratio, and related subjects are indispensable. The aim should be to design machinery that is efficient—that is, having low frictional resistance. Also due attention should be given to the elimination of noise. Friction means wear, and excessive friction will cause rapid wear and reduce the working life. Noise is generally evidence of mechanical inefficiency. The clash of moving parts and consequent vibration tends to rack the machine and to distract the operator. But these refinements should be studied after the main features of design have tentatively been chosen.

Many machine designers work in a haphazard way, beginning, perhaps, by laying out the main center lines, outlining the bed casting, or designing the spindle and headstock of the machine. There is too little logic, system and order about machine design, and yet it is possible to introduce a systematic method of procedure that greatly reduces the time that would otherwise be required. A very successful machine designer outlines the following method as being one which could be followed to advantage in most cases of machine tool design, particularly of special machinery.

First draw in the piece that is to be made. If a number of sizes of work are to be handled, draw in the largest and smallest; then design, without considering the remainder of the machine, the best means for holding the work to be operated upon. When the chuck or faceplate for holding the work has been designed, lay out in the proper positions the kind of tools that would be employed under ideal conditions; next design the tool-holder for holding the tools, and then lay out the slide or carriage for holding this tool-holder to provide the required movements. Lay out the spindle that is to support and drive the chuck, making its dimensions just what they should be under the ideal condition; then provide the bearings for the spindle and a head for holding the bearings. The design of the drive for the spindle, comprising gears, cones or other parts, follows. If the machine is automatic, it requires a camshaft. Place the camshaft in the air in the most desirable position and locate cams on it just where they ought to be without reference to the rest of the machine; then build up a frame or bed with bearings as required for the various shafts, and provide the necessary clearance.

When a machine is designed in this way, it will be possible in nearly every case to select for each detail the most satisfactory design and to use such dimensions as are most appropriate for each part. There will be no difficulty in finding room for this or that part, because the whole machine has been built from the center outward instead of having been built in a predetermined space as in the usual procedure. In the latter case, it is often difficult to get parts to clear one another and to find room for all the mechanism. The design has to be stunted and warped and parts placed in improper positions. By following the method of building out from the center in all directions, the machine will be made just as long, wide and high as is actually necessary to admit the parts required to perform the work satisfactorily.

* * *

ECONOMY IN AUTOMOBILE MANUFACTURE

The recently published announcement to the effect that the builders of the most costly automobile in America would discontinue its manufacture and sale because of losses sustained, has awakened wide interest in the problems of building high-priced and low-priced cars. The announcement came shortly after the division of a $10,000,000 surplus by a concern building an automobile costing about one-tenth as much as the other. Why is the latter concern so prosperous when the first one has found the building of $6000 automobiles unprofitable?

While an answer cannot be given in a single sentence, the gist of it is that the large market for the low-priced automobile warrants the most advanced and economical means of production, whereas the demand for the high-priced automobile is so limited that expensive methods of manufacture are necessary. Poor management could not succeed with this handicap.

The prosperity of the automobile concern building the low-priced automobile whose name is almost a household word throughout America, and which is well known abroad, is a triumph for interchangeable manufacture and specialized machinery. It is a triumph for a plant organized in considerable part on the twenty-four hour production basis where the means of production are thus kept in constant use. The ordinary plant runs nine or ten hours a day except when the pressure is greatest, and then it runs a few hours overtime each day, at a high cost for labor. The inequality in cost of production under the two systems is startling. The disparity in weight and character of material entering the two cars cannot be offered as an adequate reason for the great difference in cost. But there is a great difference in the selling cost, for the low-priced car virtually sells itself, while the high-priced car requires high-priced salesmen and an expensive selling organization generally. The fact that the plant was not in the geographical center of the automobile trade was also of some importance. Another disadvantage was the heavy overhead charges due to injudicious investments of capital; but the principal cause of failure was the lack of demand and the consequent high-cost methods.

FIRES IN FACTORIES

One of the serious hazards of manufacturing is fire. Many prosperous concerns have been ruined by fires even when their actual loss on buildings, machinery and material was covered by insurance. Their insurance, however, did not cover the loss caused by stopping the output, by the demoralization of the working force, the loss of records, diversion of trade to competing concerns and destruction of means of production that could not be immediately replaced.

Many factories are built of wood and are poorly designed to resist a destructive fire when it has once gained headway. It may be impracticable to replace the buildings with stone, brick or concrete, but that does not mean that adequate fire protection cannot be provided. The way to prevent fires is to provide automatic means for quenching them at the start, and the sprinkler system does just that. No concern having inflammable buildings or product, or both, can afford to take the risk of having its business ruined, with loss of life perhaps, when the expenditure of a few thousand dollars will reduce the risk to a minimum. In some industries the reduction of insurance rates will effect a saving amounting to more than enough to pay the interest on the investment. A fire-resisting roof to protect from outside fires and the sprinkler system to quench small interior blazes will give to the proprietors peace of mind and permanancy of plant—two conditions necessary for success.

* * *

THE SPECIALIZING MANUFACTURER

Specialization in the manufacture of engine and transmission parts has become one of the many noteworthy developments connected with the growth of the automobile industry. Nowadays one concern produces the gears, another is equipped exclusively with automatic machinery for turning out small parts, and so on. Finally the various members all come to the central plant and are assembled. While this method of manufacturing is not new, it is an interesting development and is conducted on a much larger scale in the building of automobiles than in any other line of machine construction. Of course a machine or tool is rarely built entirely under one roof, or in one plant; usually some small parts, such as screws, lubricating devices, etc., are purchased from another concern which specializes in that particular line. But the automobile manufacturers have gone a step further, and not only buy accessories, but many important parts, so that at the present time some of them have ceased to become builders and are simply assemblers.

If the advantages of this method are as great as the extent of the practice in automobile manufacture indicates, it is reasonable to suppose that it may become more general in other lines of work. The continual introduction of new machines and methods doubtless has had much to do with this system of manufacture. While the variety of machine tools now being built enables work to be done more economically, the variety also makes the proper selection of tools more complex. Take turning, for instance; it might be possible to turn a given part that is required in large quantities, in a half-dozen "automatics" of different design, all of which are capable of handling the job. But which type will be the most efficient? The automobile manufacturer leaves the solution of this problem to the screw-machine products man. He is equipped with automatic screw machines of all kinds, and knows from experience which type is best adapted for turning various classes of work. And so it is with many other machining operations that are highly specialized. Just how far this practice could be profitably applied to machine construction in general, it would be difficult to predict. We have seen large concerns making small parts by obsolete methods so costly that money would be saved by buying from a manufacturing specialist even at prices yielding fancy profits.

* * *

"Non-productive" labor may be a necessary evil; yet the manager who tries to dispense with the product of the non-productive labor will soon find that he has no other product to dispose of.

SYSTEM CARRIED TO EXTREMES

BY M. T.

The story of Benjamin Lawrence and cost-keeping which appeared in the August number of MACHINERY reminds me of some of my own experiences while in the employ of a big automobile concern. The firm in question is enjoying a well deserved national and even international reputation for the quality and reliability of its product. It knows no dull seasons and it furnishes steady employment to thousands of men; its financial standing and reputation are an object of envy to all its competitors. It has a rigid system which is a model of thoroughness and waste.

High standard of workmanship is a part of this system. Every bushing used in the construction of the product must be reamed within prescribed limits, the most liberal margin being 0.0005 inch above and below the standard. Likewise, all the pins fitting in these bushings must be ground within the same limits and no deviation from this rule is permitted. A glaring example of waste resulting from such inflexible rules is to be found in the construction of the propelling mechanism of the car, where four bronze bushings and four steel pins are being used. On account of the twisting action of the frame resulting from unevenness of the road, it has been found advantageous to give the pins about 1/64 inch clearance in their bushings and thereby secure a sort of universal action. The arrangement proved a success and was promptly adopted, but the usual limits for reaming and grinding were retained. The bushings are drilled and then reamed to within 0.0005 inch, and the pins are ground to within 0.0005 of 63/64 inch.

The folly of such fine workmanship is only too apparent. I had a friend in the cost-keeping department who furnished me with some figures pertaining to the cost of extra machining, inspection and shop charges on these bushings and pins, and with the aid of simple arithmetic I calculated that if someone in authority cared to give a jolt to this iron-clad rule he could effect a yearly saving amounting to the cost of two complete cars, which, by the way, sell for a snug sum each. But, as long as the firm is enjoying good business and its stockholders get their regular and occasionally extra dividends, who dares to pick faults with the system?

Another curious feature of this system was the filling out of time cards by the employes of the drafting-room. The latter, while being on the monthly salary basis, were required to fill out a time card for every drawing made. While such a system may be desirable and even essential for a jobbing concern, it is entirely out of place in a big firm turning out a staple product and disposing of it in the market through an organized sales force. I had a chance to observe some of the effects of this regulation. A spends three days in an effort to improve a certain oil pump fitting which was causing a good deal of trouble. At last he succeeds and produces a very neat and simple article that overcomes every objection and meets every requirement; it takes him only one-half hour to make a complete drawing. Presently he is filling out the time card, but instead of putting down three days consumed in arriving at his goal all he dares to put down is two hours; the fitting looks so simple and the drawing consists of so very few lines that no man who has not followed A's mental process closely can account for the time actually spent in producing the drawing. The time card never did and never will record one's mental process, and for A to put down three days, as he is supposed to do, is to invite criticism. The balance of two days and six hours he charges to "miscellaneous work," "changes," or some large pattern on which he spends only two days but to which he can fearlessly charge five days' time.

The "boss" knows and admits that time cards in his department are absurd and accounts for them by the desire on the part of the management to have a uniform system throughout the plant, but he thinks it really does not make much difference one way or another. But it does. These time cards, many of which do not record the correct amount of time consumed within several hundred per cent, become a matter of record; the cost of drawings is figured separately

and with departmental charges added to the cost of the particular pattern or forging, and for all I know they might have also served as a basis for plotting efficiency curves for the individual members of the company's engineering department.

Quite a number had a vague suspicion that somewhere someone was keeping an accurate record of the work turned in; the practical results of this suspicion may be illustrated by the case of B who spends five days in making a sketch of some proposed mechanism and turns to his neighbor C for a friendly criticism. The latter discharges his duty in a very thorough and conscientious manner. B goes back to his table and while admitting that C is right—he remembers the time card, and rather than spend two additional days redesigning the mechanism, he hands it in just as it is. The "boss," the "chief" and the "governor" get their heads together and after a few hours of consultation they turn it down for the reasons fully anticipated by C and admitted by B. The drawing, however, is not destroyed; it is preserved as a matter of record. In two days' time B turns out another design of the same mechanism which after a close scrutiny is accepted by the department heads. Thus B's efficiency curve is maintained at a satisfactory height by the fact that he has two drawings instead of one to his credit, and, by the way, B and C are the only souls who know that the time card is responsible for two instead of one consultation on the part of the department heads.

The system in this plant is not unlike the proverbial Hydra of Greek mythology; it has many an ugly head. One of them was the limit placed by the management upon salaries connected with various positions both high and low, and as these limits were set some five years ago; they are considerably out of date. As a result the more capable men were constantly leaving for more lucrative positions elsewhere and the least efficient men in all departments would hang on to their jobs as long as they could. The theory and practice of placing a limit to compensation on any given position rather than on the man filling it is contrary to every known rule of common sense. Coupled with this practice, there was among the employes a general feeling—which came as a result of long observation—that it was not the policy of the company to promote its men to positions of responsibility. As a consequence, rising young men possessed of spirit and ability would leave the firm's employ to be appreciated elsewhere. I was told by old-timers of three men who never rose above subordinate positions in their engineering department and who are now occupying positions as chief engineers with various concerns. I had the good fortune of meeting one of them—Mr. D——. When asked if he knew the reason for placing a price on the position rather than on the man, he replied: "Why, yes, it is intended to prevent graft. If it were not for this limit any department head might bring in his friends to work for him and pay them anywhere from fifteen to twenty-five dollars more a month than they are worth and—in some cases—as much as they dare. Of course you understand," added he, "that this plan does not eliminate graft—it merely keeps it within certain bounds."

This method of dealing with petty graft in no way interfered with unworthy men getting into responsible positions and drawing fat salaries. D——'s own case fairly illustrates the point. He spent four years with this firm as chief designer on experimental work. At the end of that period the firm expanded, several new positions were created, and the most lucrative of them were going one by one to young men just out of college who had little or no practical experience but who had considerable "pull." D—— took the matter up with the chief engineer, pointed out his long experience in the automobile field on both sides of the Atlantic and his four years' faithful service and excellent record with the firm and wanted to know what show he stood of being promoted to a higher position. "None," frankly replied the chief engineer; "while you are an excellent man in every respect, there is one thing against you—you are a foreigner." Two weeks later D—— left the company's employ to be appreciated elsewhere.

The system in this plant was unique in that it left but small scope of action to individual departments and provided for matters both important and trivial. As an example of the latter, I may cite the stupid demand made on the engineering department that no drawing, however simple, should have less than three views on it. The result was that such simple parts as bolts, studs, nuts, washers, etc., which could be fully illustrated by two views, were invariably shown in three views, two of which were, of course, precisely alike. The boss himself could not give any plausible explanation for this state of affairs, merely stating that it was a "time-honored" custom with this particular firm. Yes, indeed, system was the keynote in this plant, but the question is was it worth while?

* * *

WATERPROOFING CEMENT STUCCO

It must be emphasized that with a lean mortar the permanency of the waterproofing compound is a very important point, as the stucco is exposed to beating storms. That class of compound using stearates, oleates, resinates or other soapy material as a base, gradually washes out under prolonged action of water which slowly but surely dissolves even stearate of lime. A permanently waterproof stucco is dependent on using a compound that is absolutely insoluble and unaffected by the elements. Bituminous waterproofing products belong to this class and compounds have been developed which are miscible with water yet become absolutely insoluble after the mortar has set. This result is obtained by emulsifying the bitumen, which then mixes with water as easily as milk does (milk is an emulsion). But when the mortar sets, it de-emulsifies the bitumen, which then becomes as insoluble as a milk spot. (Butter is de-emulsified milk and is not miscible with water). Bituminous materials so prepared give a very high degree of permanent waterproofing. They are absolutely unaffected by salt air, brine, running water, boiling water and ordinary chemicals. Weight for weight, they give four times the efficiency of soap compounds, yet they actually strengthen the mortar instead of weakening it, and because of the lack of all harmful action the amount of compound is not limited to 2 per cent. If desired 10 per cent or more may be incorporated in the mixture and the waterproofing effect correspondingly increased. In this way a factor of safety may be secured which is as important in waterproofing as in other branches of engineering. It then becomes possible to waterproof under guarantee a cellar fifty feet below tide level, by means of a three-fourths inch interior mortar facing. Evidently this is the kind of material which will give satisfaction also in external stuccos, where no pressure is encountered, but where on account of the lean mixture, a safety factor is desirable to cover variations in mixing and plastering.—*Architecture.*

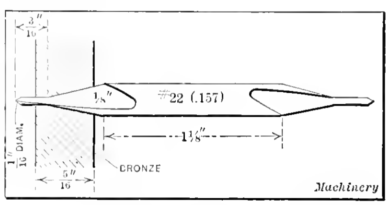
ENDURANCE RECORD OF SLOCOMB COMBINATION CENTER DRILLS

The illustration shows one of a lot of special Slocomb combination center drills made by the J. T. Slocomb Co., Providence, R. I., for a customer of the Seattle Hardware Co., Seattle, Wash. These drills are of unusual form because of the fact that the countersink has a long taper. The Seattle Hardware Co. reported that its customer drilled and countersunk 212,000 holes in bronze cylinders 5/16 inch thick, using eighty of the special countersinks. In view of the slenderness of the drill, this seems to be a remarkable record, the average number of holes drilled and countersunk by each center drill being 2650.



Special Slocomb Combination Center Drill used on Bronze

LENGTHS OF WORMS AND HOBS

BY E. WINSLOW BAXTER[*]

The derivation of a formula for quickly finding the approximate length of a worm, to run with a worm-wheel having hobbed teeth, depends primarily upon an assumed relation between the worm and worm-wheel and also upon the pitch and size of the wheel. The relation between the length of worm and the dimensions of the worm-wheel differs with the conditions under which the gears are to run or the standards of the manufacturer.

In the accompanying illustration the hob (or worm) is shown extending from A to B, which produces a hob having

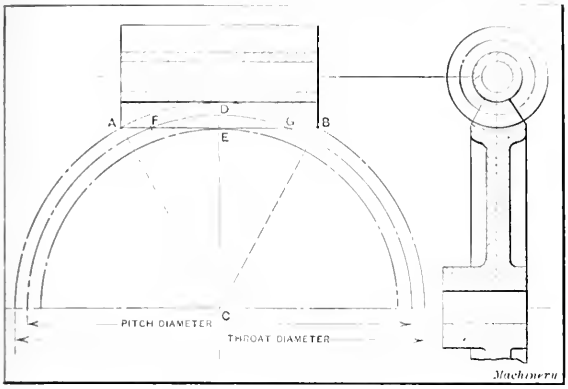


Diagram of Worm and Worm-wheel

the maximum generating action. This length also provides a safe allowance for any end adjustment which may be necessary for the worm. A hob to cut a worm-wheel without interference should be as long as the worm to be used, and neither should be less than the length of the chord between points F and G, which are both on the pitch circle of the wheel.

Let AB or length of hob $= f$;
BC or throat circle radius $= r$;
DE or whole depth of tooth $= d$;
Number of teeth in worm-wheel $= N$.
$CE = BC - DE = r - d$.

Solving the right-angle triangle enclosed by the lines BC, CE and BE or r, $r - d$ and $\frac{f}{2}$

$$(r-d)^2 + \left(\frac{f}{2}\right)^2 = r^2$$

$$r^2 - 2rd + d^2 + \frac{f^2}{4} = r^2$$

$$d^2 + \frac{f^2}{4} = 2\,rd$$

$$\frac{f^2}{4} = 2\,rd - d^2$$

$$f^2 = 4\,d\,(2\,r - d)$$

$$f = 2\sqrt{d\,(2r - d)}$$

In order to further simplify the formula, we will assume the pitch to be 1 inch circular pitch.

DE or d (whole depth of tooth) would then equal 0.6866 inch, and BC or r (throat circle radius) would be equal to $\frac{N + 2}{2 \times 3.1416}$

Substituting we get:

$$f = 2\sqrt{0.6866\left(\frac{N + 2}{3.1416} - 0.6866\right)}$$

which can be simplified as follows:

$$f = 2\sqrt{\frac{0.6866\,(N + 2)}{3.1416} - (0.6866)^2}$$

$$f = 2\sqrt{0.21855\,(N + 2) - 0.47142}$$

$$f = 2\sqrt{0.21855\,N + 0.43710 - 0.47142}$$

$$f = 2\sqrt{0.21855\,N - 0.03432}$$

Squaring both sides of the equation we get:

$$f^2 = 0.8742\,N - 0.13728$$

As the value for f need be only approximate, we can write the equation as follows:

$$f^2 = \frac{7\,N}{8} - \frac{11}{80};$$

$$f^2 - \frac{7N}{8} + \frac{11}{80} = 0;$$

$$80\,f^2 - 70\,N + 11 = 0.$$

Now, if we solve for f for different numbers of teeth, the length of hob or worm when the pitch is 1 inch circular, will be obtained.

For other pitches it will be necessary to multiply by the circular pitch to obtain the correct length.

The accompanying table gives the values of f for 1 inch circular pitch. To illustrate the use of this table, suppose we desire to find the length of a worm to suit a 3/4-inch circular pitch worm-gear, having 39 teeth. Find the value for f in the table opposite 39 teeth. This value is 5.83 and multiplied by the pitch, 3/4 inch, gives 4.37, or about 4 3/8 inches, which is the length of the worm or hob.

TABLE OF CONSTANTS FOR DETERMINING THE LENGTHS OF WORMS OR HOBS

Factor f equals length of worm when circular pitch is 1 inch. To find length for any other pitch, multiply factor f corresponding to given number of teeth in worm-wheel by the required pitch.

No. of Teeth in Worm-wheel	Factor f for 1-inch Circular Pitch	No. of Teeth in Worm-wheel	Factor f for 1-inch Circular Pitch	No of Teeth in Worm-wheel	Factor f for 1-inch Circular Pitch	No. of Teeth in Worm-wheel	Factor f for 1-inch Circular Pitch	No. of Teeth in Worm-wheel	Factor f for 1-inch Circular Pitch

Machinery

* * *

Rich cements are likely to crack if dried rapidly. To avoid hair cracks in stuccos, builders are advised to use three-to-one mixtures rather than two-to-one mixtures which are common. The rich mixtures are more nearly waterproof than the lean mixtures if they dry without cracking, but unless extraordinary precautions are taken to prolong the drying-out process they will be more permeable by water on account of many cracks.

MAKING STEEL WIRE BELT LACING

THE CLIPPER BELT LACER CO.'S STEEL WIRE BELT LACING AND LACING TOOL

The steel wire belt lacing and method of application developed by the Clipper Belt Lacer Co., Grand Rapids, Mich., consists of wire clips which are clinched in each end of the belt to be joined, forming loops at the outer ends, and locked together by means of either a rawhide or bamboo pin. This

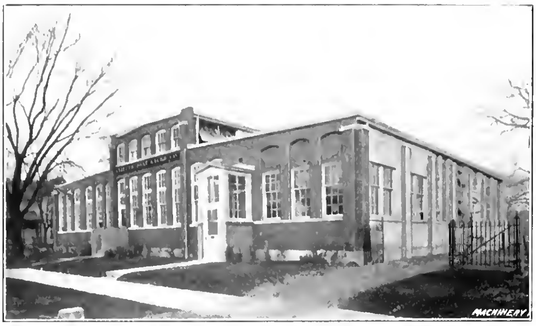

Fig. 1. Factory of the Clipper Belt Lacer Co., Grand Rapids, Mich.

method of lacing makes possible the disjoining of the belt without destroying the lace or in any way affecting the joining members, it simply being necessary to pull out the rawhide pin. Fig. 2 shows two ends of a belt joined in this manner at *A*; at *B* the pin has been removed, disjoining the belt; at *C* a section of the belt is shown with a rawhide pin in place; and at *D* is shown the shape of the hook before being clinched in the belt.

Construction and Operation of "Clipper" Belt Lacer

The "Clipper" belt lacing tool shown in Fig. 3 consists principally of a frame or base *A*, carrying a comb *B* and

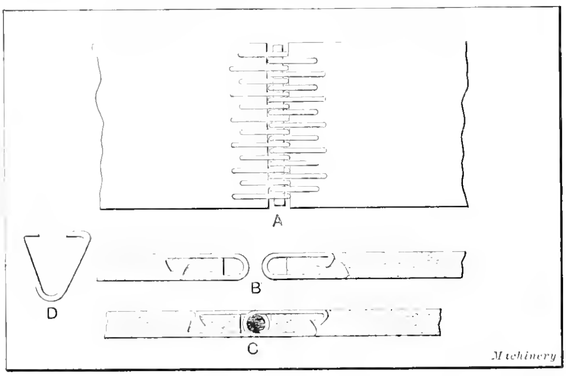

Fig. 2. The "Clipper" Method of lacing Steel Wire Belt

lacer *C* for holding and closing the steel wire hooks, respectively, and an anvil *D*, on which the hooks are closed by means of the clinching bar *E*. Bar *E*, in turn, is held in a swinging arm or bracket fulcrumed on the king pin *G*. Center head *H*, carrying the operating lever sockets *I*, is also fulcrumed on this pin and is held in the desired position when inserting the hooks by means of a dog *J*, hinged to it and located by a ratchet *K*. Power to insert and clinch the hooks in the belt is secured by means of operating levers inserted in sockets *I*, the levers being eccentrically fulcrumed and carrying the rollers *L*, which bear on the tracks *M* and operate the clinching bar.

In operation, the head is first thrown back by removing the dog from the ratchet; then the card of hooks is cut to suit the width of the belt being laced. This is accomplished with a pair of scissors supplied with the lacing tool, by cutting first one edge of the card and then the other, and then bending the card slightly back and cutting through the center. The card of hooks is now inserted in the lacer where it is held in place by the pin *N*. The center head is next brought forward and the dog and ratchet put in place, after which the belt, which has been previously cut square on the end, is placed between the hooks in the tool and on top of the belt holder *O*, care being taken to keep the end of the belt tight against the lacer. Next the levers are inserted in the socket and pressed down, forcing the hooks into the belt. As the head is forced down it is drawn slightly forward each time the levers are raised, and this operation is repeated until the hooks are flush with the surface of the belt.

For lacing a belt wider than the capacity of the lacing tool, the hooks are inserted in sections. On a belt of such a width as to require two lacings, one section is put in at one end, clinched, and brought flush with the belt, and another section of lacing is put in at the other end, thus completing the lacing of one end of the belt; the other end is handled in a similar manner. For a belt requiring three lacings, the hooks are first inserted in the center portion of the belt, after

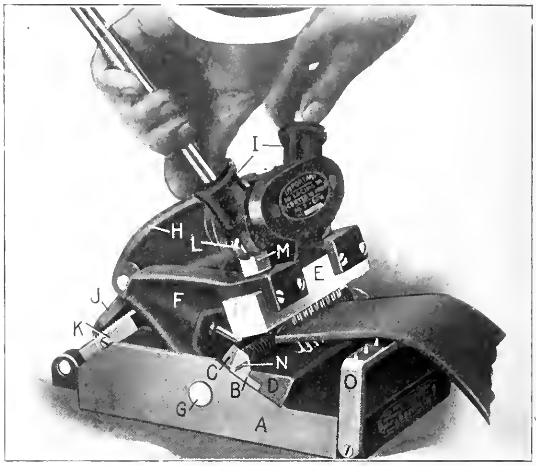

Fig. 3. Operating the "Clipper" Belt Lacing Tool

which the hooks are put in on both sides of the center portion. It is always advisable to locate the hooks as near the center of the lacing tool as possible, as this obviates any unnecessary strain on one side of the tool, insuring a much more even pressure.

Making the Steel Wire Lacing

The steel wire lacing is made from 0.054-inch specially treated steel wire, which is formed into a hook of the shape

Fig. 4. Automatic Wire Forming Machines used in making Steel Wire Belt Lacing

shown at *D*, Fig. 2, in the special wire forming machine illustrated in Fig. 4. This machine, which is known as the regular type of four-slide wire forming machine, completes the hook in one operation. The wire is held on a reel, as shown in the illustration, and pulled through a straightener by means of a feeding device actuated by a crank motion, which, in turn, receives its operation from a cam.

Carding the Lacing Hooks

After the hooks have been formed, the next operation is to place them in cards and thus facilitate their easy insertion in the lacing tools. Previous to the adoption of this method, the hooks were placed in the lacing tool by hand, which was a rather tedious operation. The hooks to be carded are held on a hook, as shown in Fig. 6, and removed from this by the operator. They are placed in the slide, the ends being reversed so as to bring them in the proper position for producing the zig-zag lacing effect in the belt. The paper in which these hooks are inserted is specially treated on the edges so that it will be stiff and at the same time brittle enough to allow them to make their own passage into it without being previously cut. This paper is held on a roll under the machine, and is brought up over a small pulley *B*. From this it passes down through a chute which gradually diverges

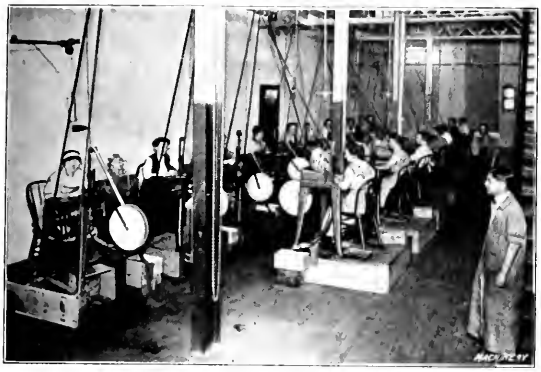

Fig. 5. View of Wire Hook Carding Department

towards the bottom so as to loop over the paper. The hooks are placed in a slide by the operator and fed in, being alternately located as previously described. The paper is forced out by a plunger and the hooks fit into slits which they form in the paper. As the strip of paper feeds down and the hooks are inserted, it is cut off to the required length (containing

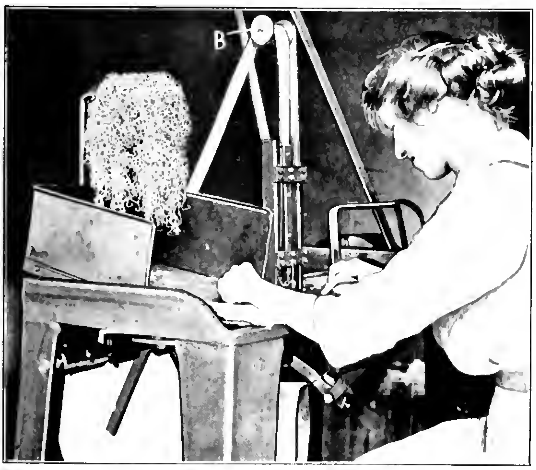

Fig. 6. Machine used for carding the Steel Wire Lacing Hooks

thirty-seven hooks) by a knife which receives its motion from a cam-operated slide. Fig. 5 shows the department in which the carding is handled.

Machining Parts and Assembling "Clipper" Belt Lacing Tool

The frame members for the "Clipper" belt lacing tool require principally milling and drilling. Fig. 7 shows a row of Leland sensitive drills which are used for performing the drilling and reaming operations on the different parts of the frame. The arrangement of these machines is worthy of special mention. Those parts requiring just one drilling and reaming operation are handled on the single-spindle machine at the far end of the line, while those requiring two drilling and reaming operations are handled on the two-spindle machine, this order being followed until the parts requiring the largest number of operations are handled on the four-spindle machine. Thus it will be seen that these machines are so arranged as to handle the work in accordance with the number of operations required on them. This eliminates

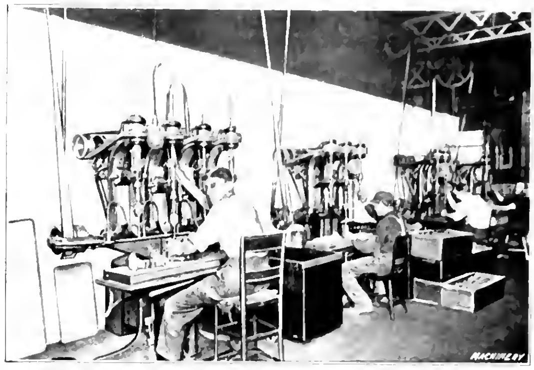

Fig. 7. Drilling Parts of "Clipper" Lacing Tool Frame

the necessity of changing the tool frequently, and increases the output.

Another interesting feature used in making parts of the "Clipper" belt lacer is shown in Fig. 8. This is a grinding device, made by the Grant Automatic Machine Co., used for grinding king pins. This fixture *A* is set at an angle with the

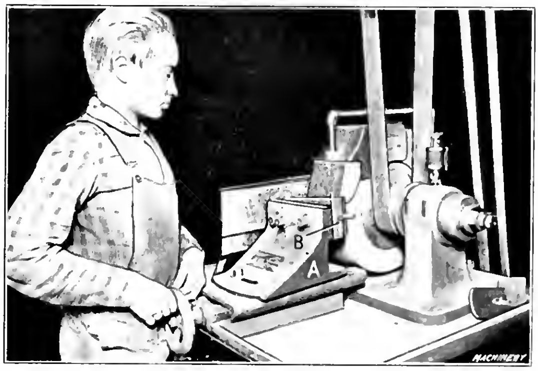

Fig. 8. Fixture used in grinding King Pin

side of the grinding wheel and is also tilted in relation to the horizontal base of the machine. The king pin to be ground is held in a V-slot in the face of block *B*, being pushed in from the right-hand side; the inclined position of the holder in both directions causes it to be fed in by the action of the grinding wheel. This continues until the pin has been ground for its entire length, after which it drops out

Fig. 9. Assembling the "Clipper" Lacing Tool

at the other end. Of course the production obtained on this fixture is much greater than that secured from a regular cylindrical grinding machine, and it also obviates the necessity of centering the ends of the work. As regards accuracy,

the results obtained are close enough for this class of work.

Upon the completion of all the parts of the lacing tool they are brought to the assemblers where the units are collected, hand reamed where necessary, and then assembled. Fig. 9 shows this step in the production of the "Clipper" belt lacer, and illustrates the final work that is done on it.

MILLING MACHINE DYNAMOMETER

BY R. POLIAKOFF*

The dynamometer shown in the accompanying illustration was designed to measure the force exerted by the teeth of a cylindrical milling cutter with straight grooves. Fig. 1 shows the dynamometer mounted on a No. 2 Cincinnati mill-

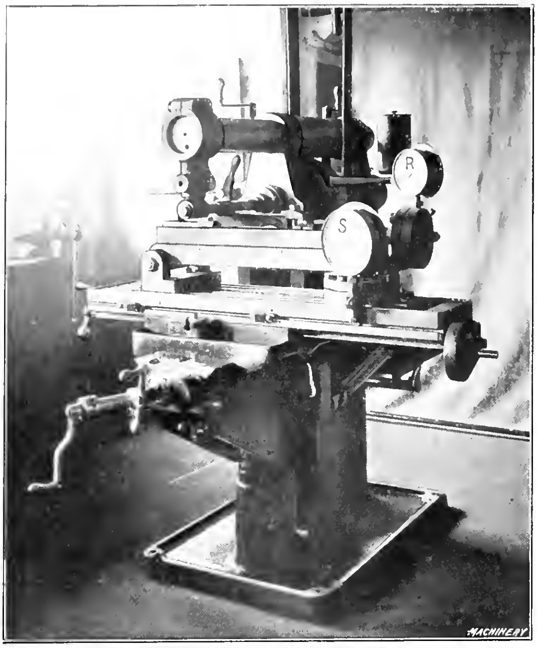

Fig. 1 Milling Machine Dynamometer mounted on No. 2 Cincinnati Miller

ing machine, and Fig. 2 gives details of the design. The work to be milled is shown at *A* in Fig. 2. The work is mounted on the slide *C* instead of being bolted to the table of the milling machine in the usual manner. The longitudinal movement of slide *C* is guided by a wing which runs in a groove in the lever *E*. This lever is fulcrumed on points *F* of screws *G* which pass through stay *H*. This stay is secured to the table *B* of the milling machine by means of two bolts *I*. Slide *C* bears against the point *K* of screw *L*; this screw presses against the thin brass diaphragm *M*, the diaphragm being filled with glycerine which transmits the pressure applied by screw *L* to the recording gage shown at *R* in Fig. 1. In a similar way lever *E* bears on the point *N* of screw *O*, which applies pressure to the diaphragm *P*. This pressure is indicated on the gage shown at *S* in Fig. 1.

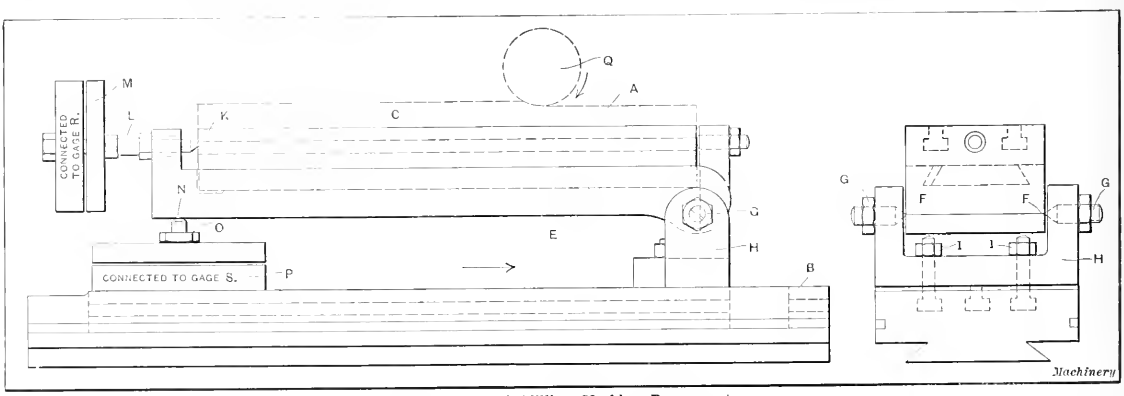

Fig. 2. Design of Milling Machine Dynamometer

When the cutter *Q* rotates in the direction indicated by the arrow, the force exerted by the teeth resolves itself into a longitudinal pressure acting parallel to the table and a downward pressure acting perpendicular to the table. The longitudinal pressure is transmitted to the gage *R* and the vertical pressure to the gage *S*, so that these pressures can be accurately determined if the gages have been calibrated before the test is started. In determining the magnitude of the longitudinal and vertical pressures the following conditions must be considered. By referring to Fig. 2 it will be evident that the lever arm of the vertical pressure changes as the table moves in relation to the fulcrum *F* about which lever *E* swings. As the feed is known, however, the lever arm of the vertical pressure is also known at any moment. The downward pressure also produces a frictional resistance which decreases the longitudinal pressure indicated by gage *R*. By determining the coefficient of friction between the two sliding surfaces *C* and *E* in the usual way before starting the test, it is possible to correct for friction and thus obtain the true value of the longitudinal pressure. This correction is made by adding to the reading of gage *R* the correction for the resistance due to friction between slide *C* and lever *E*.

MOVING PICTURES OF FLYING BULLETS

Moving pictures have unlimited possibilities apparently for the study of rapidly moving objects. An apparatus capable of making pictures at the rate of 100,000 a second has been made. With it seventy-two pictures of a revolver bullet were taken while moving ten inches. Pictures of a bullet passing through a stick of wood showed a curious condition. The bullet passed completely through the thin stick and was well on its way beyond before the wood gave any sign of distress. Then some tiny splinters started out, following the bullet; the stick began to split, and after the bullet had proceeded some distance the stick suddenly fell to pieces. No camera shutters are fast enough to take pictures at anything like this speed, so no shutter was used. Instead, a series of electric sparks was flashed, the sparks following one another at the rate of 100,000 a second, each spark making a picture. The film was mounted on a wheel about three feet in circumference, and the wheel was revolved at the rate of 9000 revolutions a minute. When all was ready, the bullet was shot, the spark flashed and the wheel revolved, the actual exposure being limited to a fraction of a second so as not to pile up pictures one over the other.

* * *

Hardening pots for molten lead baths, etc., should preferably be made from seamless drawn steel rather than from cast iron. Experience has shown that the seamless pots will, in some cases, last for six months' continuous service, while cast-iron pots will last on an average only four days.

ON DRIVING LINESHAFTING

BY GEORGE N. VAN DERHOEF*

The question of what is the best method of driving lineshafting is one that must be considered in the case of the layout of almost every mill. The form of power to be used for driving the mill—water, steam, electric, gas or oil—generally depends upon local conditions. On account of efficiency, as well as first cost, electricity is seldom utilized as a motive power unless it can be obtained from an outside generating station, so that the maintenance of a complete power plant can be avoided. This is quite a factor where current can be obtained at a low price and the installation of large hydroelectric plants all over the country is making this possible. But in almost all cases where the mill has its own waterpower or must install its own steam, gas or oil engine, electricity becomes too expensive and inefficient a means of transmitting power to the different parts of the mill to be attractive. On account of their low first cost, flexibility and high efficiency, rope drives offer greater advantages.

In the case of mills buying outside electric power, the utilization of this current in the most advantageous way is a matter of the greatest importance. There are two methods of doing this. A separate motor may be used for driving each individual machine or the machines may be divided into groups and each group driven by a motor. A few years ago the manufacturers of electric motors advocated the use of the individual drive; today they are arguing for the group system. This is due to the actual demonstration of the superiority of the latter system in mill practice, and in the majority of cases it is only by the use of the group system that it is possible to equal the high efficiency of a well laid out mechanically driven mill. The individual motor offers a real advantage in the way of convenience. A machine may be placed in any position, without regard to the location of other machines, and the light is not obstructed by overhead belts; furthermore, each machine is a unit by itself and only consumes power when in actual operation. Unfortunately this is not the whole story. The individual motor must usually be a small one; consequently the first cost must be relatively high.

At the very outset, the mill owner is confronted by two horns of a dilemma. If the motor selected is of such a size that it will take care of the maximum requirements of the machine, it must usually be operated at a point below its full load capacity, as the overload capacity is not enough above the full load capacity to equal the difference between the maximum and normal requirements of the individual machine. Hence we have a piece of apparatus that has a high efficiency at full load, running most of the time below rating and with an actual current consumption per horsepower due to the low efficiency at small load which makes it a most expensive form of transmitter. On the other hand, if the size of the motor is kept down to the normal requirements of the machine, the reserve capacity of the machine becomes zero, and pushing the production beyond normal would be impossible.

The advantage of being able to place a machine in any position is seldom of great practical importance; certainly not enough to warrant any increase in either first cost or operating expense. The increase in shop light due to the absence of belts is more fanciful than real, as a fraction of the current wasted by individual motors would give all the illumination that is necessary. Besides, window glass is cheap. The individual control of the machine is also more imaginary than real, as the ordinary tight and loose pulley or the friction clutch pulley often affords a better control from the operating point of view. Still, there are many cases where the individual motor should be used. A machine may be so placed or the power required to run it may be so small, relatively speaking, that the question of power efficiency is purely secondary, as, for instance, the portable tools used in large machine and erecting shops or the large special tools used in a number of the industries. In all of these the actual efficiency of the motive power is purely a secondary matter.

In the group system of driving there is a chance to adjust matters with some regard to efficiency, by playing up the law of averages. The overload capacity of a motor that is large enough to drive a group of machines at normal load will almost always be found ample to take care of the maximum requirements of any machines in the group that could possibly be expected to have peak requirements at the same moment. This makes it possible to select motors of a size that is in accord with a reasonable consideration of efficiency; but it should be remembered that errors in judgment will interfere with efficiency, unless the groups can be so arranged that one or more machines can be easily shifted from one group to another. On this account and in order to get the best average load conditions, as well as to economize in motor cost per horsepower, it is well to determine how large rather than how small the group can be made. In a general way the interests of the mill owner are on the "other side of the fence" from those of the motor manufacturer and the company furnishing the current. There is one condition, however, where the interests of the mill owner and the motor manufacturer are in accord. That is when the lineshaft speed is such that it can be direct connected to a low speed motor. Low speed motors are relatively expensive, but direct connection eliminates the friction losses due to speed reduction transmissions. The ideal arrangement of a motor-driven lineshaft is with the motor situated at the middle of the line. This permits the use of shafting of the smallest possible diameter, as the load is equally distributed over it and friction losses are reduced to a minimum. If a friction clutch coupling is placed at each side of the motor, either half of the line can be run by itself.

Where direct coupling is not feasible the question of what form of reduction transmission is most suitable, and whether the reduction should be made in one or more stages will depend on local conditions and the difference in the speeds of the motor and lineshaft. With small motors and a large speed reduction, cut gears are commonly used for at least the first reduction, but this method is seldom used in driving lineshafts. In the case of medium-sized motors, some form of silent chain or leather or rubber belts are generally used. If silent chains are used, the reduction is generally made in one stage; and if belting is adopted the reduction may be made in one or two stages. The mill owner should bear in mind that a two-stage reduction sometimes shows a higher efficiency than a one-stage reduction, where the pulleys differ greatly in diameter. In the case of large motors, rope transmission will be found the most satisfactory and efficient means for reducing the speed, the freedom from slip giving as uniform rotation to the lineshaft as could be secured by direct coupling. This whole question should be carefully considered before deciding upon the type of transmission to install. The direct drive is, of course, the most efficient, but the low speed motor is expensive. In the case of the larger sizes of motors, the question of support is one that must be carefully considered, as large low speed motors are very heavy. This question of weight sometimes makes it necessary to place the motor at one end of the line near a wall or even to choose a high-speed motor and use the necessary transmission to reduce the speed to the desired point.

Countershafting should be eliminated entirely, or, at least, as far as possible. The ideal construction is high-speed shafting, small pulleys of either the tight and loose type or with attached friction clutches, and direct drive from the lineshaft to the individual machine. This plan is now in use in many of the most up-to-date mills. In mills where the load per lineshaft is light, maximum efficiency is sometimes secured by what may be called the "compound group" system, in which a single motor is used to drive several lines—usually an entire floor. The motor is direct connected or belted to one shaft and the other shafts are driven from this shaft by either belts or ropes. By using the Dodge American system of drop-off rope transmission, each shaft can be driven direct from the motor with one rope and without any intermediate losses, such as must occur where the shafts are driven, one from the other, all across the room. In the smaller mills, where the individual floor loads are light, two or more floors

* Address: Dodge Mfg. Co., Mishawaka, Ind.

can be driven from the same motor by using this form of rope drive, which works just as well vertically as it does horizontally. There is no question but that rope gives a better and more efficient drive from a motor than a belt, and it should be employed whenever possible. It is not possible, however, to use as small wheels with rope as with belting, so that the choice of which to use is frequently limited by the speed of the motor and the amount of speed reduction required. With large motors, particularly those designed to run at low speed, either form of transmission can generally be used. When rope can be used and the transmission is a plain, straight drive from the motor to the shaft, either the American continuous system or the English separate wrap system will work all right; but it will generally be found that the continuous system will be rather more satisfactory in the long run.

In selecting motors, it is well to determine whether the overload and starting torque characteristics of the motor can be fully utilized in actual service. Many motors have a very high starting torque when thrown directly on the line. This is a very valuable feature from the mill owner's point of view, but commonly the service company will not permit the use of such motors on account of line disturbance, and insist upon the use of compensating coils that completely nullify this advantage. It is usually better for the mill owner to purchase his motors direct from the manufacturer, but he should not do so until after full consultation with the company from which he expects to buy current. The question as to whether or not to use electric power is almost always a difficult one for the mill owner or his consulting engineer to decide. Except in a few cases, the actual net saving is small and this saving is only possible when the utmost care is exercised in laying out the whole proposition. Applied engineering is not an exact science and good "horse sense" is more conducive to dividends than too much efficiency figuring.

GUARDS FOR POLISHING WHEELS

At a recent visit to the small tool department of the Pratt & Whitney Co., Hartford, Conn., the writer had his attention called to an interesting and effective type of sheet steel guard for polishing wheels. Two types of these guards are shown in Figs. 1 and 2. That shown in Fig. 1 is used in connection with the polishing of the flutes of small taps, while that shown in Fig. 2 is used for larger sizes, such as staybolt taps and other tools of the same type. A particularly interesting feature of the guard shown in Fig. 1 is that it is provided with glass sides or "windows" on both sides, so that the workman always has the proper light on the work being polished. This is a very important consideration in the design of guards for polishing wheels or for other parts. Often these guards are made from solid sheet steel or cast iron in such a manner that the workman cannot see the work properly, and he naturally objects to the use of the guard. Many cases are known where the workman has taken the first opportunity to discard guards so designed. In the present instance, however, this difficulty is entirely eliminated and the guard can be carried forward to a point where it almost encases the polishing wheel without interfering with the work.

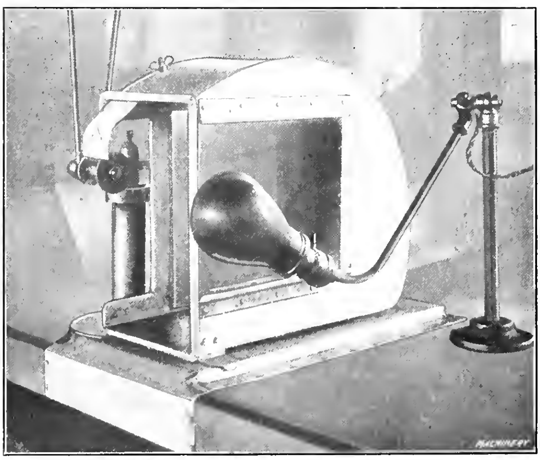

Fig. 1. Guard used for Polishing Wheels for Small Taps—Note "Windows" in Sides of Guard

It will also be noticed that an electric lamp bracket is provided in such a position that the light can be placed directly outside of the window, thus getting the full benefit of the light on the work at night. The lamp bracket is of the universally adjustable type made principally from pipe and pipe fittings. The lamp shades are of the type which should always be provided for machine tool work, as these prevent the light from being thrown into the operator's eyes, and reflect it against the work.

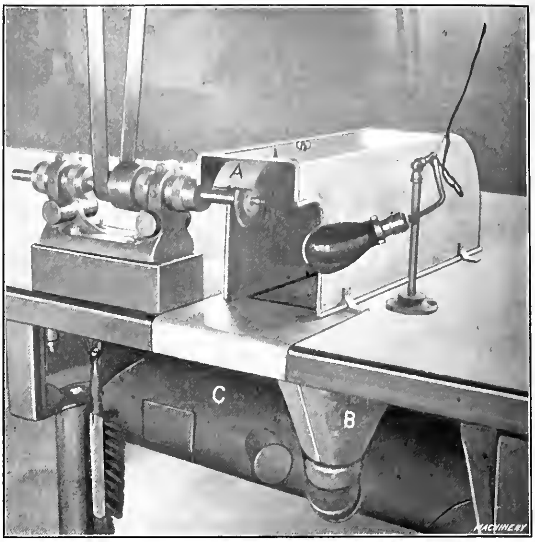

Fig. 2. Guard for Large Polishing Wheels—Sparks from Work provide the Necessary Light

The glass sides of the guard are slid into position as indicated, and can be easily removed and replaced. Immediately over the wheel a small adjustable sheet steel extension guard *A* is provided. This can be pulled out or pushed in according to the nature of the work being done, and prevents any sparks from being thrown into the operator's eyes. This guard can be bent to suit different diameters of wheels, and it is adjusted by a thumb-nut shown in the top.

All dust from the polishing operation is removed by suction through the bottom of the hood which is provided with a screen as shown in Fig. 2. From here the dust passes through duct *B* into the main pipe *C* of the suction blower. The type of guard shown in Fig. 2, which is intended for large tools, is not provided with glass sides. The reason for this is that the sparks produced when polishing large work give the operator all the light necessary inside the hood.

These guards have proved very convenient and are a safeguard to the operators' health, in that the dust is completely removed; they also prevent injuries due to wheel breakages. The sheet steel used is amply strong to resist the small fragments that would be thrown in case of breakage of the thin, small wheels. The effectiveness of these guards is proved by the fact that there is practically no dust in the polishing room, nor is there any evidence of dust settling on the benches or machine bases, as is often the case in workrooms where operations of this kind are carried on.

* * *

Experiments carried out with compressed seamless zinc tubes are said to have proved that in point of strength and elasticity they are approximately equal to copper and brass tubes. Owing to the fact that they are not chemically affected by naphtha or petroleum, they may be found useful in the petroleum refining industry.

HOLDING DEVICES FOR FIRST-OPERATION WORK*

DESIGN OF CHUCKING FIXTURES—CONSTRUCTION OF VARIOUS TYPES FOR TURRET LATHES AND VERTICAL BORING MILLS

BY ALBERT A. DOWD†

The methods of holding and clamping rough castings for the first or "chucking" operation are so diversified that the subject must, necessarily, be treated by means of examples representing different varieties of work. Nearly all of the examples shown are more or less cylindrical in shape, for the reason that elliptical, rectangular, or odd-shaped parts require special treatment and, therefore, can only be touched upon in an article of this kind. In the general course of manufacturing, there are occasionally pieces of peculiar shape which require chucking fixtures, but as this work is of such great variety, it is difficult to give much information regarding its handling except in a general way. Any piece of work of peculiar shape requires a thorough knowledge of the conditions governing its use, in order that it may be chucked properly and located from the surfaces which are of the greatest importance.

Important Points in Design of Chucking Devices

In the design and construction of chucking devices, there are a number of points to which the most careful consideration must be given. In some cases, the work must be held by the cored interior, as, for example, an automobile piston, or, in fact, any other work in which it is necessary to have

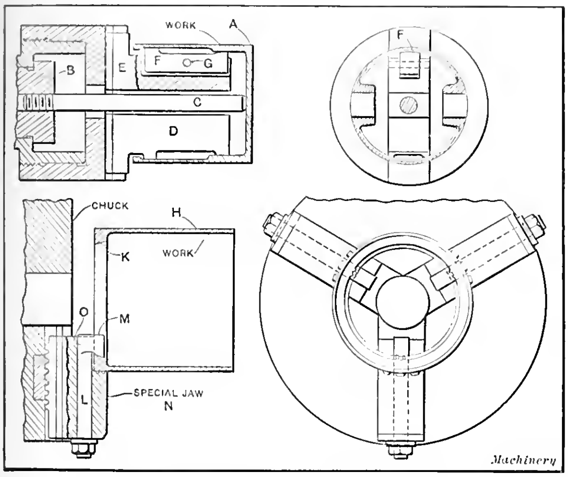

Fig. 1. (Upper View) Two-jawed Chuck for holding Piston internally; (Lower View) Chucking Fixture for Piston Ring Pot

an equal division of metal throughout the cylindrical walls. In other instances, however, some method of exterior holding may be perfectly satisfactory. The term "exterior holding" does not necessarily mean that chuck-jaws are referred to, for various devices other than jaws, will be cited during the following discussion of holding methods.

Having determined whether the work is to be held externally or internally, let us take up the important points in the design of holding devices.

First: The important locating surfaces should be carefully considered, always having in mind the future handling of the piece in its various operations. Great care should be taken that no locating points are so placed that they will come in contact with the work in places where the pattern is gated, or where numbers or letters may appear.

Second: In setting up a rough casting there should never be more than three fixed supporting points; any others which may be necessary for the proper support of the work must be made adjustable, with some approved method of clamping securely after adjustment.

Third: The work must be firmly secured so that no distortion can take place under the strain of clamping.

Fourth: When the work is of such a nature that difficulty is experienced in obtaining proper clamping surfaces, it is sometimes advisable to consult with the patternmaker in regard to the addition of clamping lugs to the pattern. In

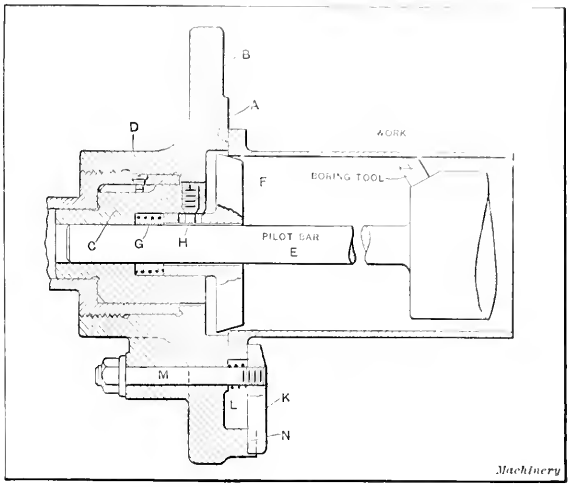

Fig. 2. Another Ring Pot Chucking Fixture

cases of this sort, these lugs should be so applied that their subsequent removal can be effected readily.

Fifth: In designing a chucking fixture the safety of the operator should be considered carefully, and by that is meant that protruding heads of screws, bolts, clamps and similar parts should be avoided as much as possible. A little forethought in this regard may be the means of saving an operator from mutilation or death.

Sixth: Convenience and accessibility in setting, locating and clamping the work, are also of primary importance.

Individual points regarding the work-holding devices shown in the illustrations will be discussed. We shall consider holding devices for the horizontal turret or chucking lathe, the vertical turret lathe, and the vertical boring mill. In describing these devices, the work and its requirements will be considered, as well as the important locating surfaces, the method

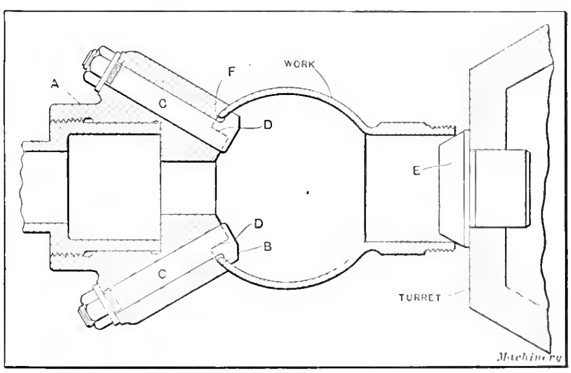

Fig. 3. Fixture for Ball-and-socket Pipe Joint

of handling the work and important points in the design of different fixtures.

Two-jaw Chuck arranged for Internal Chucking

It is essential that the cast-iron piston shown in the upper part of Fig. 1 be located from the cored interior, in order to have the outer walls concentric with the core, thus obtaining an equal distribution of metal throughout the piston walls. Due to the formation of this casting, the core is poorly supported at the closed end and, therefore, has a tendency to drop slightly when the metal is poured into the mold, thereby

* For information on this subject previously published in MACHINERY, see "Arbors for Second-Operation Work" in the October, 1913, number.
† Address: 84 Washington Terrace, Bridgeport, Conn.

producing a lack of concentricity between the cored portion and the exterior surfaces. It is logical then, in order to obtain uniform results, to work from the cored portion when setting up the casting. Many methods of holding have been devised for this purpose. The fixture shown in Fig. 1 is one of the simplest, an ordinary two-jaw chuck with special internal jaws being used for holding and locating the work *A*. A steel bushing *B*, fastened into the spindle, contains the stop-rod *C*, which comes against the head of the piston, thus insuring a uniform thickness of metal at this point. The chuck is supplied with the two special jaws *D* and *E*. The former is a plain jaw with two bearing points, while the other has a swivel-jaw *F*, pivoted on the pin *G*, which allows it to conform to the inequalities of the casting. This method of chucking is one of the cheapest, and the results obtained by its use are fairly satisfactory. There is a tendency toward inequality in the thickness of the piston walls in the direction of the wrist-pin bosses, due to the fact that the centering action of a chuck of this type is in two directions only; however, at least one large manufacturer in the East uses this method entirely. The chuck is employed for rough-turning only, thus securing a partially finished surface which is true with the core and which may be used to work from for subsequent operations.

The work *H*, shown in the lower view of Fig. 1, is a cast-iron piston ring pot, which must be held in such a way that it can be bored, turned eccentrically, and separated into narrow rings for a gas engine piston. As the ring pot is very thin, it must be carefully held to avoid distortion and yet be very rigidly secured, as there are several tools working at one time so that the torsion produced by the cut is excessive. The pot is made with an internal gripping ring *K*, which is slightly beveled to assist in keeping it back against the chuck jaws. The chuck is an ordinary three-jaw, geared-scroll type, having jaws as shown in section at *N*. These jaws are of steel and are drilled to receive the hook-bolts *L* which pass entirely through them and grip the ring from the inside. The heads of the bolts *M* come out through slots in the jaws, the heel having a backing at *O*. When setting a casting the bolts are left free while the jaws are brought up against the outside of the casting with just enough pressure to get a bearing. The bolts are then set up tightly on the gripping ring, so that the work is held firmly but without distortion. This method is very good and can be applied successfully to many varieties of thin work. (The July number of MACHINERY, page 888, shows another application of a similar set of jaws applied to a much larger piece of work.) The hook-bolts are of tool steel and are hardened and drawn to a deep straw on the hook end. The backing up of the hook-bolt at *O* is very important, for unless properly supported at this point its action is greatly impaired and it soon becomes bent out of shape and is absolutely useless.

Ring Pot Locating Fixture without Chuck-jaws

Another cast-iron ring pot of somewhat different form is shown in Fig. 2. The operations on this piece are identical with those for the casting shown in the previous illustration, but the holding method is entirely different. This form of pot is used by one of the largest manufacturers in this country. Before it is placed in the fixture, the face of the gripping ring *A* is ground square with the outside of the pot. The body of the fixture *B* is of cast iron and is screwed fast to the spindle nose of the horizontal turret lathe upon which it is used. The annular ring or pad against which the ring pot lies is faced square in position on the machine. A hardened and ground tool-steel bushing *C* is accurately fitted to the inside of the spindle and is held in position by the teat-screw *D*. It will be noted that this bushing also acts as a guide for the boring-bar pilot *E*. A tapered plunger *F* is forced outward by the spring *G* and centralizes the inside of the pot. The screw *H* simply acts as a retainer to keep the plunger in position. There are three clamps, 120 degrees apart, on the face of the fixture. One of these is shown at *K*; obviously this is tightened by the screw *M*, while the coil spring *L* serves to keep the clamp away from the work when not in use. The lug *N* prevents the clamp from twisting around when the screw is being tightened. This fixture is a very good one, except that its operation is rather slow.

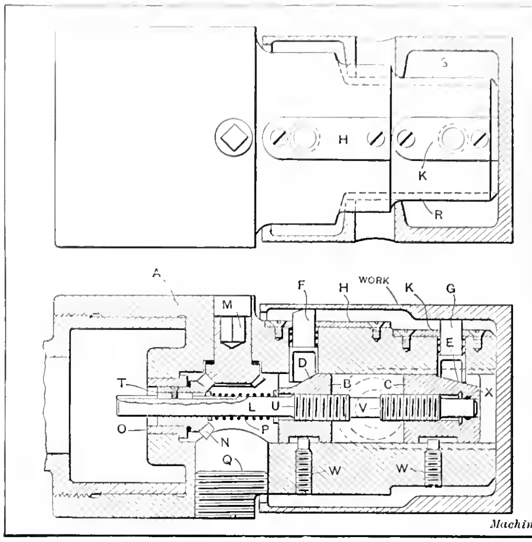

Fig. 6. Special Chuck for holding Gas Engine Pistons internally

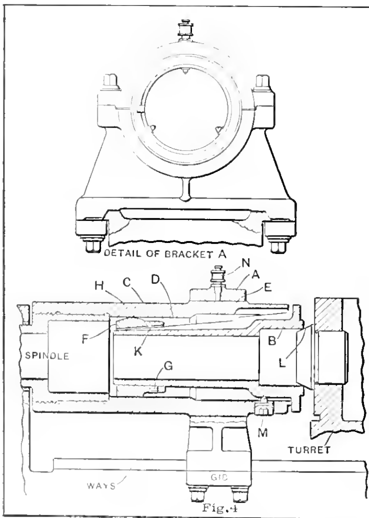

Fig. 4. Fixture for holding a Long Part—Outer End is supported by Bracket

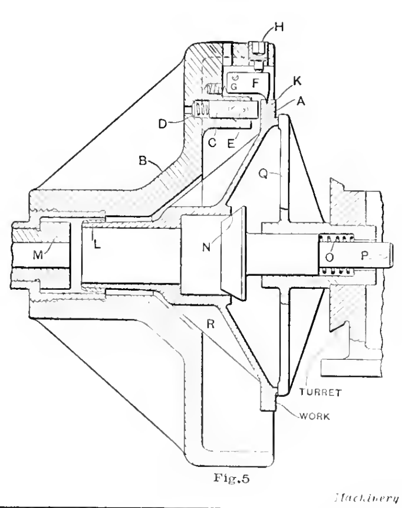

Fig. 5. Casting A held so that it can be machined at One Setting

Locating Fixture for a Ball-and-Socket Pipe Joint

The requirements for the work shown in Fig. 3 need little explanation. The piece itself is a steel casting. A cast-iron "cat-head" or fixture *A* is screwed onto the spindle nose, and is faced at *B* to an arc corresponding with the rough ball-portion of the pipe joint. The two hook-bolts *C* obviously grip the work from the inside and hold it firmly against the finished face *B*. A centering plug *E* fits the turret hole and is brought up and entered into the casting before the hook-bolts are set up tightly. This fixture was not entirely satisfactory owing to the condition of the rough castings at the end *F*, for at this point they varied greatly and were very rough, making the holding somewhat

uncertain. A method of holding this work by the interior undoubtedly would have been more satisfactory.

Chucking Device having an Outboard Supplementary Bearing

The automobile tail-shaft housing shown at *B* in Fig. 4 is made of malleable iron and is so long that chucking by means of jaws is out of the question, on account of the excessive overhang which would be necessary. The piece was to be finished complete in one setting and the fixture shown was designed and used for this purpose. The body *C* is of cast iron and is screwed onto the spindle nose. The inner cylindrical surface *D* is very carefully bored and the outer bearing surface *E* is turned and finally lapped to a nice running fit in the bracket *A*. The periphery *H* of the locating and centering bushing *F* is crowned on a radius and is slotted in various places, as shown at *K*, to receive the exterior ribs on the housing. A pointed set-screw *G* keeps the bushing in position. The tapered plug *L* is located in the turret hole and serves to center the work, and the pointed set-screws *M* (three of which are used) are sunk into the casting and act as drivers in addition to holding it in the position determined by the tapered plug. The bracket *A* (also shown in detail) acts as an outboard bearing for the long body of the fixture and prevents the vibration which would otherwise result from the excessive overhang. A glass oil cup was an added refinement to the equipment and may be noted at *N*. This fixture has been used with great success by one of the large manufacturing firms in the West.

Method of Chucking One-half of a Rear Axle Housing

The male portion of an automobile rear axle housing is shown in Fig. 5. This is machined in one setting on a horizontal turret lathe. The body of the fixture *B* is of cast iron and is screwed onto the nose of the spindle. Three steel pins *C* are located 120 degrees apart, around the inside of the fixture body, the coil springs *D* forcing them outward and the set-screws *E* securing them in place when properly located against the work. The method of clamping is somewhat peculiar and should be carefully noted. The swinging dogs *F* have a knife-edge at *K* and are pivoted on the pins *G*, which are set back in such a position that the action of the dogs (controlled by the hollow set-screws *H*) has a tendency to carry the work back against the body of the fixture and the spring jack pins. A steel bushing *L* is forced onto the small end of the work and assists in centering it in the spindle. This bushing is crowned on a radius the same as that shown in Fig. 4. The taper locating plunger *N* is forced out by the spring *O* and is restricted in its action by the pin *P*. The two-arm support *Q* is of cast iron and is of assistance in keeping the work in position while the various screws and dogs are being tightened. The bushing *M* acts as a guide for the boring-bars and reamers used in machining the work. The work is driven by the ribs *R*, which enter slots in the body of the fixture. This method of holding gave satisfactory results, although considerable care was necessary to avoid springing the casting, when tightening the clamping dogs.

Equalizing Pin Chuck for a Gas Engine Piston

One of the many varieties of internal holding piston chucks is illustrated in Fig. 6. Although rather expensive, it is an excellent example of this type of chuck, and is very well made. All working parts are of steel or bronze and all parts requiring such treatment are carefully hardened and ground. The body of the chuck is of machine steel, carbonized, pack-hardened and ground; the pins, cams, operating rod, screws and bushings, are of tool steel, while the miter gears are of bronze. The body of the chuck *A* is screwed onto the spindle nose and is ground or lapped at all important points. The operating cams *B* and *C* are slotted in three places around the periphery at *D* and *E*, these slots being angular and forcing the six pins *F* and *G* out against the interior walls of the piston. It may be noted that the steel plates *H* and *K* are let into the body of the chuck, and act as retainers for the pins. These plates are clearly shown in the upper view. The operating rod *L* is revolved through the action of the miter gears *M* and *N*. The latter has a key *T* engaging a long spline in the operating rod, which is thereby permitted to move longitudinally. The threaded portion *U* is 6-pitch right-hand thread, while that at *V* is 6-pitch left-hand thread. The forward cam is packed with felt at *X* to keep out the dirt. The bushing *O* is of tool steel, hardened and ground. The plug *Q* simply closes the hole which has been put in for assembling purposes.

By referring to the upper view it will be seen that the chuck body is cut away on the sides at *R* and *S*, on account of the wrist-pin bosses in the piston, and the overhanging lip at *R* acts as a driver. In designing a chuck of this kind, it must be remembered that while the rear clamping pins may be equally spaced, the position of the forward pins will be determined by the diameter and spacing of the wrist-pin bosses, and an end view will be found essential to determine the correct position. In general it will be found that two of the forward pins seldom can be spaced more than 80 degrees apart and often the spacing cannot be made more than 55 or 60 degrees. Another point in design which is of great importance is the amount of clearance between the ends of the wrist-pin bosses and the flattened sides of the chuck body. It is seldom safe to allow a clearance of less than $\frac{3}{16}$ inch on each side, over the finished sizes called for on the drawing of the piston. The location of the stop-pins *W* is also important, and sufficient allowance should be made in the length of the cam slots to take care of variations in the piston castings. A chuck of this type gives results which are satisfactory in every respect.

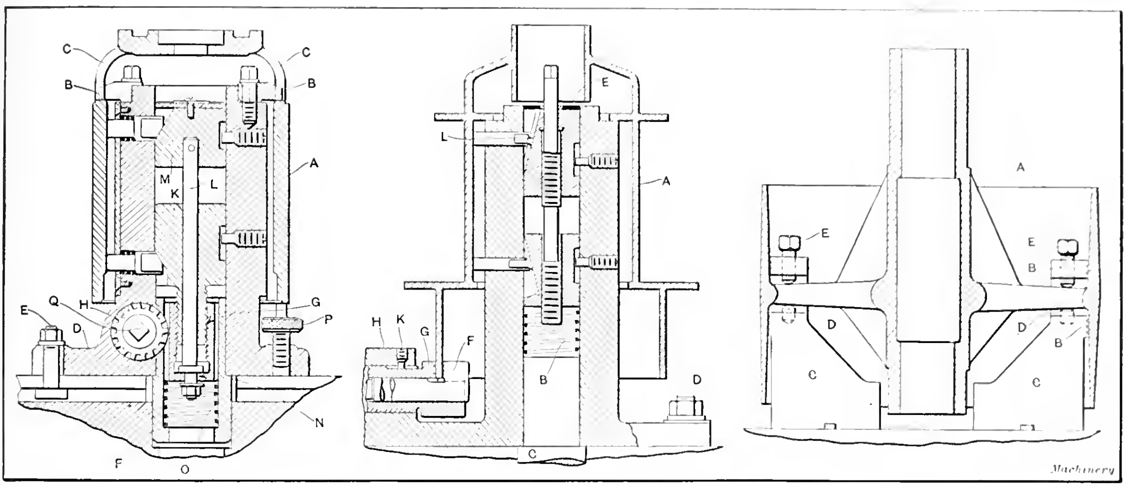

Fig. 7. Vertical Boring Mill Fixture for holding Part A internally

Fig. 8. Vertical Fixture having Internal Clamping Pins and Hook-bolt Clamps for Lower Flange

Fig. 9. Special Chucking Jaws for Large Pulley

An Equalizing Pin Chuck for an Electric Generator Frame

The examples which have been referred to in the foregoing are all adapted for use on the horizontal type of turret lathe, but we shall now go a step farther and take up chucking devices designed for the vertical turret lathe and the vertical boring mill. As machines of this type are adapted more to heavier classes of work, the fixtures should be designed with relation to the work and also to the power of the machines

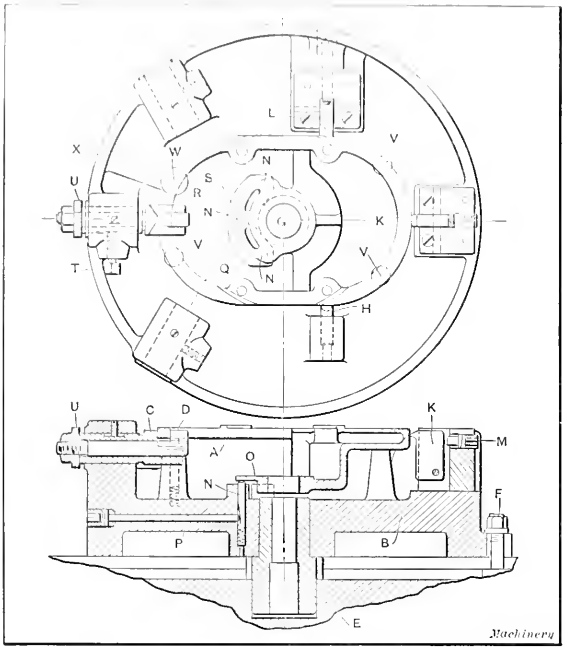

Fig. 10. Ingenious Chucking Device for holding Odd-shaped Aluminum Casting without Distortion

upon which they are to be used. For machining the steel generator frame shown on the fixture in Fig. 7 the working points specified by the manufacturer are at *B* between the ribs *C* on the upper portion of the casting *A*. It was further specified that the work must be held by the core to insure an evenly balanced casting.

The design of this chuck resembles that shown in Fig. 6, in that both chucks are fitted with pins and operating cams; the operating mechanism, however, is entirely different. The body of the chuck *D* is of cast iron; it is carefully reamed and lapped at important points, and is securely fastened down to the table of the machine by three screws having tee-shaped heads, which enter the table T-slots as shown at *E*. The fixture is centered by the hollow stud *F*, which is of tool steel, hardened and ground inside and out. This stud also acts as a bushing for the operating sleeve *G*, and is cut away for clearance on one side where the spiral gear *H* passes through it. This gear meshes with another which is cut on the outside of the operating sleeve. The latter is of bronze and it is threaded internally with a 6-pitch Acme thread, corresponding with that cut upon the lower end of the cam *K*. The operating rod *L* is pinned into the upper cam *M*, and is shouldered and journaled at its lower end where it passes through the operating sleeve at *N*. The coil spring *O* is so proportioned that it simply supports the cam mechanism and assists in releasing. It will be noted that the arrangement of this internal mechanism permits a "floating" action for the cams, so that the clamping pins all bear uniformly against the inner walls of the casting. In setting up the work on the fixture, it is dropped over the top until the lower end rests on the three adjusting jacks *P*, which are placed 120 degrees apart and are knurled for finger adjustment. The upper locating arms *R* are swung back out of the way while the casting is being set in position, but as soon as this has been done they are brought around into the position required. The jacks are next raised until the casting has been properly located against the arms; then a long-handled socket wrench is inserted at *Q* and the gearing is revolved until the pins are securely seated against the inner walls of the work.

A Combination Device having Equalizing Pins and Hook-bolts

The piece shown at *A* in Fig. 8 is a clutch pulley for a gasoline tractor. It is made of cast iron and the method of holding from the inside was decided upon because it seemed to offer better facilities for machining. As in a former example, the body of the fixture contains the cams and the operating rod which is threaded right- and left-hand, as before. The lower ends of the pins and the slots in the cams are dovetailed in this instance, so that the outward and inward movements are controlled mechanically, no springs or plates being required. The fixture is centrally located on the machine table by the plug *C*, which fits the center hole in the table and is held down in the usual manner by the T-bolts shown at *D*. The coil spring *B* simply acts as a support for the cams and rod. An annular groove is cut in the upper cam at *E* and this is packed with felt to assist in keeping the dirt out of the working parts. The lower part of the fixture has three bosses (one of which is partially shown at *H*), which contain the floating jaws and hook-bolts, *G* and *F*, for clamping the lower flange of the pulley. The construction of these parts is more clearly shown in Fig. 10, and, as they are identical the reader is referred to the portions marked *C* and *D* in that illustration. The results obtained by the use of this fixture were at first very satisfactory, but, after a time, the dirt which gradually accumulated in the dovetail cam slots, began to cause trouble, until, finally, it became almost impossible to operate the mechanism. Then, too, in several cases the dovetail part broke off completely, necessitating new pins, so that the chuck as a whole cannot be considered an absolute success. No trouble would have been experienced if the cam slots and pins had been made as shown in Fig. 7, with coil springs and retaining plates.

A Set of Special Jaws for a Large Crowned Pulley

The large farm engine pulley shown at *A* in Fig. 9 is of cast iron, and it must be held by the inside in such a way

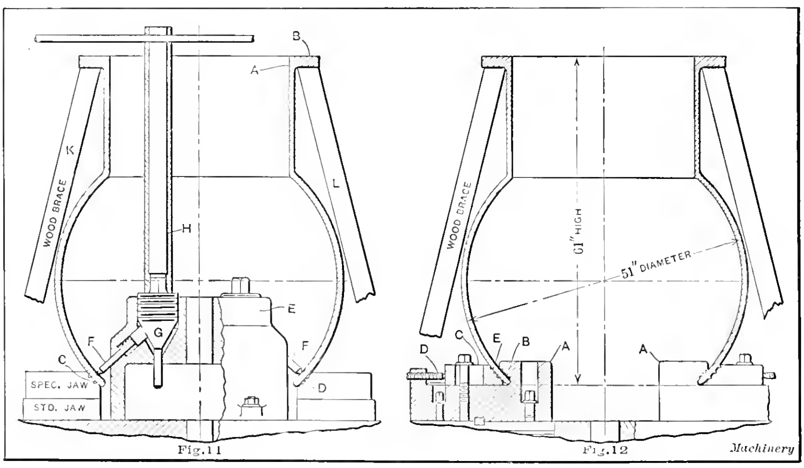

Fig. 11. Vertical Boring Mill Fixture for holding Large Ball Joint

Fig. 12. Another Method of holding Large Ball Joint

that it will not be distorted while fairly heavy cutting is being done on the periphery of the pulley. A four-jaw table was selected on which to hold the work, as there were eight spokes in the pulley. The chuck jaws *C* were made of 0.40 per cent carbon steel and were slotted out for the spokes

as shown in the illustration. The hardened steel studs *D* were set into the slots, and the set-screws *E* brought down tightly on them after the jaw surfaces *B* had been brought out to center the pulley.

This method of holding pulleys or other spoked work gives very satisfactory results and is used by many manufacturers throughout the country.

A Chucking Device for a Difficult Piece of Electrical Work

The aluminum piece shown in Fig. 10 is one of the most difficult for which I have ever had occasion to make a chucking fixture. The walls of the entire piece were of very thin section, and the overhanging portion *A* was elliptical in shape and entirely unsupported. It was necessary to so hold this casting that it could be machined without distortion. The body of the fixture *B* is of cast iron. It is centrally located on the table by means of the hollow bushing *E*, and clamped down by T-bolts shown at *F* in the table T-slots. A portion of the fixture shown in the upper view at *G* was cut out to form a V, in which the cylindrical portion of the casting is centered. One of the sides of the casting is located against the knife-edged pin *H* (shown in the upper view), and the casting is forced into the V and against this knife-edged surface by the swinging clamps *K* and *L*. It will be noted that these clamps also have a knife-edge and that the pins upon which they are hung are in such a position that their action is downward, thereby tending to hold the work securely against its supports. Hollow set-screws *M* control the action of these swinging clamps. There are three spring-pins *N* which are used to support the very thin flange *O*, and the springs which force them upward are carefully proportioned so that they have just sufficient strength to insure contact without springing the work. These pins are locked in their positions by the long hollow set-screws *P*, shown in the lower view.

One of the principal points of interest in this fixture is the method of gripping the overhanging elliptical portion *A*, without distorting the casting. This is accomplished by means of the floating jaw *C* and the hook-bolt *D*. There are three of these floating clamps which grip the work at points *Q*, *R* and *S* (see plan view). It will be noted that the clamps are free to "float" laterally, until the set-screws at *T* are tightened. The knurled hexagon nut *U* is threaded onto the head of the hook-bolt, and is lightly tightened by means of the fingers before the final tightening with a wrench. As these clamps have a perfectly free floating action, until the binding screws are tightened, obviously there can be no distortion of the piece, and yet it is held rigidly at these points. When the work is placed into the fixture it rests upon three fixed points shown in the plan view at *V* and a fourth point *W*. The latter is held upward by a light spring and it is locked in position by the long hollow set-screw *X*.

The work accomplished by the use of this fixture was true and accurate, no evidence of springing out of truth being apparent.

Boring Mill Fixtures for a Large Ball Joint

The work shown at *A* in Fig. 11 is a large ball pipe joint for a suction dredge, and it is to be faced on the upper surface *B*. Two designs were made for this work, neither of which was used, but as the conditions are somewhat peculiar the fixtures will be described, and may be taken for what they are worth. The special jaws *C* and *D* are bored to an arc corresponding with the ball, and the work rests upon and is centered by these jaws. The body of the clamping device *E* is of cast iron and is bolted down to the table. It contains four pointed screws *F*, which, normally, are kept away from the work by means of coil springs. The ends of the screws are beveled to the same taper as the operating screws *G*, which are threaded at their upper ends with a coarse pitch thread, and have squares to receive the end of the long socket-wrench *H*, by means of which the screw is revolved, thus causing the points to sink down into the casting. Wood braces are used to support the flange which is to be faced. Four are used, although only two (*K* and *L*) are shown in the illustration. This fixture would have been rather expensive, but doubtless would have produced satisfactory results.

Fig. 12 illustrates another fixture for holding the same piece of work, which probably would have given more satisfactory results than the one shown in the previous illustration. It could have been manipulated more rapidly, because it is more accessible to the operator. Four sets of special jaws *A* are used for holding the work. The part *B* is formed to an arc corresponding to that part of the work which it grips, and has teeth to assist in obtaining a firm "bite." The supplementary sliding jaw *C* is forced into position by the set-screw *D*, thus clamping the work tightly between *B* and *E*. Wooden supports are used under the flange.

In the foregoing the writer has tried to cover the majority of conditions commonly met with in chucking problems, and the examples illustrated are given as representative methods which doubtless can be applied to nearly all operations that may be required in the general course of manufacturing.

"ECONOMY IN TOOL DESIGN"

BY JAMES McINTOSH*

An article appeared in the September number of MACHINERY, engineering edition, entitled "Economy in Tool Design," which shows two milling fixtures, Figs. 2 and 3, to the disadvantage of the latter. I wish to defend a system introduced by me in 1904. Fig. 3 represents good practice in the rapid production of duplicate parts. The failure of the example described by the contributor of the article referred to was due to defects in design. In the first place, it is foolish to expect a thumb-screw to hold six pieces firmly in position while a 5/8- by 1 3/4-inch slot is being milled, even with the finest feed. The thumb-screw will inevitably be loosened by the vibration and general action of the cutter teeth. In the second place, the revolving feature is needless and defective, being an addition to my original design that adds to the cost and invites failure. This fixture reduced in height, without the turntable and provided with V-blocks embracing the part to be milled by the shank, would have been successful. It should be rigidly secured to the table and provided with a tongue to fit the table slot. The first section filled with parts is milled while the second section is being loaded, and after the cutters have passed into section No. 2, section No. 1 may be changed, the table dropped and the cut set for section No. 1.

The defect in registering mentioned must obviously appear, inasmuch as the slightest degree of looseness of the index pin will be doubled, because of the short distance of the pin from the fixture center, compared with that of the outside pieces to be milled.

The satisfactory fixture Fig. 2 is said to be "expensive but proved to be an accurate and rapid producer." Let us compare the feed travel required for milling with both jigs. We will take twelve pieces, one filling of Fig. 3, and the same number for Fig. 2. The latter jig must feed 3 3/8 inches to mill one piece, this distance being required to include the entry of the cutter. To mill twelve pieces, the feed will be 40 1/2 inches. The operator must stop or run the cutter off the job twelve times.

The feed travel required for the jig in Fig. 3 is only 10 1/4 inches—made up as follows: 3 3/8 inches for the first piece and 1 3/8 inch for each of the next five in line, or 10 1/4 inches to cut a double row, or twelve—six in a row. Hence the discarded jig using the same feed is evidently four times faster by feed time and is even faster because the feed fixed on sets the pace of the operator. This is not the case with the jig shown in Fig. 2 any more than with a standard table vise.

* * *

Metallic sodium hardens lead without changing its color. Two per cent of sodium will harden lead so that it will ring when struck; a larger amount causes it to become brittle. The lead-sodium alloy is sometimes used as a bearing metal. One of the bad features of the alloy is that it corrodes rapidly in damp air or in contact with water.

ALTERNATING-CURRENT MACHINERY TROUBLES—1

BRIEF AND CONCISE ANALYSIS OF THE DIFFICULTIES MET WITH AND THE REMEDIES TO APPLY

BY E. A. LOF*

[In September, 1906, MACHINERY published a data sheet supplement entitled "Diseases of Dynamos and Motors," which gave directions for overcoming the difficulties which are met with in the operation of direct-current electrical machinery. This data sheet somewhat revised was later republished in MACHINERY'S Reference Book No. 34, "Care and Repair of Dynamos and Motors." Several requests have been received from the readers of MACHINERY asking that similar directions be published relating to alternating-current machinery, and the following article has been prepared to cover the subject in a concise and yet complete manner.—EDITOR.]

In treating of the chief troubles of alternating current apparatus, the following classes of machinery will be dealt with: (1) alternators; (2) synchronous motors; (3) induction motors; (4) transformers; (5) synchronous converters. Troubles due to mechanical causes, such as heating of the bearings, etc., will not be considered in this connection as the same remedies that are given in the matter previously published on direct-current machinery apply to this class of apparatus also.

ALTERNATORS

Practically all alternator troubles may be subdivided into the following: Failure to generate; excessive heating; poor voltage regulation; and bad parallel operation.

Failure to Generate

The failure of an alternator to generate is very often due to exciter troubles, and it is therefore essential that exciter failures be analyzed in detail. Exciter troubles were considered in the data sheet supplement previously published under the heading "Dynamos." With the assumption that full exciter voltage is applied to the field terminals, the failure of an alternator to generate the normal terminal voltage at no load may be due to any of the following causes:

Armature winding open circuited.— Failure to generate from this cause can only occur with Y-connected machines, while for the delta-connected machines full voltage will be obtained across all terminals. The open circuited phase can be found by a magneto and bell, ringing from the neutral to each of the terminals.

Field winding open circuited.— This is the most general cause, and the break usually occurs in the connection between the coils.

Field coils short circuited.— Sometimes a short circuit may take place between adjacent field turns. This may be caused by mechanical injury, or by high induced voltages set up in the field winding, if the circuit is suddenly opened without being at field discharge resistance. A short circuit eventually results in a burnout. A resistance test should be taken of the field winding with the drop across each individual coil. A short circuited pole will show a reduced drop.

Reversal of individual field coils.—This may occur when reconnecting disassembled machines. It results in a reduced terminal voltage. Tests for determining if coils are reversed can readily be made by an ordinary compass.

Excessive Heating of Field Coils

Generator overloaded.—No defect of machine. Relieve generator of part of the load before the consequent overheating reaches a dangerous point. The generator may also become overloaded due to incorrect instrument calibrations.

Low power factor of load.—If the power factor of the load is too low, the field distortion due to armature reaction will increase, thus weakening the resultant effective field. Increased excitation, followed by increased heating, is therefore required in order to maintain the voltage. Generator can only carry partial load when the power factor is lower than that for which the machine is designed.

Operation below normal speed.—In this case the field excitation must be increased to maintain the rated voltage, which may result in excessive heating of the field coils. Check speed.

Operation above rated voltage.—This may be due to incorrect voltmeter readings, or intentionally in order to compensate for excessive voltage drop. It can only be obtained by increasing the field excitation and heating may result.

Short circuit in field winding.—This will render a portion of the field winding inoperative and a consequent increase in the exciting current is required to compensate for the now smaller number of effective field turns. It can best be located by resistance measurement of the field system. To guard against any danger of an internal breakdown of the field coils, field discharge switches with resistances should always be provided. Where this has not been done, turn in all resistance of both rheostats before opening the alternator field switch.

Excessive Heating of Armature Iron

The causes of excessive heating of the armature iron are generally the same as those causing overheating in the field coils, as previously outlined, *i.e.*, overload, low power factor of load, slow speed, operation above rated voltage, and short circuit in field winding.

Excessive Heating due to Defective Insulation between Stator Laminations

This will result in energy losses with consequent heating due to hysteresis and eddy currents. Can only be remedied by rebuilding the core.

Excessive Heating of Armature Coils

Generator overloaded.—May be due to incorrect meter readings, or may also be intentional.

Conduction of heat from armature iron.—Due to causes referred to under "Excessive Heating of Armature Iron."

Open circuit in one phase.—This occurs only with delta-wound armatures. The result is that the entire load is placed on the remaining two phases, thus overloading them and causing overheating. An open circuit can be tested out simply by a magneto and bell, or by applying to the armature winding a low voltage with an ammeter in the circuit, comparing the results for the different phases.

Grounding of one phase.—With Y-connected windings having a grounded neutral, a ground in any one phase will short circuit part of the winding. With delta or non-grounded Y-wound windings there must be two grounds in order to make a short circuit.

Short circuit in armature coils.—This will sooner or later result in the burning out of the short-circuited coils, due to excessive circulating currents therein. The overheating of certain coils can generally be detected by smoke issuing therefrom or by feeling the end connections with the hand. A definite method to detect a short circuited phase is by resistance measurements. This is readily accomplished with Y-connection having grounded neutral, and involves only a comparison of the resistances of the three phases, from the neutral to each terminal. With delta-connection or Y-connection with insulated neutral it becomes necessary to measure the resistance of two phases at a time and compare the results, which will then reveal which phase is short circuited.

Collector rings.—Overheating of the collector rings is often caused by an excessive field excitation, the same as overheating of the field coils. This cause can readily be detected by inserting an ammeter in the field connection and measuring the field current. Heating of collector rings may also be caused by excessive brush friction due to too high brush-tension. Incorrect brush alignment or dirty collector rings may also be the cause.

Poor Voltage Regulation

Low power factor.—A poor regulation is often found to be caused by the fact that a highly inductive load is being placed

* Address: 214 Glenwood Blvd., Schenectady, N. Y.

on the machine, which has not been provided for in the design of the machine or guaranteed. If the load cannot be changed, the only remedies are to redesign the alternator or provide synchronous condensers which will supply the magnetizing current for the inductive load and thus raise the power factor of the load at the generator.

Alternator speed variations.—Variation in voltage may be caused by poor speed regulation of the prime movers, due to defective governors.

Exciter troubles.—A speed variation of the exciter sometimes causes voltage fluctuations, especially when the exciters are direct-connected to the main generators and thus subject to the speed variations of the latter under different load conditions.

Automatic voltage regulators.—Almost all plants of any importance are nowadays provided with T. A. automatic voltage regulators, and, if so, moderate speed variations or load changes should not impair the regulation. Troubles may, however, occur with the regulator, and can be investigated as follows:

Should the regulator fail to build up its voltages, see that the reversing switches are thrown to the extreme position, either up or down; see if the rheostat shunt circuit switches are closed on the exciters which it is intended to run; look for improper connections.

Should the voltage fall, examine the rheostat shunt circuit connections to see if they are not so connected as to short-circuit the exciter field instead of its field rheostat.

If, after placing the regulator in service, the potential fluctuates to the extent of several volts, proceed as follows:

See if contact screws are loose. If so, they should be properly adjusted and set-screws securely tightened; observe both levers at the points where the core stems are attached, to see that there is no friction at these points.

The regulator should not be subjected to excessive vibrations, such as might be the case when it is mounted on iron brackets. If this is so, some rigid support should be provided to overcome the vibration.

The dashpot should be carefully inspected to see that it is actually full of oil to within 1/8 inch of the top; the dashpot should also be examined to see that it is securely attached to the supporting posts; the dashpot may be adjusted for too free a movement. This adjustment should be made as free as possible without causing pumping of the voltage at no-load.

Examine cores to see that they do not touch the inside of the magnet spools.

Carefully inspect all wiring, also look for flat spots on the commutators, loose brushes, or any other poor contact, that might cause an unsteady voltage.

If there is an error in the voltage from no-load to full-load without the compensating winding in circuit, it must be due to improper adjustment of the alternating current magnet core.

If, after the load has become steady in going from no-load to full-load, the main alternating current voltage has fallen off, the alternating current magnet core should be slightly lowered until the voltage is the same at full-load as at no-load. If the main alternating current voltage is too high, the alternating current core should be raised slightly to overcome the error and the voltage will be the same at full-load as at no-load.

If there is excessive arcing at the relay contacts, check the connections of the rheostat shunt circuit to see that they are properly made, and that the rheostat only is being short circuited. The connections of the condensers should be checked.

Bad Parallel Operation

Resonance.—The trouble mostly encountered in the parallel operation of engine-driven alternators consists in a tendency of the impressed oscillations or impulses to coincide with the natural periods or swing of the alternator, causing resonance. This trouble can often be overcome by the attachment of simple dashpots to the governors, which delay the governor sufficiently to prevent the troublesome periodic action and which at the same time do not prevent sufficient promptness in governing.

It is often feasible to decrease the amplitude of the oscillations when the generators are rope- or belt-driven, by changing the length of the drive. The rotor displacement can be reduced or increased by providing a heavier or lighter flywheel. The natural period of swing of the alternator can be changed and resonance avoided by increasing or reducing the reactance of the machine.

With gas-engine-driven generators it is customary to place amortisseur windings in the pole faces to act as an additional drag on the engine to prevent displacement. Sudden tendencies to change in speed cause currents to be induced in the low resistance bars of this winding which produce a torque similar to that of a squirrel-cage induction motor and help out the flywheel to some extent.

Excessive cross currents.—Cross currents between alternators operating in parallel may be either wattless, or they may represent a transfer of energy. The former is caused by a difference in the excitation or voltage of the two machines, while the latter is caused by periodic oscillations of the generators, this being generally due to irregularities in the speed of the prime movers. They can therefore be reduced by improving the parallel operation as previously described.

SYNCHRONOUS MOTORS

Excessive Heating

Excessive heating in the different parts of a synchronous motor is generally caused by the same defects as for alternators and may be located and corrected in the same manner.

Power factor correction.—Excessive heating is very often caused when the field excitation of the motor is increased for low power factor correction, in order that the motor may draw a leading current and compensate for heavy inductive loads in other parts of the system. Such increased excitation will therefore increase the total armature current, slowly at first, but thereafter more rapidly, at low leading power factors. Hence over-excitation should be kept within certain safe limits, both as to its effect in regard to the armature as well as the field heating.

Open field circuit.—In the same manner as an increase in the field excitation causes the motor to draw a leading current from the line, a decrease in the normal excitation will cause the motor to draw a lagging current from the line, thus also increasing the total armature current and the heating. It becomes important, therefore, with synchronous motors to have the field current permanently established.

Voltage too low.—A synchronous motor should be operated normally at its rated voltage, as a reduction in voltage means increased current, and increased heating of armature.

Frequency low.—Operation at normal frequency is desirable, as at a reduced frequency and normal voltage the iron losses are increased due to higher density, and consequently also the heating.

Wrong polarity.—Since the winding of a synchronous motor armature is in series all the way around the circumference and under all of the poles, except in exceedingly rare cases, the trouble from a reversed pole is not very serious. Everything operates fairly satisfactorily, the only trouble being that the fields require more current than they should, to make up for the pole that is opposing the other fields. If, therefore, excessive field current is required for the minimum input to the motor, it would be well to try the polarity of all the spools, using a compass for the purpose.

Difficulties in Starting

The revolving fields of most synchronous motors have amortisseur windings, and are started by reducing the voltage to the armature winding. Failure to start and come up to synchronous speed may be due either to faults of the starting auxiliaries or to the motor.

Open circuit.—Difficulty in starting may be caused by an open circuit in one of the lines to the motor. When this happens, a polyphase motor becomes single phase and is not self starting. The motor will, therefore, stand still and soon get hot.

Applied voltage too low.—The starting torque of a synchronous motor is proportional to the square of the applied voltage. When, therefore, a synchronous motor will not start, it may be due to the fact that the voltage on the line is pulled down below the value necessary for starting. If the motor is provided with a starting compensator it may be possible to re-connect the leads and thus obtain a higher terminal voltage. Care, however, should be taken that the starting current does not become too high.

Increased friction.—Difficulties in starting may be caused by an increase in the static friction, due to bearings being too tight, cutting of bearings, belt friction, etc. For very large motor generator sets it sometimes becomes necessary to reduce the bearing friction by oil pressure, so as to reduce the current drawn from the line during starting.

Field excited.—If the field is on, most synchronous motors will not start at all.

Incorrect design of starting winding.—It sometimes happens that the manufacturer has not been properly informed as to the true operating conditions, and that the proper starting winding has not been furnished. A motor driving a generator will, for example, require a high starting torque compared to the pull-in torque, while for a motor driving a fan or centrifugal pump the reverse will be the case. A motor with a high-resistance starting winding will have a high starting torque, but at the same time such a winding increases the motor slip and may prevent the motor from pulling into synchronism if the load at this point is high. Such a condition would require a low-resistance starting winding.

Synchronous Speed

All synchronous motors must have 92 to 96 per cent synchronism, depending somewhat on the flywheel effect of the load, before the field excitation can be put on. If the excitation is applied below this speed the motor fails to pull into synchronism and either shuts down entirely or runs along at a reduced speed, taking a heavy fluctuating current. In some cases additional torque near synchronism can be obtained by short circuiting the field winding through the field rheostat. This has the effect of reducing the resistance of the motor winding to some extent and causing the motor to have less slip with a given load. The gain from this source is small, however, in most cases, as the self-inductance of the field winding is so high as to allow very little current to flow, even if the field is dead short circuited, so that the total effective resistance of the rotor winding is not materially reduced. In some cases, where the torque is nearly sufficient, however, enough may be gained to take care of the conditions. If the field is short circuited before the motor is started, there will be a reduction in starting torque and an increase in current from the line, so that, if this method is resorted to, arrangements should be made to short circuit the field after the motor has come to constant speed.

It often occurs, when the motor has reached synchronous speed and the direct current excitation has not been previously applied, that when it is excited by direct current, the poles will not be in the proper position relative to the stator conductors. If the direct current excitation is increased sufficiently, the rotor will "slip a pole," and then, the poles being in the proper relative position, the rotor will lock into synchronism. This method of forcing the rotor to "slip a pole" may cause excessive currents to flow in the armature conductors, as it tends to lessen the flux to the stator magnetizing currents, which generate the counter electro-motive forces. However, this condition may be prevented and the desired results obtained by either reversing the polarity of the applied excitation, by slightly loading the machine mechanically, or by disconnecting the motor from the supply. There is, of course, an even chance that the same polarity may be in the same relative position to the stator conductors.

Incorrect Connections

Incorrect connections usually manifest themselves by unbalanced entering currents and by the fact that the starting torque is very much less than it should be, or perhaps negligible. The circuits should be traced out and the connections remade until the three entering currents in the case of three-phase, or the two entering currents in the case of two-phase, agree approximately. It should be noted that these currents do not agree even with correct connection when the armature is standing still. The reading should be taken with the armature revolving slowly, mechanically, which, with the proper connection, should average up the entering currents.

Failure of Motor to Develop Full Load Torque

The failure of a motor to develop full load torque after having attained synchronous speed is due entirely to failure of excitation.

Exciter failure.—The exciter should be inspected as to whether it is operating satisfactorily.

Open circuit.—This may be the case either in the leads between the exciter and the motor field, or in the connections between the field coils. The majority of the troubles of this nature are generally to be found in the coils themselves. In starting a synchronous motor, a transformer action exists between the armature winding and the field winding, the comparatively large number of turns on the field causing a high voltage to be induced in the field windings, resulting in a breakdown of the same. A field discharge switch and resistance should therefore always be provided with synchronous motors.

Motor Stops under Maximum Load

The maximum torque of a synchronous motor is in proportion to the square of the voltage and over-excitation of the field will also increase it to some extent. If the motor, however, breaks down from excess of load it will not recover when the load is removed, as will the induction motor, but it is necessary to remove the field excitation and start up in the regular way.

Hunting

When synchronous motors are operating in parallel under normal conditions, periodic variations in motive power or load may cause the machines to oscillate in speed. These oscillations, unless opposed in some manner, may become more and more aggravated, until the machines either "fall out of step" or serious line surges occur. One of the most valuable features of the amortisseur winding is its tendency to prevent these oscillations. When the machine is retarded or accelerated, the bars of the winding are cut by the flux. The cutting of the flux produces energy currents in the bars which tend to dampen out these oscillations. The energy that would otherwise be expended in retarding or accelerating the motor is thus absorbed and dissipated.

INDUCTION MOTORS

Failure to Start

No voltage.—No voltage at the motor terminals may be due to blown fuses or breaks in the connections to the motor. See also "Defects in Starting Compensator."

Low voltage.—Low voltage is the most frequent external trouble causing a motor to refuse to start. Since the torque of an induction motor is proportional to the square of the applied voltage, a reduction in the applied voltage has a very great effect upon the starting torque. A low applied voltage may be due to several causes. The motor leads may be connected to too low a voltage tap on the compensator or the voltage drop in the supply circuit may be excessive. In testing for low voltage, measure the voltage at the motor terminals as soon as the motor is thrown on the line. Although the no-load voltage may be all right when the motor is thrown on the line, the heavy starting current taken may pull the voltage down too low, if there is not carrying capacity enough in the transformer windings and the line. In considering the sizes of transformers and lines for induction motors, allowance must be made for the excess in starting current as compared to the running current.

One phase of stator open circuited.—Reading of current can be obtained only in two legs of the three-phase leads if the motor is Y-wound and the motor will not start by itself. In the case of a three-phase delta-wound motor, an open circuit in one phase will result in an open circuited delta, ex-

cited with three-phase current. Such a winding will produce a rotating magnetic field and consequently develop a starting torque, although of smaller value than the normal three-phase torque. If, therefore, the normal starting torque is just sufficient to start the load, the motor will most likely refuse to start when suffering from this defect.

One phase of stator reversed.—The motor will have a greatly reduced torque and probably will not start with any load.

All phases of rotor open circuited.—Motor will not start, and the current taken is the exciting or no-load current. This trouble can be distinguished from blown fuses and open circuits in the stator and leads by connecting an ammeter in the line; if it shows current flowing in each of the phases, the trouble is in the rotor. If there were open circuits in the stator or in the leads, no current would flow in the affected lead.

One phase of rotor open circuited.—Running light, the current taken in the three lines will be practically balanced, but the motor in starting has a decided tendency to remain at half synchronous speed.

Defects in starting compensator.—When a motor will not start, having been connected to a compensator, the cause may be entirely in the compensator. This may have become open-circuited, due to a flash within. The compensator switch may have become deranged, so that it will not close, or a connection within the compensator may have become loosened. Possibly when a motor will not start when connected to a compensator just put into use, a secondary coil may be bucked against another secondary coil within the compensator, so that no voltage is produced by the compensator at the motor. This results in no particular heating which would account for the motor not starting. An ammeter in the motor leads would show the absence of current, or a voltmeter the absence of voltage between the lines.

Starting resistance too high.—A few tests may be made in short-circuiting some of the units in the starting resistance.

Controller troubles.—The motor will sometimes run one way and refuse to start in the other direction. The cause of this is that the contacts on the primary drum touch in one position, but fail to make contact when thrown to the other position. If the motor will not start in either direction and the fuses are all right, set the controller on the first notch and pull out the fuses one at a time, leaving the two fuses of one phase in each time. If the motor hums loudly on each phase, the primary connections are all right, and the trouble must be looked for either in the secondary drum contacts, the collector rings or the wiring.

Excessive load at starting.—This is often the case and can only be remedied by removing some of the load. Excessive bearing friction or too tight belts may often be the cause of this trouble.

Excessive Current at Starting

Voltage too high.—It is often found that a motor is connected to a compensator in such a way that the applied voltage is too high, resulting in an excessive starting current. Compensators are usually supplied with various taps, and one should be chosen which produces the least disturbance on the line, giving at the same time the desired starting torque on the motor.

Wrong connections.—Sometimes a mistake in connection is made on the compensator so that full voltage is used at starting and the lower voltage after throwing over the switch. Thus the motor at starting takes excessive current, and, since the maximum output is in proportion to the square of the voltage, the motor capacity is much reduced when it is apparently running on the operating position.

Overheating and Failure to Carry Load

Voltage too low.—Since the torque is proportional to the square of the voltage it can be seen that lowering the voltage has a positive effect upon the ability of the motor to carry load, and may be the cause of its stopping.

Overload.—The load put on the motor may be more than the designed maximum output. Excessive bearing friction or worn bearings may also be the cause for overloading. For some reason the bearings may have become worn, so that the air-gap at the bottom has gradually so reduced that the rotor commences to rub on the stator. The friction may then become so great that the load represented by it is more than the motor can carry, with the result that it shuts down.

Too frequent starting.—On account of the increased current required, a motor should not be started too often, as this may cause overheating.

Speed too low.—With variable speed motors it is often found that full load is carried on the motor at reduced speeds. This will cause an overheating of the motor unless it is specially designed for this service.

One phase of stator open circuited.—In this case the motor will continue to operate single phase, with a pronounced lack of power.

Short circuit in stator.—A short circuited coil in the stator will cause it to buzz and hum, and if the motor is run for any length of time the coil will overheat and smoke.

Open circuit in Y-connected rotor.—This usually manifests itself by overheating, and if the motor is running under load, the speed will drop considerably, on account of the fact that the rotor is running on single phase, so that only a portion of its winding is operative.

Short circuit in rotor winding.—This will cause an overheating of the rotor, and the short circuits are generally caused by the winding being grounded in two places.

Unbalanced voltages.—The maximum output can be seriously affected by the fact that the voltages applied to the motor are not equal in amount.

Changed voltage.—If a standard induction motor is run on a changed voltage, the heating will vary in accordance with the losses. The copper losses being greater than the core loss results in increased heating at reduced voltage, when operating with the same horsepower output.

Variation of frequency.—An increase in the frequency results in a considerable reduction in the maximum load which an induction motor can carry.

Sparking

The cause of sparking of the collector ring brushes with phase-wound induction motors is generally the high current density therein, caused by an excessive overload. This furthermore causes the collector rings to become pitted, and the brushes to wear away rapidly. Excessive brush pressure may also cause overheating of the collector rings.

Vibration

Vibration may be due to mechanical unbalancing, but this occurs chiefly in high-speed machines and is, as a general rule, easily detected. Loose parts are also often responsible for this defect. When due to an unbalancing of magnetic pull caused by a combination of faulty air-gap and eccentricity of rotor circumference, it may in some cases be remedied by the adoption of a multiple wound stator. It can always be improved by the proper adjustment of the air-gap by "truing up" the rotor.

* * *

The introduction of the motor truck has added a new vehicle for pleasure as well as business. Motor trucks are finding favor with parties bent on straw rides, outings, moonlight excursions, etc. Motor truckmen in some places are able to add substantially to their incomes from these sources. The motor truck may be used all day for hauling goods and all night, if need be, for lighter pursuits with no detriment to its "health," provided ordinary care is bestowed on upkeep. A two-ton truck can comfortably seat eighteen or twenty people and carry them at a rate of ten or twelve miles an hour, and a trip of twenty miles into the country and return can be easily accomplished in five hours. A charge of a dollar a head yields good pay for the service.

* * *

A hard solder of low fusing point that is used extensively by one of the largest electrical companies, is composed of 34.36 per cent copper; 49.24 per cent silver; and 16.40 per cent zinc. Borax is used as a flux.

A NEW ZEALAND SCHOOL WORKSHOP

SOME EXAMPLES OF WORK DONE BY STUDENTS IN THE ANTIPODES

BY JOHN PEDDIE*

Readers of Mark Twain's "A Tramp Abroad" no longer labor under the delusion that New Zealand is somewhere close to Australia and that you cross to it by a bridge. Another delusion which is not quite dispelled, however, is that New Zealand is a new country, inhabited by savages and backwoodsmen, among whom the industrial problems of the older countries are unknown. New Zealand has industrial problems of the same kind that afflict older countries, and is trying to solve them in much the same way, *i. e.*, by the erection and equipment of technical schools and colleges, where special education is given to young people of both sexes to fit them for various trades and professions.

Fig. 1. Examples of Students' Work in Toolmaking

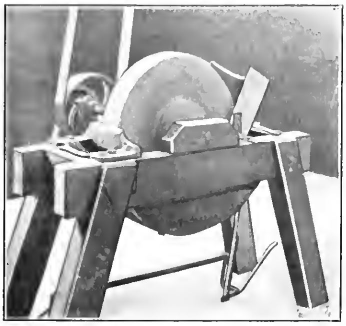

Fig. 2. Grindstone Frame made in Woodworking Shop

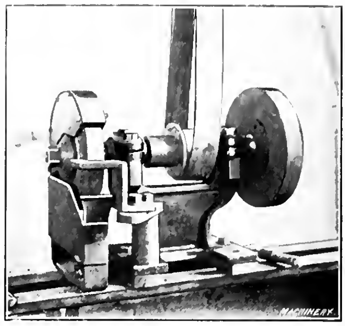

Fig. 3. Grinder Head built in a New Zealand School Workshop

It is the purpose of this article to deal with the practical workshop instruction given in the Christchurch Technical College to youths who propose to follow the engineering or machinist trade. In addition to the work to be described, day school pupils receive instruction in patternmaking and blacksmithing. Free evening pupils take one lesson of two hours per week in the workshop and are also required to take two other subjects per week in the classroom. These subjects comprise English, shop mathematics, mechanics and mechanical drawing. As regards practical instruction given in the workshop to evening students, who are mostly apprentices to the machinist trade, it ought to be remembered that the whole time actually available in one year amounts to only seventy hours, or less than a fortnight's full time in a shop. When this fact is kept in mind, an unprejudiced observer will probably admit that the majority make surprising progress.

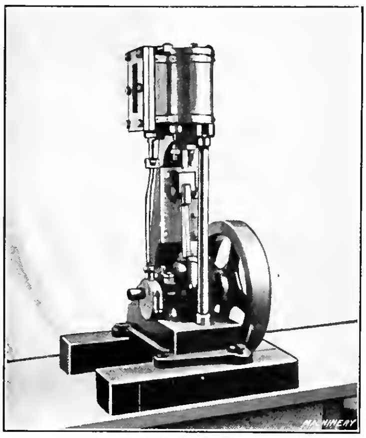

Fig. 4. Small Steam Engine built by Students

We do not claim that in such a length of time we are able to give instruction in a great variety of processes nor can we allow the student to spend sufficient time on any one process to gain great manipulative skill. Neither, on account of the number who are receiving instruction at one time, can each individual be given as much attention as would be beneficial. The cost of the classes would be regarded as prohibitive if the numbers were kept low enough to admit of this. But we find apprentices coming to us in order to learn processes which they are afforded no opportunity of learning in the workshop where they are employed. Some are being kept entirely on fitters' work and wish to gain some familiarity with machines. Some are getting plenty of practice in plain turning and boring and would like to learn to cut screw threads or turn and bore tapers. Some have devices of their own which they wish to perfect, and if these appear to be practical, every facility is afforded for bringing them to a successful issue. The writer is of the opinion that the value of any exercise depends greatly on the interest it excites in the student. For this reason the mere fact of a student wishing to devise and construct any tool or apparatus is a good reason for allowing him to do it. If, in addition, a class of workmanship suitable for the project is insisted on, considerable educational value is secured.

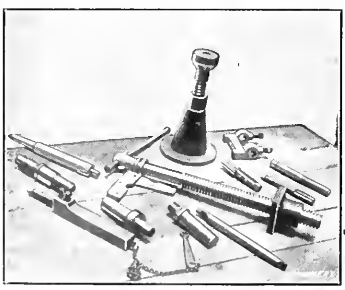

Fig. 5. Examples of Lathe and Vise Work

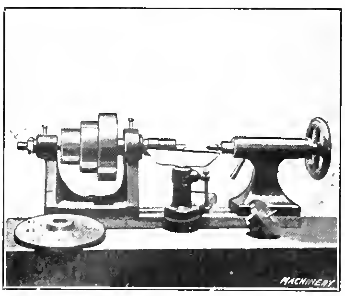

Fig. 6. Lathe Heads built by Students

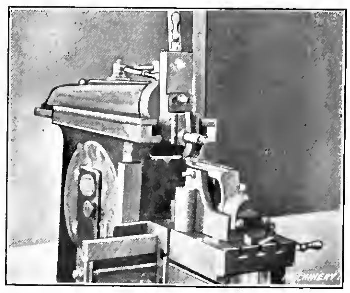

Fig. 7. Fixture made for planing Lathe Heads

It is a striking fact that the founders of the most successful engineering firms of the world have started in life as fine ingenious workmen. Their chief characteristic has been a love of working with and thinking about the tools and machines which they so successfully produced. In general, their purely scholastic attainments have rarely been worth recording. Dr. Smiles in his introduction to the life of Brindley observes in this connection: "Nor did any of the great mechanics who have since invented tools, engines, and machines, belong to the educated classes. They received no college education. Some of them could scarcely write their own names. But where learning failed natural genius triumphed. These

* Address: Technical College, Christchurch, New Zealand.

men gathered their practical knowledge in the workshop or acquired it in manual labor. They rose to celebrity chiefly through their habits of observation, their powers of discrimination, their constant self improvement, and their patient industry."

The writer quotes the preceding to emphasize the importance of the workshop as a training school for mechanics, not with the view of depreciating theoretical training. The great mechanics mentioned by Smiles would no doubt have been still greater mechanics if they had had a college education, unless that education had been of such a nature as to paralyze their natural powers. Again, it should not be the purpose of such a school as this merely to produce skillful submissive drudges to be employed by the employing class. If it does not tend to develop intelligent, resourceful men, who are well informed regarding matters related to their trades, the work of the school can hardly be called complete. It is to be regretted that many employers simply demand a supply of human machines, possessing all the gifts and none of the failings of the human family, and because they do not often get them they talk loudly of inefficiency. If you look up past records of the engineering profession back to the days of Boulton and Watt, you will find that the most notable characteristic of the workman has been his inefficiency.

Many boys who go through the engineering course in the day school do not take up that profession on leaving. While some might claim that the special training they have received has therefore been wasted, many educational authorities maintain that it is precisely those who do not intend to follow engineering work who derive the most benefit in after life from such a course of study. The writer finds that better work is generally done by day school boys than by older lads in the evening classes who are engaged as apprentices with the various engineering firms in the city. This is no doubt owing to the class of work that is given to the apprentices in the shops, and the scramble for quantity of output. Most of the work shown in the accompanying illustrations has been done by day school boys.

Fig. 1 shows a set of exercises (mostly hand tools) made by day school boys during a two years' course. Each boy in addition to making these tools will have done a considerable amount of lathe work on jobs for school use. Examples of the latter kind may be seen in Figs. 2, 3, 4 and 10, which show a grindstone stand, a grinder head, a steam engine and a shear, which have been entirely made by students. The grindstone frame was made by boys in the building class. Water is applied to the stone by depressing the foot lever, which raises a pan till the water reaches the stone. Fig. 5 shows various samples of lathe and vise work. When a student has learned to cut screw threads on a practice piece, he generally makes something of actual use, as indicated by the screw jack, vise screw, threaded mandrels, etc. The screw shown to the left of the picture is for a hand drilling machine and has a hole bored through its length by the aid of the center rest. Several counterbores and boring tool holders like the ones shown have been made by the students.

Fig. 6 shows a pair of lathe heads for wood-turning, of which several sets have been made for use in the school. Several special fixtures and tools were made for producing these heads. For planing the heads, the fixture shown in Fig. 7 was made. The heads are located in this fixture by a recess in a clamp member which fits over the bearing boss at each end of the head. A cylinder which serves to align the bearings with the tongue on the base of the head-stock is shown on the table. The head is tightened up in the fixture by set-screws at the end, and a set-screw at the top of the fixture serves to take up side play. The top of the fixture is used to adjust the tool for height, and the width and location of the tongue is found by one or two metal gages.

Fig. 8 shows a fixture that was made for use on one of our lathes on which the heads were bored. This fixture is clamped in the cross-slide groove, the heads being scraped to fit the slot in the fixture. This rig is easy to set up when wanted. The boring-bars shown beside it were also made by students and afforded good practice in filing slots and fitting, as well as hardening and tempering the cutters.

A surface gage designed by the writer for boys to make is shown in Fig. 9. The fine adjustment is obtained through the spring. The making and tempering of this spring, forging the small bracket for the clamping head, and fitting and riveting it affords quite a variety of exercises. Many creditable tools of this type have been made, though the style shown in the group in Fig. 1 is perhaps more serviceable. Up to the present time, we have not had a milling machine, but now a No. 1 B. & S. universal is being installed as well as a Norton cutter and reamer grinder.

ARE IRON AND STEEL CHIPS COMBUSTIBLE?

BY JOHN A. GRAHAM*

I read with interest the description of a burning pile of steel chips in the October number of MACHINERY, but I do not agree with the writer's statement that the steel burned. It was stated in the article that the chips were passed through a centrifugal separator to remove the oil, but it must be remembered that this operation removes only the excess oil, and that the chips on leaving the machine are by no means absolutely dry; there is still a very thin film of oil remaining on them.

Bearing this fact in mind and the fact that the chips are very finely divided, it will be understood that the amount of oil contained in a large pile of chips is considerable, and on account of the porosity of the mass it will contain almost sufficient air to provide for the complete combustion of the oil. The sinking of the pile was no doubt caused by the crushing of the spiral or tube-like form of the chips, which naturally followed when the mass became heated.

Another point not to be overlooked is the fact that iron, when burning, absorbs oxygen; 56 pounds of iron requires 24 pounds of oxygen to form 80 pounds of ferric oxide. This reaction is accompanied by a large increase in volume. What would Mr. Rushmore think if he saw that pile of chips not only "burning" but increasing in size as it burned? Inasmuch as he does not state that he found any iron oxide after the fire, it is evident to me that it was not the iron that burned but the oil adhering to the chips.

STEAM POWER PLANT PIPING DETAILS—7*

PROVIDING FOR EXPANSION AND CONTRACTION STRAINS IN PIPING SYSTEMS (Continued)

BY WILLIAM F. FISCHER†

In Fig. 52 is shown a cross-sectional view of what is known as a standard-traverse unbalanced expansion joint of the slip type, and Fig. 53 shows what is known as a balanced expansion joint of the slip type. These expansion joints are manufactured by the Pittsburg Valve Foundry & Construction Co. and are made in all sizes to match standard steam pipes up to 24 inches in diameter, and for working steam pressures up to 250 pounds per square inch.

The expansion joint shown in Fig. 52 is known as an unbalanced joint because the steam pressure is unbalanced and acts at each end of the joint in a direction opposite to the arrows *X* and *Y*, tending to pull the joint apart and separate sleeve *B* and hub *C*. In order to prevent the joint from being pulled apart by the steam pressure, bolts *E* are attached to hub *A* and allowed to slide freely through holes drilled in the flanges of hub *C* and gland *D* as indicated. A nut on the end of each bolt prevents the joint from being pulled apart under pressure. This type of expansion joint consists simply of a cast-iron hub *A* into which is screwed a smooth finished brass tube or sleeve *B*, which, in turn, slides freely through a packed, steam-tight joint in the cast-iron hub *C*.

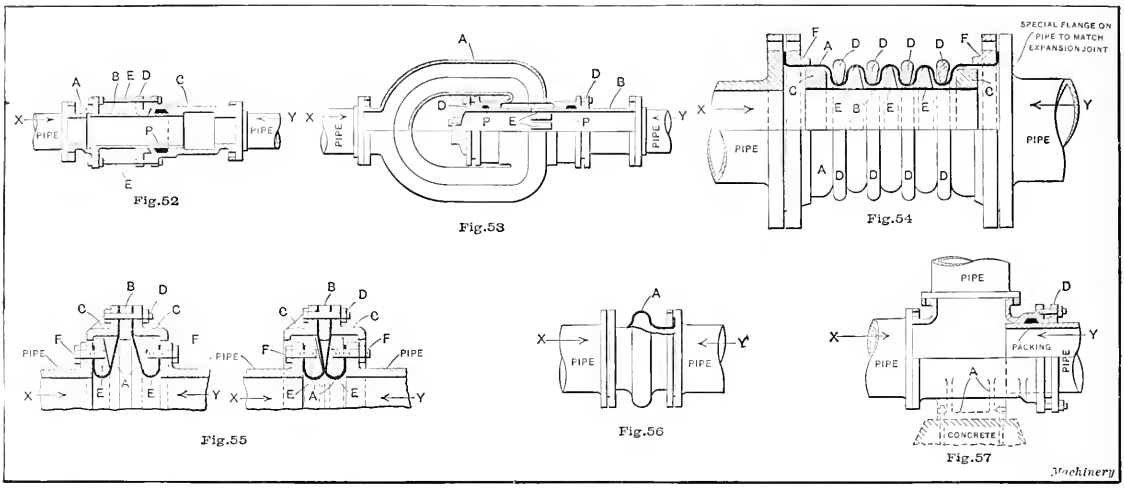
The steam packing *P* is compressed by screwing down the packing gland *D* until the joint is sufficiently tight to prevent the leakage of steam through the packing. When the steam main expands in the direction of the arrows *X* and *Y*, the sleeve *B* slides through the packed joint in *C*, thus relieving the expansion strains on the piping system.

With the balanced type of expansion joint shown in Fig. 53, there is no danger of the joint being pulled apart due to the pressure of the steam, as the construction is such that the steam pressure is balanced. This is accomplished by passing the sliding sleeve *B* through the joint and packing each end of the cylinder steam tight, as shown at *P*, thus preventing the pressure from separating the members *A* and *B*. The packing is compressed by screwing down the glands *D*. By studying the illustration, it will be seen that if blind flanges were attached at each end of the joint and steam was admitted to the joint, the pressure of the steam acting against the flanges at each end would have no tendency to pull the joint apart. The sleeve *B* is made to slide freely through chamber *A*, thus relieving the expansion and contraction strains in the piping system. The rectangular holes *E*, in sleeve *B*, provide for the passage of the steam from one section of the expansion joint to the other depending upon the direction of the steam flow.

With this type of expansion joint there is less danger of the sleeve binding in the joint than there is with the unbalanced type shown in Fig. 52.

Slip expansion joints are sometimes used for high pressure work where sufficient space is not available to accommodate a long radius expansion bend. Where it is possible to use them, however, expansion bends should always be given the preference. The Wainwright improved expansion joint, shown in Fig. 54, is manufactured by the Alberger Condenser Co. With this type of joint, the compactness of the slip expansion joint is secured without the necessity of providing stuffing-boxes, which, unless properly cared for, are apt to leak and cause more or less trouble.

This type of joint, known as a corrugated joint, is made for both low pressure and vacuum exhaust mains, and also for high pressure steam mains. For low pressure and vacuum exhaust mains the joint consists simply of a main corrugated tube *A* made of soft wrought copper, two flanges *F*, and an inner tube *B*, the equalizing rings *C*, *D* and *E* being omitted.



Figs. 52, 53, 54, 55, 56 and 57. Different Forms of Expansion Joints used to take up Contraction or Expansion in Power Plant Piping

The expansion joint shown in Fig. 54 is for use with high pressure steam and consists of a main corrugated copper tube *A*, which is rolled over the face of the connecting flanges *F*, and an inner cylindrical tube *B*, made of brass or hard composition, to the ends of which are attached the rectangular cast-iron rings *C*. The triangular shaped cast-iron equalizing rings *D* and *E* are provided to limit the movement of the corrugations in any one section, and thus cause each of the corrugations to take up its share of the travel and prevent the expansion strains from falling on any one corrugated section of the outer tube.

The inner equalizing rings *E* are made to slide freely on the inner tube *B* as the joint contracts or expands. The outer equalizing rings *D* also act as reinforcing rings which assist in holding high steam pressures as well as equalizing any movement of the corrugated sections. The construction of this joint is such that it can be readily covered with non-conductive pipe covering material by first placing two overlapping tubes of sheet iron over the outer rings of the joint and then applying the covering over these tubes in order to provide free movement of the corrugated sections without danger of breaking up the covering as the pipes expand or contract.

* The sixth installment of this series was published in the September number of MACHINERY.

† Address: 3959 Fulton Ave., Woodhaven, L. I.

The expansion joint shown in part section in Fig. 55 is made by the Central Steam Co. This joint is more compact than most joints of equal traverse and requires no packing of any kind as there are no sliding or rotating parts to be packed tight under pressure.

This expansion joint consists of two annular diaphragms *A* made of heavy annealed copper, which are clamped at their outer edges between the inner cast-iron stop ring *B* and outer stop rings *C*; the diaphragms are clamped at their inner edges between the backing rings *E* and the flanges of the pipe to which the joint connects. The inner edges of the diaphragms *A* are rolled over the outer face of the backing rings *E* as shown in the illustration, and firmly secured by bolts *F*. Lips cast on the outer edge of the stop rings *C* prevent the joint from being pulled apart due to the pressure in the steam main. In operation, the joint is placed in the line with the backing rings *E* drawn out as far as the stop rings *C* will permit as shown at the left-hand side in Fig. 55. As the steam main expands, the backing rings *E* and diaphragms *A* are forced toward each other in the direction of the arrows *X* and *Y*, the joint being shown at the end of its traverse at the right-hand side of Fig. 55. When the pipes begin to expand, the weakest diaphragm acts first until the outer edge of the backing ring *E* comes in contact with the inner edge of stop ring *C* which stops its travel, thus causing the other diaphragm to act in a similar manner and take up its part of the travel.

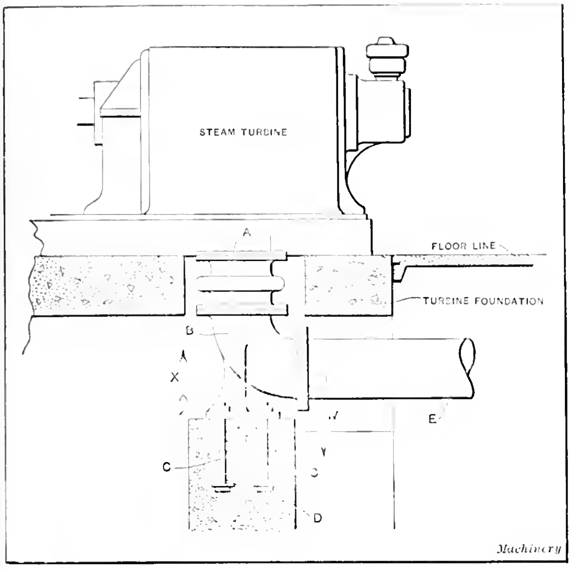


Fig. 58. Arrangement of Expansion Joint between Turbine and Condenser

The diaphragms of these expansion joints are made without corrugations and the joints are so constructed that the maximum bending of the copper diaphragms *A* at any point, due to change of position, will not exceed ten degrees. The backing rings *E* are made of finished cast iron, thus presenting a smooth unbroken surface to the copper diaphragms. Joints of this type are largely used for underground heating mains and are made in several different types to suit the service for which they are required.

The expansion joint shown in Fig. 56 is for use on short exhaust mains, and is used quite extensively on vacuum exhaust mains, being placed between the steam turbine or engine and the condenser, as shown in Fig. 58. This joint consists of a corrugated copper tube *A* of practically the same inside diameter as the exhaust main, and two loose ring flanges. The corrugated copper tube is rolled over the inner faces of the ring flanges and is firmly clamped between the flanges of the expansion joint and the flanges of the pipe or fittings to which they connect. This joint, having but one corrugation, is not as well suited for use on long exhaust mains as the types previously described. For long exhaust mains, where considerable expansion has to be taken care of, the number of corrugations should be increased so that all of the bending is not thrown on a single corrugation. Very long exhaust mains, when served by a single expansion joint of the type shown in Fig. 56, are apt to cause considerable bending action on the corrugated section of the joint, which, in turn, is very apt to cause the copper to crystallize and break in service. For long exhaust mains a type of expansion joint having a number of reinforced corrugated sections, similar to that shown in Fig. 54, is better suited to the service, as the bending action is more or less uniformly distributed over a number of corrugated sections instead of being concentrated on a single one.

The expansion tee, shown in Fig. 57, provides another means of caring for expansion and contraction in exhaust mains. The tee shown in the illustration is arranged with a stuffing-box and gland at one end through which the pipe moves as the steam main expands or contracts. These tees are only made to special order, and may be obtained with a stuffing-box and gland at each end, if so desired. In a case of this kind it is advisable to provide a ribbed base flange on the tee, opposite the outlet flange, as shown at *A*, the base flange being anchored to a concrete pier or other suitable support.

Caring for Expansion and Contraction in Steam Turbine Exhaust Mains

Fig. 58 shows a common method of arranging the exhaust main leading from a steam turbine to the steam condenser, when the turbine is provided with a bottom exhaust outlet as shown.

The corrugated copper expansion joint *A* is connected direct to the exhaust flange of the turbine and to the flange of the base elbow *B*. The elbow *B* is anchored to concrete pier *D* by means of the anchor bolts *C*.

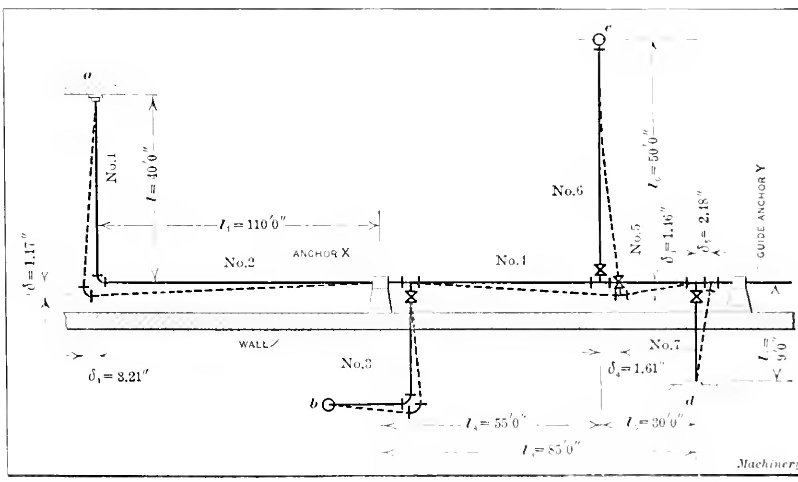

Fig. 59. Layout of Piping illustrating Method of calculating Stresses due to Expansion

Pipe *E* leads to the condenser, which is not shown in the illustration. It is also advisable to install an expansion joint in the horizontal exhaust main *E*, as the expansion joint *A* only takes care of the expansion in the vertical line. Owing to the small clearance space usually allowed between the rotating blades and the casing of a steam turbine, the exhaust mains should always be equipped with an expansion joint between the turbine and exhaust pipe in order to pre-

vent expansion strains in the piping system from being transmitted to the turbine casing. In vacuum exhaust mains, the pipe or fittings beyond the expansion joint should be securely anchored in such a manner as to prevent the pipe from being raised bodily against the expansion joint and crushing it.

The necessity of anchoring vacuum exhaust mains will be better illustrated by the following example. Assume the vacuum exhaust main shown in Fig. 58 to be 36 inches inside diameter, leading direct to a condenser which operates under a vacuum of 28 inches, as recorded on a mercury vacuum gage. A column of mercury approximately 2 inches high will exert at its base a pressure of one pound per square inch. Therefore 28 inches of mercury is equivalent to a pressure of $28 \div 2 = 14$ pounds per square inch, and the condenser is working under a pressure of $15 - 14 = 1$ pound absolute, or approximately 14 pounds lower than atmospheric pressure. In other words, the pressure of the steam flowing through the exhaust main and elbow *B*, Fig. 58, is approximately 1 pound (absolute) per square inch, while the pressure of the surrounding atmosphere is approximately 15 pounds per square inch (absolute), depending upon the altitude. This leaves an unbalanced pressure of $15 - 1 = 14$ pounds acting on each square inch of outside surface of the exhaust main. This unbalanced pressure tends to lift the base elbow *B* bodily (in the direction of arrow *X*) and crush the corrugated expansion joint *A*.

The internal cross-sectional area of a 36-inch inside diameter pipe $= 36 \times 36 \times 0.7854 = 1017$ square inches. Therefore the total pressure tending to lift the elbow and crush the expansion joint $= 1017 \times 14 = 14{,}238$ pounds, which acts upward in direction of arrow *X*. From this, we must subtract the weight of the elbow and exhaust pipe which acts downward, in the direction of the arrow *W*. A 36-inch cast-iron base elbow *B* will weigh, on an average, about 2200 pounds. Assuming the length of the horizontal exhaust pipe to be 10 feet, it will weigh in the neighborhood of 4000 pounds, one half of which will be supported by the condenser and the other half (2000 pounds) by the concrete pier *D* (Fig. 58). From the preceding, we find the weight of the base elbow and exhaust pipe acting downward, in the direction of the arrow *W* to be $2200 + 2000 = 4200$ pounds. Subtracting this from the upward pressure of 14,238 pounds we find $14{,}238 - 4200 = 10{,}038$ pounds to be the pressure tending to crush the expansion joint.

In this case, in order to prevent the joint from being crushed, it is necessary to add sufficient weight to concrete pier *D* to hold the elbow down. This means that the weight of concrete pier *D* should be in excess of 10,000 pounds to be safe, say 15,000 pounds. As concrete weighs about 150 pounds per cubic foot we require about $15{,}000 \div 150 = 100$ cubic feet of concrete in pier *D*. Assuming the pier to be 4 feet square at the top, the depth required would be $100 \div (4 \times 4) = 6$ feet approximately. Assuming that four anchor bolts *C* are used to anchor the elbow to the pier, the size of the bolts required should not be less than 3/4 of an inch in diameter, or if two bolts are used, they should be 1 1/8 inch in diameter. The anchor bolts should project far enough below the top of the concrete pier to prevent them from pulling out or shearing through the concrete, and they should be provided at the end with suitable steel or cast-iron washers, to distribute the load over a sufficient area to accomplish the desired results. The concrete pier shown in Fig. 58 may be omitted, if so desired, and steel channel irons or I-beams built into the turbine foundations to support the weight of the piping and at the same time prevent the elbow from being raised against the expansion joint, by enabling the base elbow to be anchored to the steel work.

In one case that came to the writer's attention, a base elbow in a vacuum exhaust main supported on a concrete pier, as shown in Fig. 58, was raised against the expansion joint and crushed it. The concrete pier was pulled up bodily with the elbow. Calculation showed the concrete pier to be very much lighter than would be required to hold the elbow down against the unbalanced pressure acting upward. It is always advisable in designing a case of this kind to be certain that proper weight is allowed and to see that the elbow is properly anchored against the uplifting pressure of the atmosphere.

Calculating the Bending Stresses in a Piping System due to Expansion

To calculate the exact stresses and deformations that take place in a steam main due to expansion and contraction of the different branches of the piping system would be a difficult and rather tedious operation. In the first place, the different branch pipes of the system are, as a rule, of varying lengths and do not always lie in the same plane, in which case shearing, tensile, compressive, bending and torsional stresses are frequently developed in certain branches of the system. The tensile, shearing, and torsional stresses developed are, as a rule, very slight and in all ordinary cases they may be neglected entirely. Direct compressive stresses of any magnitude are only developed when the pipe is anchored at two points close together in such a manner as to prevent the pipe from expanding (See the fifth installment of this article, August, 1913). Bending stresses are developed in almost every branch of a steam piping system, however, as will be shown by the following and should therefore be considered in the design of the piping system.

As an example showing the approximate bending stresses caused by expansion of the different branches of a piping system, consider the branch pipes Nos. 1, 3, 6 and 7 in Fig. 59 to be rigidly connected at points *a*, *b*, *c* and *d* respectively, to the flanges of the units which they serve. Also consider the main steam header to be rigidly anchored to the wall at the point *X*, and supported by a guide anchor at point *Y*, in such a manner that the pipe is permitted to slide freely through the guide. In this case, when steam is turned into the piping system, the expansion of the branch pipes, and the main header, will cause the whole piping system to deflect and assume the position shown by the dotted lines (Fig. 59). The expansion of branch pipe No. 1 causes branch No. 2 to deflect at the end an amount δ. At the same time, the expansion of branch pipe No. 2 causes branch pipe No. 1 to deflect an amount δ_1 as shown by the dotted lines and the figures in the illustration. As the main header is anchored rigidly at point *X*, we will, in this case, ignore the expansion of branch pipe No. 3, as the expansion and deflection in this branch of the system are calculated in exactly the same manner as that for branches Nos. 1 and 2. Next we have the expansion in branch pipe No. 4 which causes branch pipe No. 6 to deflect at the end an amount δ_4. At the same time, the expansion of branch pipe No. 6 causes branches Nos. 4 and 5 to deflect an amount δ_3, this deflection reaching a maximum at the intersection of the branch pipes Nos. 4, 5 and 6. Furthermore, the expansion of pipes Nos. 4 and 5 causes pipe No. 7 to deflect an amount δ_5, all as shown, greatly exaggerated, by the dotted lines in Fig. 59. The next thing to determine is the expansion of the different branches of the piping system, in order that we can determine the deflection at the different points, as shown by δ, δ_1, δ_2, δ_3, δ_4 and δ_5.

Assume the pipe to be of wrought iron, erected during the winter months at a temperature of 40 degrees F. and to be conveying saturated steam at approximately 200 pounds gage pressure, after erection.

By the aid of Table II (See the fifth installment, August, 1913) we find the expansion of the different branches of the piping system to be as given in Table VIII.

Having found the deflection of the different branches of the piping system, let us consider the resulting bending stresses produced in the different branches of the system. For ordinary purposes of calculation, branch pipes Nos. 1, 2, 6 and 7 may be considered as cantilever beams, fixed at one end and deflected at the other end, as shown. Also, pipes Nos. 4 and 5 may be considered as a beam supported at each end and deflected as shown at δ_3. For a cantilever beam fixed at one end and loaded at the other, we have: Greatest deflection δ at the end of the beam:

$$\delta = \frac{f\, l^2}{3\, E\, Y} \qquad (7)$$

from which the extreme bending or fiber stress f in terms of the deflection is given by the following:

$$f = \frac{3\, E\, Y\, \delta}{l^2} \qquad (8)$$

For a beam supported at both ends and loaded with a concentrated load at any point of its length, we have: Greatest deflection

$$\delta = \frac{f}{27\, E\, Y} \times \sqrt{3 l_2 \; (2l - l_2)^3}. \qquad (9)$$

from which the extreme bending or fiber stress f in terms of the deflection is:

$$f = \frac{27\, E\, Y\, \delta}{\sqrt{3 l_2 \; (2l - l_2)^3}}. \qquad (10)$$

where l = length of beam in inches, between points of support.

E = modulus of elasticity of piping material, in pounds = approximately 29,000,000 for steel pipe.

f = extreme fiber stress in pounds per square inch.

Y = distance in inches from neutral axis of beam to the most distant fiber $= \frac{\text{outside diameter of pipe}}{2}$

l_2 = greatest distance in inches from either point of support to concentrated load.

Assuming all of the pipe shown in Fig. 59 to be 8-inch standard pipe, 8⅝ inches outside diameter, we have (Formulas (7) to (10) inclusive), $Y = 8.625 \div 2 = 4.313$ inches. Taking the modulus of elasticity E as 29,000,000 and substituting in the formulas the various lengths in inches, we find the extreme fiber stresses due to bending, to be as follows:

TABLE VIII. DEFLECTION OF PIPING DUE TO EXPANSION

Branch Pipe No.	Length of Pipe in Feet multiplied by Expansion Constant		Expansion in Inches		Deflection	Branch Pipe No.
1	40 × 0.0292*	=	1.17	=	δ of	2
2	110 × 0.0292	=	3.21	=	δ_1 of	1
4	55 × 0.0292	=	1.61	=	δ_4 of	6
4 and 5	85 × 0.0292	=	2.48	=	δ_5 of	7
6	50 × 0.0292	=	1.46	=	δ_3 of	4 and 5

Machinery

* Constant 0.0292 is found in the tenth column of Table II, opposite 40 degrees F. initial pipe temperature

Extreme fiber stress in the outermost fibers of pipe No. 1 due to bending $= f_1$, and from Formula (8):

$$f_1 = \frac{3\, EY\delta_1}{l^2} = \frac{3 \times 29{,}000{,}000 \times 4.313 \times 3.21}{(12 \times 40)^2} = \frac{1{,}204{,}491{,}510}{230{,}400} = 5230 \text{ pounds per square inch.}$$

Extreme fiber stress in the outermost fibers of pipe No. $2 = f_2$:

$$f_2 = \frac{3\, EY\delta}{l_1^2} = \frac{3 \times 29{,}000{,}000 \times 4.313 \times 1.17}{(12 \times 110)^2} = \frac{439{,}020{,}270}{1{,}742{,}400} = 252 \text{ pounds per square inch.}$$

Extreme fiber stress, pipe No. $6 = f_6$.

$$f_6 = \frac{3\, EY\delta_4}{l_6^2} = \frac{3 \times 29{,}000{,}000 \times 4.313 \times 1.61}{(12 \times 50)^2} = \frac{604{,}121{,}910}{120{,}000} = 5034 \text{ pounds per square inch.}$$

Extreme fiber stress, pipe No. $7 = f_7$:

$$f_7 = \frac{3\, EY\delta_5}{l_7^2} = \frac{3 \times 29{,}000{,}000 \times 4.313 \times 2.48}{(12 \times 9)^2} = \frac{930{,}572{,}880}{11{,}664} = 80{,}000 \text{ pounds per square inch, approximately.}$$

If pipe No. 7 were 8 feet long instead of 9 feet, as shown, the extreme fiber stress would be $\frac{3 \times 29{,}000{,}000 \times 4.313 \times 2.48}{(12 \times 8)^2} = \frac{930{,}572{,}880}{9216} = 100{,}970$ pounds per square inch, in either case sufficient to cause rupture of the piping material.

The allowable safe fiber stress on piping material of wrought iron or mild steel may be taken as 12,000 pounds per square inch, allowing a factor of safety of 5 for the strength of the material. Therefore, all stresses falling below 12,000 pounds per square inch may be considered safe, while stresses above 12,000 pounds per square inch should be considered unsafe.

In the preceding examples, the bending stresses falling on branch pipes Nos. 1, 2 and 6 would be considered well on the safe side, as they fall below 12,000 pounds per square inch. The bending stresses of 80,000 pounds per square inch falling on branch pipe No. 7 should be considered unsafe, as it exceeds the breaking strength of the material. In this case, the piping connection should be changed and proper provision should be made to relieve the strain at this point; otherwise the pipe flanges would be very apt to fail and cause considerable damage to the plant.

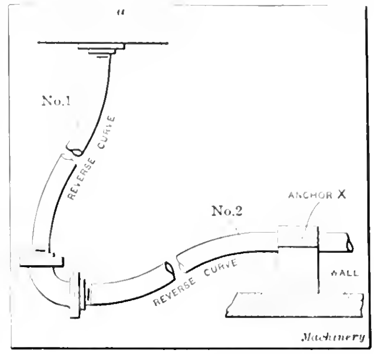

Fig. 60. Actual Condition of Pipes Nos. 1 and 2 when bent by Expansion

Considering pipes Nos. 4 and 5 as a beam 85 feet long supported at each end and deflected as shown by δ_3, we find by the aid of Formula (10) the extreme fiber stress in the outer fibers of the 8-inch pipe to be:

$$f_4 = \frac{27\, EY\delta_3}{\sqrt{3 l_4\, (2\, l_3 - l_4)^3}} = \frac{27 \times 29{,}000{,}000 \times 4.313 \times 1.46}{\sqrt{3 \times 660 \times (2 \times 1020 - 660)^3}} = \frac{4{,}932{,}900{,}000}{2{,}281{,}136.24} = 2162 \text{ pounds per square inch.}$$

The preceding examples are all worked out for 8-inch pipe. For any other size of pipe the conditions would be the same except that the value of Y would be increased or decreased in the formula to suit the outside diameter of the pipe. For example, if the outside diameter of the pipe had been 12¾ inches instead of 8⅝ inches, as shown, the value of Y would be $\frac{12.75}{2} = 6.375$ inches. In any case, Y is equal to one half the outside diameter of the pipe in inches.

All of the examples are based on assumptions which are approximate only, but correct enough for all practical purposes. They are intended to give the reader a general idea of the bending stresses liable to be encountered in the different branches of a piping system due to expansion of the pipe and fittings in the line. The exact calculation of stresses and deformations in any branch of a steam main similar to that shown in Fig. 59, would be a very difficult and tedious operation. For example, in the preceding calculations it was assumed, for convenience, that branches Nos. 1 and 2 acted as a cantilever beam fixed at one end and loaded at the other, in which case the pipe would bend in one direction only, as shown by the dotted lines in Fig. 59. In reality, however, the pipe is not free at the end, but is fixed by the flanged elbow which connects pipes Nos. 1 and 2, in which case the pipes would tend to bend to a reverse curve, about as shown in Fig. 60, providing the elbow was sufficiently heavy to resist all bending stresses and retain its original shape as shown. In reality, pipes Nos. 4 and 5 are partly fixed at each end by the fittings to which they connect, but as this would greatly complicate the calculations, the pipes have been assumed to be merely supported at each end, as previously mentioned.

INERTIA OF RECIPROCATING PARTS

BY E. D. GAGNIER*

In bringing the reciprocating parts of an engine to rest at the end of the stroke a force F is developed which is given by the following formula:

$$F = \frac{WDN^2}{70392} \qquad (1)$$

It is frequently desired to know the value of this force in terms of the piston speed and stroke. This result is given by the following formula:

$$F = \frac{WS^2}{1955D} \qquad (2)$$

Formula (2) was derived by combining the formula $S = \frac{DN}{6}$ with Formula (1). In the preceding formulas:

W = weight of reciprocating parts;
F = inertia of reciprocating parts;
D = stroke in inches;
N = revolutions per minute;
S = piston speed in feet per minute.

The diagram presented in this connection gives the inertia of the reciprocating parts for engines with strokes ranging from 5 to 30 inches, operating at piston speeds of from 500 to 1200 feet per minute, as will be seen.

In deriving Formula (1) the weight of the reciprocating parts is considered as concentrated at the crank-pin. The force required to bring the parts to rest is found by the formula $F = \frac{WRN^2}{2933}$. This formula is derived by substituting $\frac{2\pi RN}{60}$ for V in the expression for centrifugal force $\frac{WV^2}{32.16R}$. The stroke in inches (D) is $24R$, R being given in feet. Substituting $\frac{D}{24}$ for R in the expression $\frac{WRN^2}{2933}$ gives the value of the force of inertia of the reciprocating parts F which is given in Formula (1).

PASSING OF MILE FOR ELECTRICAL MEASUREMENT

In the infancy of the electrical industry many units in general practice were naturally used to signify various quantities and conditions of the new form of energy. Many of the available units were not well suited to electrical measurements, because electricity and the various industries to which it has given rise have developed standards which are entirely different from all precedents. It was therefore necessary to devise new units in order to insure a better understanding of the actual conditions and to provide for greater efficiency in the long run. It is undoubtedly because of this early necessity for breaking away from old traditions that the electrical engineering profession has always been among the first to adopt new methods and new units. A pertinent example is the invention and use of the circular mil, which has eliminated π from computations of the cross-sectional area of wires and cables. It now seems probable that the practically universal unit of length, the mile, is to be superseded by a standard of 1000 feet. Tables on costs and prices of wires and cables have been figured on this new basis for some time. Conductor resistance, particularly in the case of copper wire, is now commonly tabulated in ohms per thousand feet instead of in ohms per mile. It is interesting to note in this connection that the Simplex Wire & Cable Co. has recently abandoned the use of one mile as a unit of length for all factory measurements. This applies not only to conductor resistance, but to insulation resistance (megohms per 1000 feet), capacity (microfarads per 1000 feet), and inductance (henrys per 1000 feet). By adopting one thousand feet as the unit of length for all electrical measurements at the Simplex factory and thus eliminating (from about a thousand calculations daily) the factor 5280, an immense amount of figuring is avoided. In comparing the new standard with the mile, a close approximation for general use—involving an error of less than six per cent—is to multiply or divide the mile standards by five. For insulation resistance calculations, at least, a six per cent error is well within the limits of manufacture.

SUB-PRESS DIE FOR PIERCING AND SHAVING

BY A. VAN WAGNER

The blank shown at *A* in Fig. 1, although an innocent looking piece, was nevertheless the cause of considerable work, owing to the high degree of accuracy required. This blank had to be exactly interchangeable with either side up. Two sets of dies were made, *viz.*, a blanking die and a finishing or shaving die, and two sub-presses of the Blake & Johnson type were used. The blanking die was built in the usual manner. An allowance of 0.005 inch was left on all edges of the blank for shaving. The small holes were not pierced in the blanking operation but simultaneously with the shaving operation, as this method minimized the chance of error in locating the holes accurately in relation to the shaved surfaces.

The die for the shaving operation was built in the following manner. The die-plate *B* was made in two hardened and ground sections, inserted in a soft steel receiving holder as shown. By making this plate in two parts, it was possible to grind all surfaces. The large section of the die was first left for truing up with a diamond lap. After hardening, the large circular portion was ground on the master plate. The remaining surface grinding was simple, care, of course, being taken to make all surfaces square and in correct relation to the circular part as well as the piercing hole. The two circular sections *b* were worked up in one piece. The work was first bored and turned; it was then set up on the master plate and the two piercing holes were bored. After placing the part on a mandrel, the slots to receive the tongue pieces *c* were milled, sufficient stock being left for grinding. A wall 1/32 inch thick was left at the bottom of each slot to keep the two parts together until after hardening, which made the circular grinding much easier. After grinding, a thin saucer wheel was used to separate the two parts. The joints on each half were next ground at the same time, while the parts were soldered into a V-block.

The tongue pieces *c* were comparatively easy to make, requiring, of course, careful grinding. The grinding or truing up of the piercing holes was deferred until after the dies were assembled in the press. The five sections of the lower die were next assembled in the soft holder *E* which had been

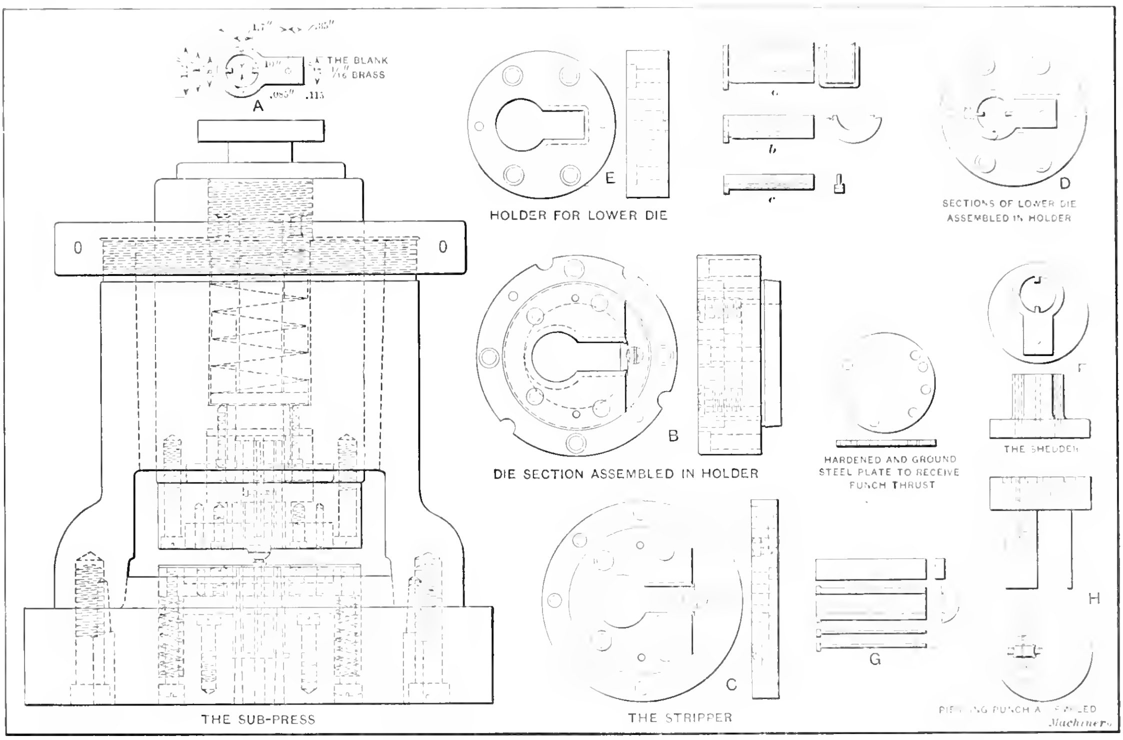

Fig. 1. Sub-press Die for piercing and shaving the Blank shown at A

carefully laid out and the necessary boring and milling done. After hardening the circular portion was first ground on a universal grinding machine. The straight walls were then ground with a saucer wheel on the surface grinder, the intersecting joint for the segment being ground off square at the same setting. Making the segment was a fairly simple job. It was relieved in the corners after milling, to allow for grinding wheel clearance. The two parts were ground on the outside, while held on a solder chuck, to fit the soft receiving holder. The stripper *C* was made in precisely the same manner as the die, corresponding surfaces being machined at the same time.

The punch or lower die, which is shown assembled at *D*, required considerably more work. It was made in five parts which were hardened, ground and lapped all over. The part *a* was rough-planed and then mounted on a master plate in its correct position. The circular portion and the piercing hole were bored on the bench lathe; all the straight surfaces were then milled, 0.005 inch being left on all surfaces with the exception of the piercing hole, where 0.002 inch was carefully bored and slotted. Care was taken that the sections did not fit so tightly as to cause springing of the parts. The shedder *F* was worked up "from the solid," all operations, as far as possible, being performed on the master plate. The piercing holes were left 0.002 inch small until after hardening; then the shedder was set on the master plate and the holes trued with a diamond lap.

The piercing punches are shown in detail at *G*, and mounted in their holder at *H*. The punch for piercing the large circular opening was made in three pieces. The center or spacing section is a plain rectangular shape as shown. The circular outside pieces were first milled to a little over grinding size. Each half was milled out through the center and relieved in the corners for wheel clearance. A screw hole was also drilled through all three parts. An arbor or mandrel was next milled square on each end, one end being the same size as the slot in the sections and the other end the finish size. The outside or circular surfaces were turned on one end of the mandrel, and after hardening the other end was used for grinding. The inner slot to receive the rectangular

section was ground out by holding the parts in a V-block so as to machine them both simultaneously. After assembling the sections in the holder and doweling them, the die work was practically completed.

The sub-press was allowed to run in the punch press for about a day, the bearing being tightened occasionally to insure a permanent bearing of the plunger in the cylinder. The centers of the plunger were then trued and the upper housing or frame was finished to fit the base concentrically. The base was then put on the faceplate and turned to a snug taper fit in the upper frame; at the same time the necessary boring was done to provide seats for the lower die or punch and the stripper plate. The plunger was again faced off and bored to form seats for the die and piercing punch pad.

After assembling the dies in the press, soft shoulder plugs were tapped lightly into the piercing holes in the lower die,

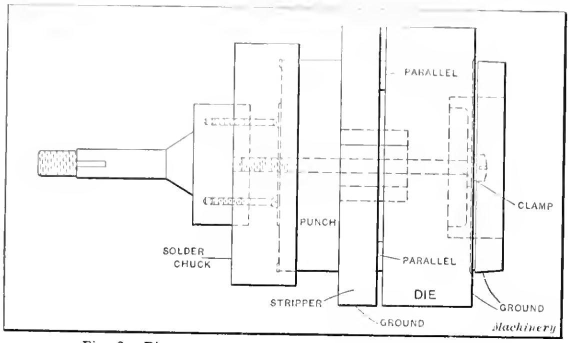

Fig. 2. Dies mounted on Solder Chuck for grinding

while in the corresponding holes in the shedder, hardened and ground shoulder centers were tapped in. The press plunger was then carefully lowered until small center marks were made in the soft plugs; these centers were then indicated on the faceplate and diamond lapped true. The way the dies were ground concentric to insure accurate alignment in the press is illustrated in Fig. 2. A solder chuck was recessed to fit the base of the lower die-holder closely. The stripper and die were then mounted in the manner shown and ground as required.

The gage-plate or "nest" for locating the blanks in the shaving die is shown in Fig. 3. This was dovetailed to 45

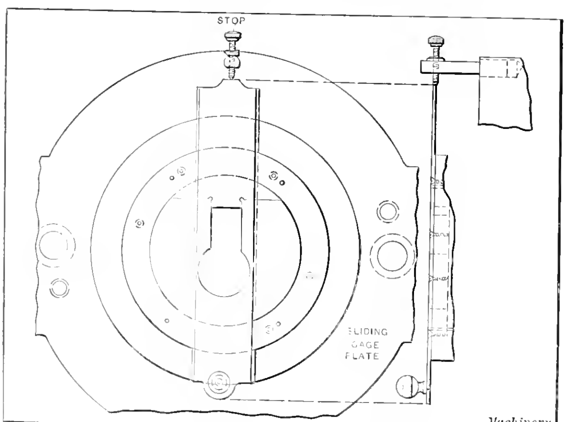

Fig. 3. Sliding Gage-plate of Sub-press Die

degrees and made a good sliding fit in the side plates. This form of gage seemed to be the best, as it is handy to operate and accurate. The time required for making this die was about 350 hours.

Drawings and blueprints which are to be varnished before sending out into the shop may be treated in the following manner: Dissolve gelatin in water and coat the drawing, using a soft brush. After this coating has thoroughly dried, give the drawing a coat of common clear varnish.

IMPRESSIONS FOR BOSSES ON DROP-FORGINGS

BY JAMES CRAN*

"Why are impressions for bosses on drop-forgings preferably put in the upper die?" When the foregoing question appeared in the April number of MACHINERY, the writer refrained from answering, naturally thinking that someone actively engaged in the manufacture of drop-forgings would come forward with the proper solution of the problem. In the writer's opinion, the cause for impressions in the upper dies filling more readily than impressions in the lower dies, is *not* that given by Mr. C. F. Brainerd in the October number.

On the face, especially to laymen, it does seem reasonable to suppose that one side of a heated piece of metal a few degrees hotter than the opposite side would flow more readily into the impression of the die on that side than the metal on the other side. It is very doubtful, however, when we consider that iron or steel to be forged is generally heated to from 1400 to 1800 degrees F., that a few degrees difference between the upper and lower sides of a forging would make a perceptible difference in the filling of the impressions.

To prove the incorrectness of this theory, a piece of lead as cold as the dies may be placed between them and a few blows struck. The result will be that the lead acts exactly the same as a piece of hot iron or steel—it flows better into the impressions in the upper die than into the lower one.

Before proceeding with the problem in question, the writer wishes to have it understood that he is not a drop-forger but that he has had a wide and varied experience in making forgings on the anvil and under a steam hammer; he is thoroughly familiar with the principles of drop-forging and has had ample opportunities for studying the problems that arise from time to time in the working of iron and steel.

The fact that the impressions in upper dies fill more readily than those in lower dies, is due to the reaction of the metal being forged. The potent elements in any kind of forging are force and resistance. In drop-forging the lower die acts as the resistance which meets the force of the falling upper die. It is a well-known fact that all ductile metals respond or react more to a moving body than to a stationary body, especially when the moving body is applied with impact or shock to the metal being forged. The effect of reaction is to cause the metal to flow freely into the upper impressions.

A good illustration of reaction to impact may be had by putting a handle in an ordinary hammer. A mechanic does not think of placing the hammer head over a hole in something solid and driving the handle as he would a fence post, but when he has the handle fitted approximately to the shape of the eye, he starts the handle into the eye while resting on something solid and then takes the handle in his hand with the head clear of everything and strikes it on the end. Thus he drives the handle into the hammer head. The inertia of the hammer head causes it to react on the blows struck on the end of the handle, and the head is forced onto the handle much more quickly and firmly than would be possible if the latter were driven into the head while resting on a solid body.

Another example of reaction may be had by forcing a piece of pipe sharply into a barrel of water. It will be found that the water inside the pipe rises several inches higher than the surrounding water in the barrel. When forgings are made by compression, instead of concussion as in hydraulic forging, the metal acts in a manner very similar to its action in drop-forging. It flows better into the impressions in the dies on the side from which the pressure is applied than into the dies on the stationary side. If, however, the pressure is applied equally from both sides, the dies on each side fill equally.

Very deep impressions in dies fill better when they are provided with air vents, and it will be found that better work can be done in forging long bosses and hubs by using a light hammer with a long stroke than by using a heavy hammer with a short stroke. The reason for this is that a light hammer with a long stroke gathers speed as it descends and strikes a much sharper blow when it reaches the point of impact, thereby causing greater reaction in the metal being forged.

TESTS FOR LEAF SPRINGS AND THEIR TREATMENT*

HEAT-TREATMENT OF SPRING STEEL AND ITS EFFECT ON THE ELASTIC LIMIT, RESILIENCY AND RESISTANCE TO FATIGUE

BY E. F. LAKE†

The automobile industry has justly been credited for a vast improvement in all the materials that enter into its construction. In the steels, several alloying materials have been developed and the manufacturing methods and processes have been improved to give steels greater strength, greater resistance to frictional wear and greater resistance to vibratorial and torsional strains. This has enabled the designer to make various steel parts lighter than when they were made of the weaker materials and, incidentally, it has made it easier to machine some of the high-grade alloyed steels. In the early days of the industry, it was necessary to go to Europe for cylinder castings, but the cast irons and foundry methods have been improved so much that they are now all made in this country. Likewise the steel castings, malleable iron castings, brasses, bronzes and other non-ferrous metals and alloys have been considerably improved. Especially is this true of aluminum alloys, as the demands for lightness in the automobile, and the use of such large quantities of light materials, were directly responsible for the investigations that perfected these alloys and built up this industry.

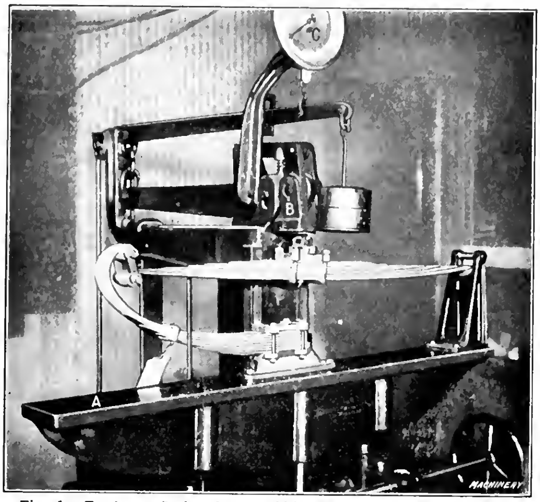

Fig. 1. Testing a Spring for Durability and the Load it will carry per inch of Deflection

In the finished materials, probably the most noted example of a betterment of the product is the gears that are used for the transmission—differential and driving. The strains and wear that these will resist are wonderful when compared with the gears made before the advent of the automobile. While this is partly due to the alloying materials used in the steel and the methods employed in manufacturing the metal, it is due chiefly to the methods, processes and apparatus that are used in annealing, hardening and tempering the gears.

The suspension of automobile bodies, however, has been neglected, as the leaf springs are made in practically the same crude inaccurate way that our fathers, grandfathers and great-grandfathers made them. What little improvement there is has been made with an idea of cheapening the cost of manufacture. Thus, the old coal fires have been replaced by gas-burning furnaces, and the machinery for cutting, punching, rolling, etc., has been improved. With all the scientific and accurate methods that have been developed for heat-treating steels very little of it has found its way into the spring-making shops, and yet the degree of resiliency in springs is entirely dependent upon the accuracy of the annealing, hardening and tempering. If this part of the work were performed with the correct temperatures, the steel could be given the greatest resiliency it is capable of attaining. Only a few degrees variation from the correct temperature, however, will sacrifice a large part of this resiliency and also reduce the metal's elastic limit and resistance to the alternating vibrations that springs receive in service.

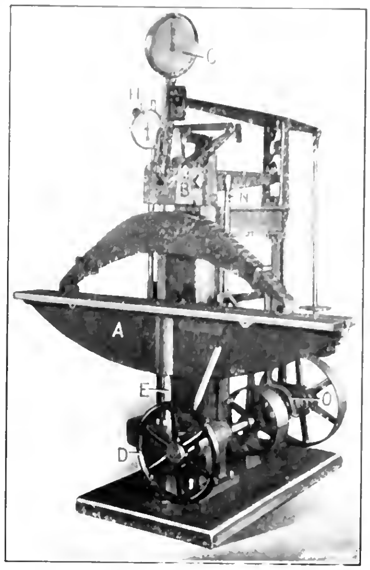

Fig. 2. Static Spring-testing Machine of 20,000 Pounds Capacity

Machines are now being designed and built that enable the large spring users, such as automobile factories, to give springs numerous tests that show whether or not they have been correctly hardened and tempered. This practice is forcing the spring-makers to investigate the furnaces, apparatus and methods that others use for scientifically and accurately heat-treating steel, and, in the end, it will cause a revolution in the methods of manufacturing springs.

Spring Testing Machines

One of the tests now given springs is shown in Fig. 1. The spring is fastened to platen *A* which is raised until the spring presses against the head *B*; then by raising the platen still farther, the dial *C* of the scale beam shows the load (in pounds) that the spring will carry for each inch of deflection or fraction thereof. The fatigue test can also be given

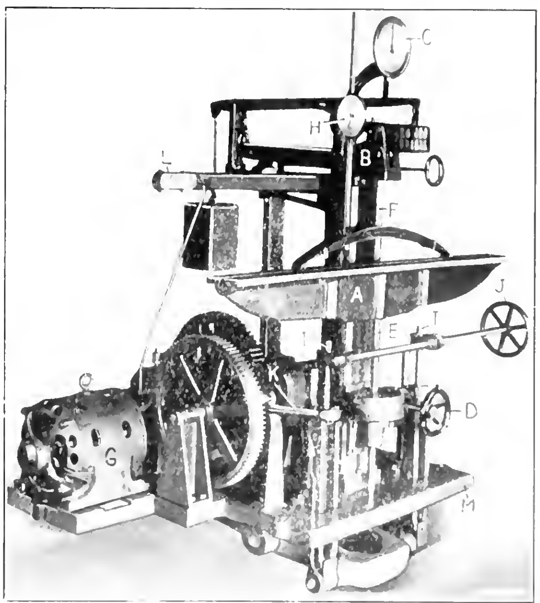

Fig. 3. Static and Vibratory Spring-testing Machine of 6000 Pounds Capacity

the spring by forcing it against head *B* until the normal load it carries when on the motor car is recorded on the dial. After that the machine is adjusted so that the platen will

* For further information on electrical methods of heat-treating steel, see "Electric Furnace Heat treatment of Steel" in the October, 1913, number of MACHINERY, and other articles there referred to.

† Address: 1453 Waterloo St., Detroit, Mich.

move up and down continuously, any given distance, until the spring breaks. The number of deflections, or upward movements of the platen, is recorded on a counter and constitutes the record for the test. The distance that a spring settles from its normal position or shape for a given load can also be measured.

The whole machine, as manufactured by the Tinius Olsen Testing Machine Co., Philadelphia, Pa., is shown in Fig. 3. Here platen *A* can be raised by handwheel *D* and screw *E*, until the spring is brought into contact with head *B*. A control lever that is back of supporting column *F* can also be used to raise and lower the platen with the motor *G*. The forward motion of the lever throws in a clutch for lowering and the backward motion operates another clutch for raising. After the spring is brought into contact with head *B*, the motor power should be used. The amount of spring deflection shows on dial *H* which registers every 0.02 inch, the circumference of the dial being 3 inches. At the same time the load required for this deflection is registered on dial *C* as previously mentioned. The capacity of the machine is 6000 pounds.

The whole spring can be given the fatigue test (after it has been brought into contact with head *B* and the load applied that it would carry when in use) by raising rods *I* with handwheel *J*, until they support the platen, and then lowering screw *E* out of the way. After that the motor is started and a clutch is thrown in by lever *K* that moves the platen continuously up and down at the rate of either 60 or 120 strokes per minute. Counter *L* records these strokes and gives the number of vibrations the spring withstands before breaking. The amount of spring deflection is adjusted by a screw crank at the back of the machine and can be made anything between 0 and 10 inches. The part below base *M* is normally under the floor.

A testing machine of 20,000 pounds capacity, for testing heavy truck springs, is shown in Fig. 2. This gives the load the spring will carry per inch of deflection, but does not subject springs to the fatigue test. It will show whether or not the springs have been correctly hardened and tempered, as improperly heat-treated springs will not deflect the correct distance under a given load. The reference letters correspond to those used in Fig. 3 for similar parts on both machines. This machine can be belt driven if desired. At *N* is shown the lever that engages the clutches at *O* for raising and lowering platen *A*.

Fig. 4. Spring Steel quenched at the Correct Temperature for Hardening

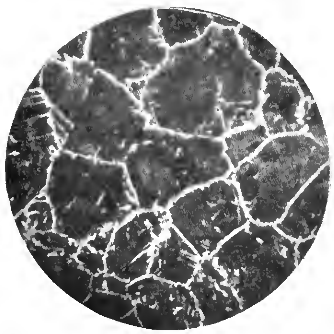

Fig. 5. Structure seen when quenched at 200 degrees F. above the Transformation Point

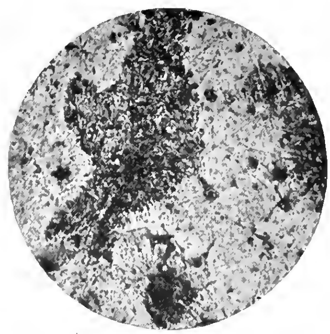

Fig. 6. Spring Steel quenched in Oil that was too Hot

Effect of Hardening Temperature on Composition of Steel

When the plates that comprise a spring have been heated too far above the transformation point, in the hardening operation, it coarsens the grain of the metal and decreases its strength and durability. Such springs will break with much fewer deflections than those that are hardened at the correct temperature. This shows that they will not last nearly as long when put into service on the car.

When the temperature of steel is being raised, it lags at the transformation point, while a new grain structure is being born, and every particle that goes to make up the mass has absorbed all of the heat at this point. After that its temperature will rise steadily to the melting point. If instantly cooled to atmospheric temperature the moment this new grain structure is born, the steel will have the finest and densest grain it is capable of assuming and, consequently, the greatest strength. Each degree of temperature to which the metal is heated above this transformation point and then quenched results in decreasing the strength and resistance to fatigue.

The microscope best reveals such conditions of steel. When heated to the correct temperature and then quenched, the hardened steel will show only a fine-grained structure called martensite, as seen in Fig. 4. The gradual coarsening of the grain when steel is quenched at temperatures above the transformation point is well illustrated by Fig. 5. The temperature of this specimen was 200 degrees F. too high when it was quenched. Distinct demarkations appear between the crystals, and, with a higher temperature, these increase until they become absolute cleavages. Fig. 6 is typical of a steel that was heated correctly but quenched in oil that was too hot. In Fig. 7 will be seen the fine dense grain of a steel that was hardened and drawn correctly.

Fig. 7. Spring Steel that was hardened and then drawn at Correct Temperature

Effect of Hardening Temperature on Fatigue Tests

The loss in fatigue is best illustrated by the chart shown in Fig. 8. Here fifteen samples of spring stock were hardened at each of the temperatures shown at the right, and they were all tempered at 700 degrees F. From the average of each set of fifteen the curve was plotted. Other samples were drawn at 750, 800, 850 and 900 degrees F., but the alternating vibrations, before breakage occurred, did not vary materially from the samples drawn at 700 degrees, although this did make a considerable difference in the elastic limit and reduction of area. The chemical analysis of the steel was as follows: Carbon, 1.01 per cent; manganese, 0.56 per cent; silicon, 0.155 per cent; sulphur, 0.046 per cent; and phosphorus, 0.044 per cent. The sulphur and phosphorus were too high, as these should not be above 0.03 per cent, the better grades of spring steel containing less than this. This might account for the alternating vibrational figures being so low, although the test was made very severe in order to shorten the time consumed in making it. Other fatigue tests, however, show that the ratio between the figures at which the breakage occurred is essentially the same as though the test were made less severe. Practically the same ratio of difference is shown in the elastic limit and contraction of steel hardened at these temperatures.

At hardening temperatures below 1450 degrees, the specimens took a permanent set when they were bent in the test, which indicated that this was below the correct hardening temperature. This coincided with the transformation point

which proved to be 1425 degrees; the 25 degrees between this and 1450 degrees being about the right amount to allow for the loss of heat between the heating furnace and the quenching bath. It will be seen from the chart that when the hardening temperature was raised to 1500 degrees, or only 50 degrees too high, there was a loss of 15 per cent in the steel's resistance to fatigue, and when the temperature was raised 100 degrees or to 1550 the loss was 29 per cent. Quenching at 150 degrees above the correct hardening temperature caused a loss of 43 per cent; 200 degrees, 57 per cent; and 250 degrees, 69 per cent. At this latter point of 1700 degrees, the steel began to crystallize and the curve dropped rapidly downward. When it reached the burnt stage, the fatigue resistance would have been practically nil.

If the spring plates are not heated up to the transformation point before being quenched, the steel will have very little hardness and the springs will take a permanent set when the load is applied. That this often happens is shown by the lop-sided appearance of some automobile bodies, which is caused by a spring settling. What has saved many a spring designer from utter failure is the fact that even thoroughly annealed steels have an elastic limit, and therefore it is only necessary to pile enough leaves on top of one another to make a spring that will carry a given load and resist the strains without settling. This does not make easy riding, however, as such springs have very little resiliency as compared with those that are properly heat-treated. For instance, the chart Fig. 11 shows that thoroughly annealed carbon spring steel has an elastic limit of 75,000 pounds per square inch, but when hardened at the correct temperature and drawn at 750 degrees F. the elastic limit is raised to about 133,000 pounds. Thus it would require nearly twice as much of the annealed steel to carry the same load that correctly hardened and tempered steel would carry.

One test of a semi-elliptic spring, which was made in the machine shown in Figs. 1 and 3, shows the weakness of a spring that is too soft. The spring tested had six plates and held about 1000 pounds when on the car under normal load; therefore, it was pressed up under head B until the scale dial registered 1000 pounds. At each upward movement of the platen, it was then deflected 2 inches until 225,000 alternating vibrations had been recorded on the counter without a breakage. To hasten the test the movement of the platen was increased to 3½ inches and the spring was deflected 32,290 additional times before breakage occurred. The top leaf then broke next to the spring seat about 3 inches away from the central bolt hole. A new top leaf was put on the spring and 24,100 additional alternating vibrations were recorded at the 3½-inch deflection before the next breakage, which occurred in both the fourth and fifth leaves and at the point where the top leaf broke.

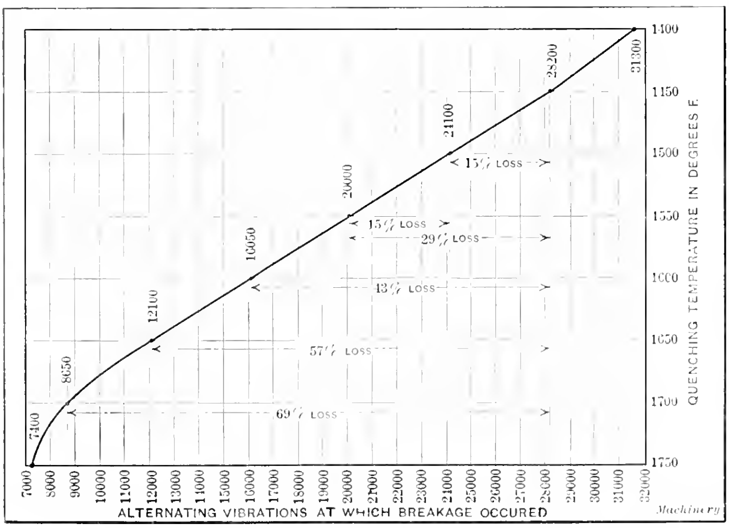

Fig. 8. Average Result of Fatigue Test on Fifteen Samples of Spring Steel, hardened at Temperatures shown at the Right and drawn at 700 Degrees F.

When the spring had been given only 25,000 of the 2-inch deflections, it had taken a permanent set, or settled 1 3/4 inch below its normal position when carrying a load of 1000 pounds. This would mean that it should be condemned as a spring, as its resiliency had been greatly decreased by incorrect heat-treatment. It continued to settle under the test; at 100,000 deflections the settling had reached 2 inches and at 200,000 it was 2 3/4 inches. A similar spring settled 3/4 inch at 500 deflections; ½ inch at 1000; 9/16 inch at 2000; and 11/16 inch at 5000. The test was then discontinued, as the spring was considered worthless.

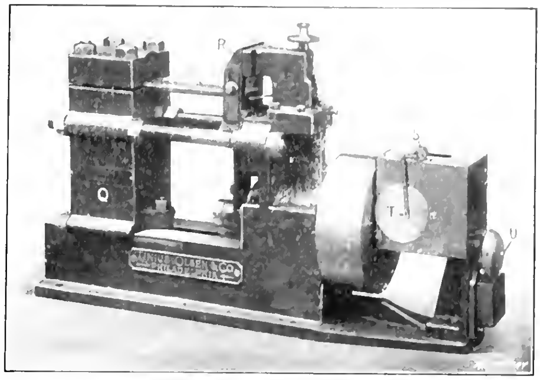

Fig. 9. Bench Fatigue-testing Machine for Specimens 2 inches wide

Testing the Spring Leaves separately

There are numerous ways of making these fatigue tests on small samples. This method often gives better results and is more economical than when a whole spring is used. For instance, each spring leaf or plate can be tested separately and also various places on the same leaf. This will show whether they have been heat-treated uniformly throughout their entire length and also whether each leaf in any one spring is the same. A spring, like a chain, is no stronger than its weakest member or section. One of the simplest ways of making this test is to use an ordinary shaper and fasten the sample in the vise that holds the work. Then a special tool for clamping the top of the specimen can be used in place of the tool-holder. The distance between the vise and this special clamp can be adjusted to suit the specimen, as well as the distance it should be bent back and forth. The number of vibrations can be computed from the number of minutes the shaper runs before breakage occurs and the number of movements that the slide of the shaper makes per minute.

A special machine that is built for this test is shown in Fig. 9. This machine is small, of simple design, and is made to rest on a bench, a number being operated from one lineshaft. It is powerful enough to bend specimens 3/8 inch thick, 2 inches wide and 4 inches between the clamps, a distance of 1 inch, at the rate of 500 vibrations per minute. The vibratory length of specimen P can be made any distance between 4 and 8 inches by moving pillar-block Q. The number of bends or vibrations that slide R gives the specimen is recorded on counter S and dial T, which stops and rings bell U when the specimen breaks.

Modern Fatigue-testing Machine

The latest style of fatigue-testing machine to be placed on the market is shown in Fig. 10. This machine was developed by G. B. Upton of Cornell University and G. W. Lewis of Swarthmore College, who turned over to the Tinius Olsen Testing Machine Co. all the rights for its manufacture and sale. The first machine was sold about one year ago, but several improvements were afterward made, and the

latest improved type, which has just been brought out, is here shown. It can be driven by power at the rate of 600 revolutions per minute, and a hand crank will drive it at 100 revolutions per minute. As variable crank-disk *A* revolves, it moves connecting-rod *B* and lever *C*. The latter tilts jaw *D* in opposite directions and bends specimen *E* which is gripped in jaws *D* and *F*. Jaw *F* is pivoted on a pin and the power exerted to bend or vibrate the specimen causes it to force arm *H* against springs *I* and *J*. Through lever *K* a record of this is scribed on chart *L* which revolves once for every 300 revolutions of crank-disk *A*. The revolutions of crank-disk *A* are recorded on an automatic counter. The angle of bend can be altered by changing the position of connecting-rod *B* on disk *A*, and the vibratory length can be made anything desired by lowering jaw *D*, which is held in place by the specimen being tested. Stop *N* prevents it from dropping when the specimen breaks and, with foot-pedal *O*, aids in setting the specimens. A brake for stopping the machine engages the flywheel and is operated by lever *P*.

With this machine, fatigue tests can be made in from 5 to 60 minutes that would take as many hours in the other machines. Breakages can be made with from 500 to 10,000 revolutions of crank-disk *A* by making the crank throw 1, ¾ and ½ inch, which would be sufficient for finding a figure of merit by which to compare specimens. The 500 cycles would take 5 minutes and the 10,000 about 60 minutes. The vibratory length of specimens between jaws *D* and *F* should be the same in all comparative tests; usually 1/10 inch gives very good results.

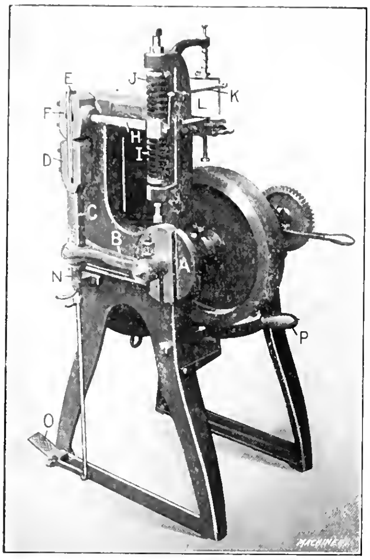

Fig. 10. The Upton-Lewis Fatigue and Toughness-testing Machine

In addition to the results obtained by other fatigue machines, this one gives the transverse load that is required to bend the specimen the maximum distance. This is computed from the strength of springs *I* and *J*, length of lever arm *H* and the travel on chart *L* of the pencil held in lever *K*. When the load begins to weaken, a shortening of the stroke of the pencil takes place and from this might be obtained the elastic limit of fatigue, if it may be so called. The angle of bend of specimens is figured from the throw of crank-disk *A* and length of arm *C*. Curves can be plotted that will show the relation of the fatigue alternations to the transverse load.

Methods of Heat-treating Springs

The old method of heat-treating springs, which is now in use in nearly all spring shops, consists of heating the plates to about 1800 degrees F. in a furnace that is supposed to be maintained at that temperature, as this heat is required to bend steel to its proper shape by the old hand methods. Each plate is then taken out and bent to the shape that will make it fit the leaf directly below. After that they are usually put back into the furnace, heated to the hardening temperature, and then quenched in oil. Then they are again placed in the furnace, until the oil burns off, to temper them.

To heat carbon steel spring plates all day in a furnace that is maintained at 1800 degrees, and have their temperature within 150 degrees of the transformation point when they enter the quenching bath, is a physical impossibility with the best of spring-fitters. The exhausting work before a furnace on a hot day affects the man's judgment of temperatures. The difference in light between a cloudy day and one of bright sunshine will also affect the man's judgment of the hardening temperature of the steel, as this must be done by noting the color. (Pyrometers only record the temperature of the furnace.) Likewise a bad stomach might affect the spring-fitter's eyes enough to make his judgment of the hardening temperature vary considerably. Numerous other reasons could be given for the lack of uniformity, strength,

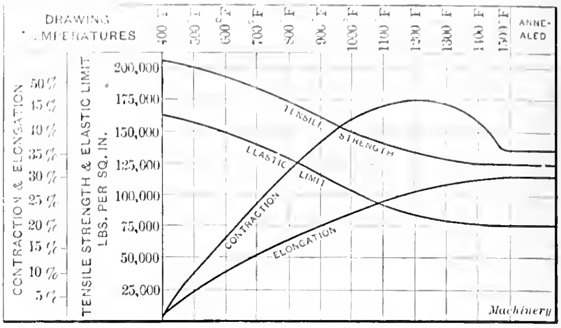

Fig. 11. Alteration in Tensile Properties of Spring Steel, caused by Variation in Drawing Temperature

and durability of leaf springs. In the heat-treatment of other products better methods have been adopted, and the spring-makers are just beginning to realize this and are now looking for more accurate methods. In most cases, however, they are beginning where the others have left off.

To put the spring plates back into a furnace with a high temperature and burn the oil off to obtain the drawing temperature is more like a huge joke than a reality, and yet this is being done every day. Hardening oils have a flash point that is anywhere between 400 and 600 degrees F., while the best results are obtained when spring plates are drawn at temperatures between 700 and 800 degrees. Furthermore, it is impossible to judge the temperature of steel in a furnace heated to 1800 degrees until the steel begins to show red. If steel is held in a dark place, this red will show at 800 degrees, but in the glare inside the furnace the red cannot be seen until nearly 900 degrees has been reached. From the time the oil flashes and burns until the steel becomes red, the steel remains black; hence it is impossible to judge any temperatures between these two points. The majority of spring leaves are tapered at each end, and where the central portion is from ¼ to ½ inch in thickness the ends would be only ⅛ inch thick. Thus the thin ends get red before the middle of the leaf, or absorb the temperature of

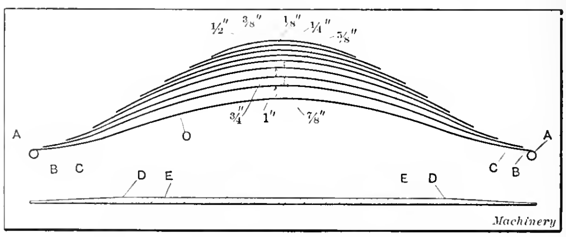

Fig. 12. Camber given Springs and Taper of Plates

the furnace faster, and the leaf is not hardened uniformly throughout its length.

In a furnace heated to 1800 degrees F., steel will absorb a temperature of 200 degrees in about 20 seconds and 500 degrees in about 40 seconds, while it only takes about 15 seconds to pass through the correct tempering range between 700 and 800 degrees. Thus the time factor would prohibit obtaining the correct drawing temperature by the method referred to. In designing springs for the load they are to carry, the thickness of the plates and the number of leaves are based on the elastic limit of the steel. The elastic limit is changed greatly by the temperature at which the steel is drawn, as can be seen by an examination of the chart Fig. 11. This shows that the elastic limit drops about 35,000

pounds between drawing temperatures of 600 and 900 degrees. Thus the spring designers have to allow an enormous factor of safety and make the springs a great deal heavier than they would if the spring leaves were heat-treated at accurate temperatures.

As proof of this, a noted example is that of the front spring on Ford automobiles. Nearly every spring-maker has said that it was too light and yet it keeps on doing its work year after year. The reason is that it is bent to shape in one furnace, heated for hardening (and quenched) in another furnace, and heated for the drawing temperature in still another furnace. In that way, pyrometers can be, and are, used and each furnace is maintained at the correct temperature. With the proper furnaces and apparatus and one man to look after the pyrometers and adjust the furnace valves so the correct temperature will be maintained, there is no excuse for a variation of 25 degrees in the hardening or 15 degrees in the drawing temperatures. Then if the steel is left in the furnaces until it attains their highest temperature and afterward is properly quenched, the metal can be given the greatest strength and durability of which it is capable. This modern way is also much cheaper than the old methods and it is surprising that it has been adopted by only one spring-maker.

Most of the spring-makers have installed pyrometer outfits, but to use pyrometers in these 1800-degree furnaces, in which the fabricating, hardening and tempering are all done, is a waste of time. However, they are a "talking point" and advertising feature to use when spring buyers visit the shop. The pyrometer is usually connected to the furnace, hung on a wall in the office or shop, and not checked or calibrated for months at a time. Under these conditions, the pyrometer readings are never reliable. In one case, the couple or fire end was inserted in the furnace inside cast-iron tubes that fitted into the floor of the furnace where the steel plates lay while being heated. As the tubes were built into the brickwork and always remained in the furnaces, they would absorb their temperature and protect the couple. On testing these it was found that furnace No. 1 recorded a temperature of 1550 degrees F. on the office pyrometer, while a pyroscope gave 2020 degrees as the temperature of the tube inside the furnace and 2015 degrees as the temperature of the steel that was being heated; furnace No. 2 registered 1750 degrees in the office and 1860 degrees on the pyroscope; and furnace No. 3, 2100 and 2000 degrees, respectively. In another case, five different couples inserted in the same accurate temperature furnace gave pyrometer readings in the office of 2200, 2175, 1875, 2100 and 1950 degrees, respectively, while an accurately calibrated checking pyrometer of the same make registered 1835 degrees. Unless pyrometers are checked every day and calibrated when they do not register correctly, they are more misleading than judging by color.

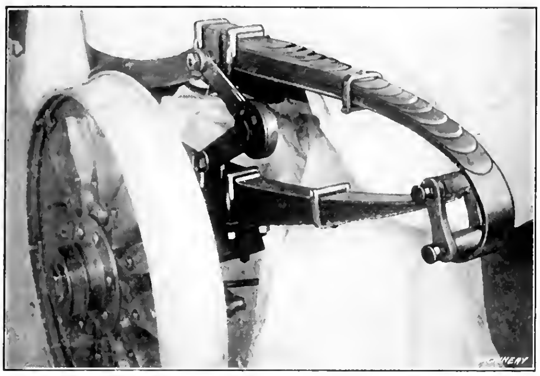

Fig. 13. Shock Absorber on a Special Spring made from Leaves one-eighth inch Thick

As the spring-fitter and his helper work for piece-work prices, it is a great temptation to raise the temperature of the furnace. The higher this temperature, the softer will be the steel and the easier it is to pinch it to the shape of the next lower leaf. A chance can then be taken on striking the correct hardening temperature, or drawing the temper of the spring leaf in this furnace. Thus the hand spring-fitter is no friend of the pyrometer which tells the office the correct temperature of his fire. In a number of cases they have been known to run the temperature of the furnace up high enough to melt down cast-iron tubes and cause the molten iron to flow around the thermo-couple and put the pyrometer out of commission. Numerous times the furnace temperature, that was supposed to be maintained at 1800 degrees, has been found to range anywhere from 1900 to 2100 degrees F. while springs were being hardened and tempered.

Under such conditions, no wonder it is difficult to obtain uniform results in the various tests that the spring users are now giving their springs and that they are demanding more accuracy in their heat-treatment. Nor is it any wonder that crystallization is often found in the spring plates. Crystallization is produced by the heat-treatment that springs are given in their manufacture and cannot be produced from any other cause, notwithstanding the fact that spring-makers like to claim that it is caused by the alternating vibrations that springs receive in service. The microscope has never revealed any crystallization in the numerous fatigue test breaks of properly heat-treated steel.

Before steel reaches the fitter's fire it may be made too crystalline to be restored by the subsequent heat-treatment it receives. In building springs, the first operation on bottom plate O, Fig. 12, is the forming of the eyes A. Each end of the steel bar is placed in a furnace and heated to a high enough temperature to bend this eye. This temperature is high enough to coarsen the grain greatly, and often crystallization is produced. If only heated as far back as B, the squeezing and hammering that the metal receives when the eye is being formed will reduce this coarsened grain to its normal state. It is, however, often heated back to the zones between B and C and made more brittle there than in the rest of the plate.

The same condition exists in the rolling of the taper on the ends of the other leaves. If the steel in the zones between D and E is heated to the high temperature that is required for rolling, the rolls will not compress the coarsened grain back to its normal degree of fineness, as they only touch that part of the leaf which is between D and the end. This view also shows the camber given the various leaves of a spring. When the center bolt is put in, it clamps the leaves tightly together. Thus, when the spring is deflected, the strains are first taken up by the outer ends of each leaf and gradually transmitted toward the center. If they fitted tightly together before being bolted, the strains would center around the bolt hole and make this the weakest part of the spring.

Sample springs made from alloyed steels have, at various times, withstood some wonderful tests. These were only wonderful, however, because of the contrast between them and the commercial springs which were so poor. These samples were carefully handled in making, were not overheated at any time, and were quenched and drawn at the correct temperatures to give them their greatest elastic limit, toughness, resiliency and resistance to fatigue. By installing modern furnaces and apparatus and subdividing some of the operations, the commercial springs could be made nearly as good as the sample.

Some spring-makers have claimed that if springs were correctly made shock absorbers would not be needed. One only has to ride in a car, however, to find that there is nothing to prevent his head from hitting the top, when the wheel drops into a slight road depression and the severe deflection given the spring causes it to rebound. When deflected all of the leaves resist their part of the strain, but on the rebound the shackle gives, and only the main leaf resists this strain until the clip is reached that binds some of the leaves together. This can be plainly seen in Fig. 13 which shows a Truffault-Hartford shock absorber attached to a special spring. This spring was made from leaves 1/8 inch thick, as a greater resiliency can be obtained with many thin leaves than with a few thick ones. The easy riding qualities of the car clearly demonstrate this fact.

LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY.

UNIQUE ARC WELDING OPERATION

Electric arc welding is now in general use for certain classes of work, and apparatus for generating and controlling the arc has been perfected and may be classed as standard. Its field for application is a wide and varied one, and as its possibilities become more widely known its use will no doubt be extended to cover many operations now performed by other means at a greater outlay of time and money.

An example of one of the many uses to which a welding outfit may be put is illustrated by the accompanying engravings which show a cast steel clamp of approximately thirteen inches inside diameter. This was designed for assembling certain machine parts and holding them against the faceplate of the lathe for finishing. The clamp, as originally made, was in two sections (one of which is shown in the right-hand view of Fig. 1), and was intended to be tightened around the parts to be assembled, by means of bolts passing through lugs on opposite sides of the clamp. It was necessary, in order to operate the finished article successfully, that the assembled sections be drawn together with an approximately even pressure from all directions, but on trying out the device, it was found that those sections at the joints, and for several inches on each side, did not come together properly, and after several trials, it was decided that a four-part clamp would have to be used.

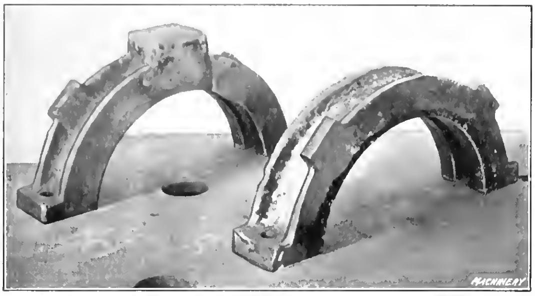

Fig. 1. Steel Casting to which Bolt Lug was electrically welded as shown to the Left

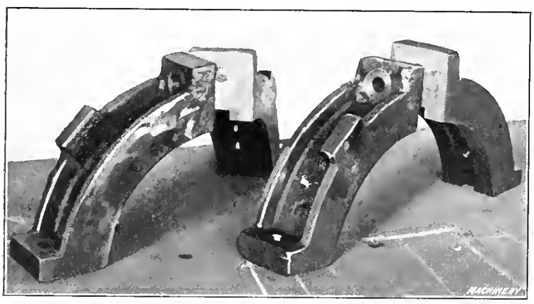

Fig. 2. Four-part Clamp with electrically welded Bolt Lugs

To avoid the delay which would have been entailed by having the pattern returned from the foundry, making the necessary alteration, and getting new castings, the welding outfit was brought into play on the existing castings. Two pieces of iron were obtained and cut to shape to fit roughly between the outer flanges of the sections. These were then welded into place, half way between the ends, as shown in the left-hand view of Fig. 1. The half rings were then cut through these lugs, and holes were drilled for bolts, after which the clamp was again ready for use. Fig. 2 illustrates the completed four-part clamp.

The welding, in this case, was done with the carbon arc, using current of approximately three hundred amperes. The operation consisted of fusing pieces of metal into the joint between the two parts to be united, and, at the same time raising the metal on each side of the weld to the point of fusion. The time consumed in welding was one and one-half hour, while the machining operations for making the extra pieces of iron, and the cutting and drilling after welding, required about four hours more; therefore, with a total time expenditure of five and one-half hours, and the aid of the welding outfit, there was accomplished what otherwise would have required, at a minimum estimate, eight to ten days from the time of getting the pattern back, until the new castings were machined and ready for use.

Westfield, N. J. ALAN M. BENNETT

CLEARANCES AND TOLERANCES

In the engineering edition of MACHINERY for March, 1913 (page 525), there was a suggestion that only three terms be used, *viz.*, "finish," "tolerance" and "clearance," when referring to the condition of machined work and its variation in size. Following this suggestion, the accompanying table was prepared for the use of designing draftsmen, so as to avoid any possibility of confusing the terms "tolerance" and "clearance." The table is practically self explanatory. The nominal size of the male part is given, with the proper clearance and tolerance. It will be noted that the table is divided into three parts, namely: for very accurate work, accurate work, and ordinary work. While this table is only for running fits, one for driving and shrink fits could be developed on the same lines.

CLEARANCES AND TOLERANCES FOR SLIDING AND RUNNING PARTS

Very Accurate Work			Accurate Work			Ordinary Work		
Nominal Size Male Part, Inch	Clearance, Inch	Tolerance, Inch	Nominal Size Male Part, Inch	Clearance, Inch	Tolerance, Inch	Nominal Size Male Part, Inch	Clearance, Inch	Tolerance, Inch
1	0.0002	0.0001	1	0.0005	0.0002	1	0.001	0.0005
2	0.0004	0.0002	2	0.0010	0.0005	2	0.002	0.0010
3	0.0006	0.0003	3	0.0015	0.0005	3	0.003	0.0010
4	0.0008	0.0004	4	0.0020	0.0010	4	0.004	0.0020
5	0.0010	0.0005	5	0.0025	0.0010	5	0.005	0.0020
6	0.0012	0.0006	6	0.0030	0.0020	6	0.006	0.0030
7	0.0014	0.0007	7	0.0035	0.0020	7	0.007	0.0030
8	0.0016	0.0008	8	0.0040	0.0020	8	0.008	0.0040
9	0.0018	0.0009	9	0.0045	0.0030	9	0.009	0.0040
10	0.0020	0.0010	10	0.0050	0.0030	10	0.010	0.0050

Machinery

The desired clearance to be subtracted from the nominal male dimensions and the remainder placed on the drawing as the required size, thus, 1.998".

The tolerance permitted from specified dimensions to be placed on the drawing as an exponent to the desired dimension; thus $2.0^{+0.001}$ inches.

The minus sign (−) is used for the male part, the plus sign (+) for the female part, and plus-or-minus sign (±) when immaterial.

The clearances given for the different classes of work allow for a sufficient difference in size to admit of motion and lubrication. A departure from the figures listed may be necessary in exceptional cases, depending upon the nature of the machined surface or its finish, the kind of materials in contact, and the length of the fit. The tolerance may also, in exceptional cases, be reduced when greater accuracy is desired. Tolerance *only* is allowed in the female part, but both clearance and tolerance should be allowed in the male part. This table is only one of many that could be prepared to suit the various requirements of machine manufacturers. The meaning of the three terms, "finish," "tolerance" and "clearance," which are the only terms used, is as follows:

Finish: The condition of the surface of the material, as "file finish," "ground," "paint," etc.

Tolerance: A tolerated departure from the dimensions specified on the drawing; this should always be expressed in the form of an exponent, as $2.0^{+0.001}$ inches.

Clearance: This term signifies the difference between working parts to admit of motion and lubrication. The

amount of clearance determined upon is always taken from the nominal size of the male part and the remainder is the dimension to be placed on the drawing, as $1.998^{-0.001}$ inch.

TOLERANCE

ADJUSTABLE INDEX MECHANISM

The illustrations show an adjustable index mechanism which has been developed by the writer and is, so far as he knows, an original idea. Several experienced toolmakers and machinists have looked over this design and pronounce it to be one which should find application for indexing various classes of work.

Referring to Fig. 1, the parts of the mechanism may be briefly described as follows: The circular slide *A* is dovetalled into the block *B* and has a taper extension which fits into the index plate *C*. The outside edge of the slide *A* is hobbed out to mesh with the worm *D*; this worm has 50 threads to the inch. The pitch line of the teeth on the slide *A* is at a distance of 2.28 inches from the center of the index plate, which makes it necessary to give the worm *D* two complete turns to index through 1 degree. The thimble *E* has 30 graduations so that each graduation corresponds to a movement of 1 minute. The block *B* is mounted on a spring steel support *F* which is fastened to the shoe on the lathe bed as shown in the illustration.

Referring to the detail of the index plate shown in Fig. 2, the method of using this mechanism may be briefly outlined as follows:

For 2 divisions take 0, 30, one revolution.

For 3 divisions take 0, 20, 40, one revolution.

For 4 divisions take 0, 15, 30, 45, one revolution.

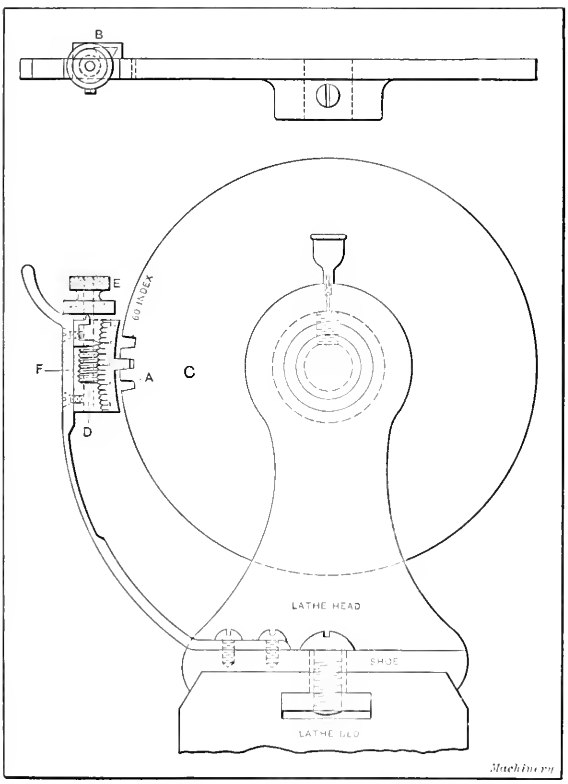

Fig. 1. Adjustable Index Mechanism for a Bench Lathe

For 8 divisions take 0, 15, 30, 45, one revolution; shift pawl 3 degrees, then take 7, 22, 37, 52, two revolutions.

For 20 divisions take 0, 3, 6, 9, etc., to 57, one revolution.

For 40 divisions take 0, 3, 6, 9, etc., to 57, one revolution; shift pawl on index 3 degrees and take 1, 4, 7, 10, etc., to 58, two revolutions.

For 80 divisions take 0, 3, 6, 9, etc., to 57, one revolution; shift pawl 4 degrees 30 minutes, and use the same numbers three times in succession, shifting pawl 4 degrees each time. (Four revolutions in all.)

For 120 divisions go around once making 60 divisions; shift pawl 3 degrees and go around again in same numbers.

By this system it is possible to get any of the following list of indices without, in any case, making more than six turns of the index plate.

One revolution 2, 3, 4, 5, 6, 10, 12, 15, 20, 30, 60; two revolutions, 8, 24, 40, 120; three revolutions 9, 18, 36, 45, 90, 180; four revolutions 16, 48, 80, 240; five revolutions 25, 50, 75, 100, 150, 300; six revolutions 72, 360.

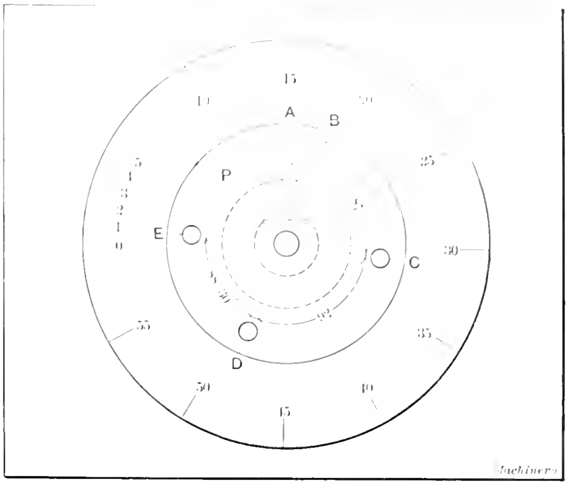

Fig. 2. Detail of Index and One Operation for which it is used

The use of a practical illustration will show another way in which this index mechanism may be conveniently used. Fig. 2 shows a plate *P* in which two notches and three holes are to be located and machined. To index this piece of work, the mechanism is set at the zero mark, after which the notch *A* is milled in the plate. The pawl is then shifted two degrees on the segment after which the index is turned to bring the notch No. 3 up to the pawl. The notch *B* is then milled in the plate. Next shift the pawl 3 degrees and engage notch No. 17 with the pawl; the hole *C* is then drilled. Next shift the pawl 2 degrees and engage notch No. 32 with the pawl; the hole *D* is then drilled. Next shift the pawl 4 degrees 30 minutes and bring notch No. 46 up to the pawl; then drill hole *E*. The desired notches and holes have now been correctly located and machined.

Elgin, Ill. ERLN LEA

USE OF RUBBER STAMPS ON TRACING CLOTH

A rubber stamp with a so-called "cushion-pad" is preferred as it allows more pressure on the stamp without blurring the imprint. Sprinkle powdered pumice stone over the part of the tracing to be stamped and rub this in thoroughly; then blow off the surplus. Thoroughly ink the stamp either on a new pad or a freshly inked pad, as it is very important to have plenty of ink on the stamp. Place the inked stamp over the desired spot and press on it firmly for a moment. Remove the stamp and sprinkle lampblack all over the stamped portion. By means of a rag over the index finger press down on the lampblack so as to soak up the ink, and then thoroughly rub in. After rubbing in the lampblack blow off the surplus. When the tracing is dry the entire surface may be cleaned off with gasoline. It is well to rub lightly over the stamped portion. Convenient receptacles for the powdered pumice stone and lampblack are talcum-powder cans, as they allow the contents to be sifted over the tracing without soiling the hands.

The stamped portion will print as clearly as the regular India drawing ink, if the foregoing directions are properly carried out. A good method of stamping tracing cloth was mentioned in MACHINERY some time ago, printers' ink being

used. But the scheme just described has an advantage over the printers' ink method, in that it allows cleaning the tracing with gasoline; this would remove the printers' ink.

By the use of rubber stamps considerable time can be saved in drafting rooms. The titles for drawings could be stamped by having a holder in which loose rubber letters were properly arranged. Stamps having general notes or instructions, the name of the company, or blank headings such as Drawing No. ....., Date ...., Drawn by ...., Traced by ...., Checked by ...., Scale ...., etc., would prove great time savers and give the drawings a uniform and neat appearance.

A. E.

A RAPID RETAPPING WRENCH

The piece *A* shown in Fig. 1 is part of the ball bearing used on a motorcycle. This part has seven notches milled on the inside of it to receive an adjustable lock mechanism. The piece is first formed, bored and tapped and the notches are then milled. This necessitates retapping the piece before it is hardened, the solid tap *B* being used for this purpose. The tool has a square shank and is clamped in a bench vise. The piece to be tapped is then turned onto the tool by hand until the notched section is reached, after which the wrench *C*, shown in Fig. 2, is used to complete the operation. The eccentric is solid and the handle *D* allows the wrench to obtain a tighter grip on the work as the strain is increased so that the necessary power is obtained to drive the work onto the tap. It will be seen from the illustrations that the clamp ring *E* is cut away at the point *G* to give the tool the necessary amount of "spring."

THE ETHICS OF CONTRIBUTING TO THE TECHNICAL PRESS

I would like to ask the readers of Machinery for their opinion concerning the right of an employe to write descriptions of improved tools or methods that are used in the shop where he is employed, for publication in the technical press. It is not my desire to bring out a technical discussion of the legal points of the case, as the preservation of harmony between employer and employe depends rather upon the way in which they regard the matter. As an example, let us suppose that John Henry is employed by Blank & Co. John is a progressive man and utilizes his spare time during working hours, and also at home, in studying out and developing improvements along the particular line of work in which he is engaged. For the sake of argument, it must be assumed that his daily task is not slighted by so doing. Some of the ideas which he develops are adopted by his employer although John receives no compensation other than the good will of the heads of the firm. It is evident that such ideas are regarded as a natural product of John's daily work.

Under such conditions, I should like to know whether John has a moral right to write a description of his improvement for publication in a trade journal. Would he be treating his employer fairly by so doing? Should he first ask and receive his employer's permission to write such an article? Has his employer the right to refuse such a request? Would John be behaving dishonestly if he did not turn over any new ideas which he develops to his employer? Could he ignore his employer in the matter of publishing an article and still remain loyal? If not, where does John stand and how is he to know what ideas he has a right to describe, and what sort of ideas has his employer the right to expect him to keep from the public? There are many John Henrys and many firms such as Blank & Co., whom I believe would like to hear the other fellow's opinion on this subject.

Delphos, Ohio. A. J. Brickner

NICKEL PLATING WITH BICHLORIDE OF MERCURY

The following formula for "nickel plating" brass and copper parts has proved very satisfactory in our shops during the past four years. In using this method, the first step is to see that the parts to be plated are quite clean and free from grease. The work is then dipped in a saturated solution of bichloride of mercury or else a paste is applied by rubbing. This treatment causes a film of mercury to be deposited on the work, and when this result has been obtained the pieces are dried in sawdust and then lacquered in the usual way.

If a paste is found more convenient to use than the solution, it may be prepared by adding water to the powdered bichloride of mercury to obtain the required consistency. It is essential that the parts be lacquered after they have been plated in this way; otherwise the mercury will wear off in a short time.

Bichloride of mercury may be obtained at almost any drug store. If difficulty is experienced in purchasing it, it may be prepared by allowing metallic mercury to dissolve in hydrochloric acid until the strength of the acid is used up. The liquid is then boiled off, leaving white crystals of bichloride of mercury in the vessel. Either a glass or earthenware vessel should be used to prepare the bichloride of mercury, as hydrochloric acid will act upon any metal vessel which may be used.

East Orange, N. J. George Garrison

DRILLING GLASS

In the June number of Machinery, Mr. S. Queer states that he has found it much easier and quicker to drill glass by hand than by the method described by Mr. O. M. Hance in the December, 1912, number. I did not read Mr. Hance's article but feel sure that the following method will prove more rapid than that described by Mr. Queer.

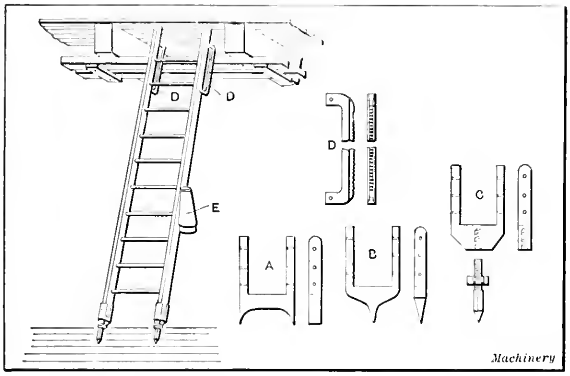
I use an ordinary twist drill of the size of the hole which is required. A mixture of turpentine and camphor is used as a cutting compound. The glass is drilled about half way

through and then turned over so that the remaining depth may be drilled from the opposite side. No jig or other fixture is required for this purpose. When the work is turned over, the bottom of the hole will be clearly shown by a white spot and by centering the drill on this spot, a good, clean hole can be produced. I have drilled quite a few holes in glass, using a small drill press running at high speed, and had no more trouble than if I were drilling cast iron.

Auburn, N. Y. JAMES BURKE

SAFETY EQUIPMENT FOR LADDERS

Almost every industrial plant maintains one or more ladders which are used in attending to shafting and for similar purposes, the ladder seldom being laid down lengthwise. This



Assembly and Detail Views of Safety Equipment for Ladders

is due to the fact that there is no room in the average factory for a ladder to be laid down without being in the way. There are few forms of shop equipment that require more caution in their use than a ladder which is used to reach the belts and shafting in a factory, and no matter how careful the workman may be there is still a certain amount of danger.

Insecure footing for a ladder on the floor is frequently the cause of accidents, due to the ladder slipping away from its overhead support. Most ladders used in factories are provided at their lower ends with forged braces which prevent the ends of the ladder from splitting. These braces are forged with a single or double point which digs into the floor and prevents the ladder from slipping. There are a number of different designs of these braces, two common forms of which are shown at *A* and *B*. The chief objection to the brace shown at *A* is that it does not afford a reliable grip when placed across the grain of the floor. The brace at *B* is more reliable until it becomes worn down, but this form is rather difficult to sharpen.

The form of brace illustrated at *C* is an improvement over the two preceding designs. It consists of a piece of square stock hardened and ground to a point at one end and threaded at the other end. The threaded end fits into a tapped hole in the forging secured to the foot of the ladder, and is furnished with a check-nut to guard against its working out of place. When the points of these braces become dull, they can be easily removed and sharpened.

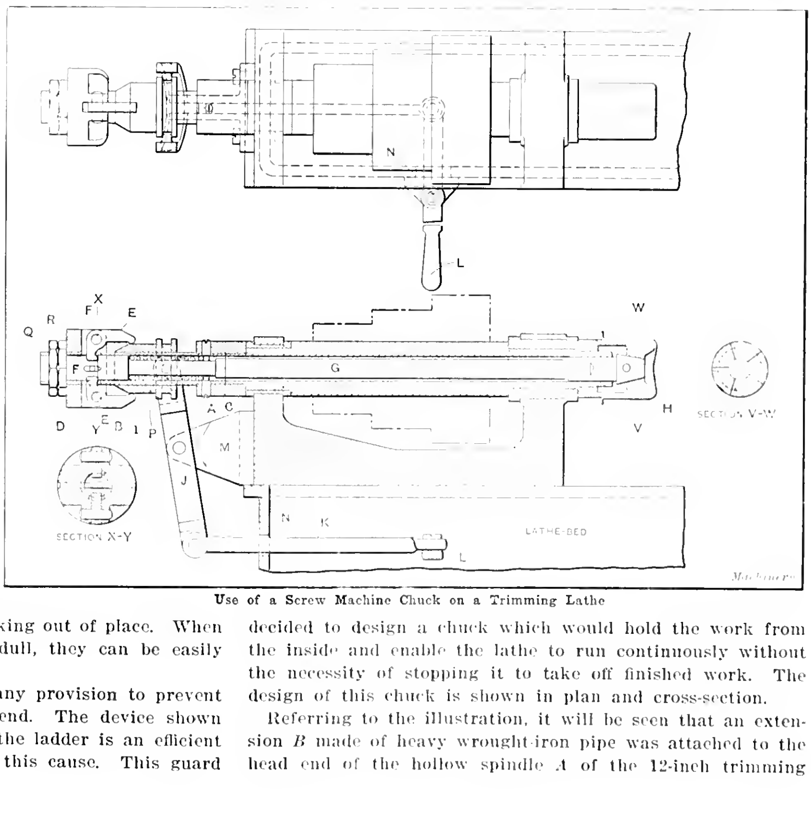
Very few ladders are made with any provision to prevent them from slipping at their upper end. The device shown in detail at *D* and also attached to the ladder is an efficient means of preventing accidents from this cause. This guard is made of ¾ by 1 inch flat stock, the ends being bent back at right angles and teeth milled on the front edge of the guard. Holes are drilled at each end of the guard to receive screws for securing it to the ladder. Where a ladder is equipped with these guards at its upper end and has points at its lower end securely imbedded in the floor, there is little danger of slipping, no matter how roughly the ladder is handled.

The danger or accidents from loose or torn sleeves being caught in belts, gears or other moving parts has been written about too often to require repetition. It is not out of place, however, to state that for an employe wearing a shirt or jumper with loose sleeves to go up a ladder to adjust moving parts of a machine is to invite a serious accident. To avoid this danger, it is advisable to have a pair of sleeves attached to every ladder used in a factory, as shown at *E*. These sleeves can be slipped on over an ordinary pair of shirt or jumper sleeves before going up the ladder, and practically do away with the danger of being caught. There are a number of different kinds of sleeves made and no particular kind is recommended. It is only necessary that the sleeve shall be made of stiff material, the most suitable being those made of fiber or matting. The important thing to remember in order to avoid accidents when working on a ladder is to see that the feet are firmly imbedded in the floor so that they cannot slip and also that the ladder is securely anchored at its upper end. As a supplement to the use of these safety devices, a point should be made of instructing the workmen in regard to the danger which they run in mounting a ladder and the proper method of avoiding it.

Hartford, Conn. JAMES E. COOLEY

SCREW MACHINE CHUCK ON A TRIMMING LATHE

Some time ago I was called upon to trim a large number of metal caps which had been drawn from 24 gage sheet brass. One of these caps is shown in position on the spindle of the trimming lathe, from which the general form is apparent. I first tried to chuck these caps from the outside, but found that the metal was too weak to support the strain. After trying one or two other methods without success, it was



Use of a Screw Machine Chuck on a Trimming Lathe

decided to design a chuck which would hold the work from the inside and enable the lathe to run continuously without the necessity of stopping it to take off finished work. The design of this chuck is shown in plan and cross-section.

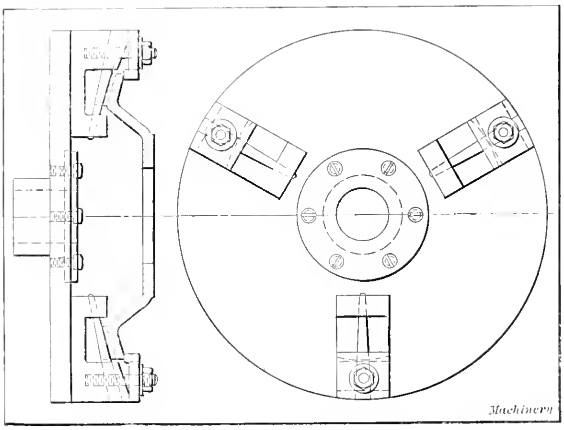
Referring to the illustration, it will be seen that an extension *B* made of heavy wrought-iron pipe was attached to the head end of the hollow spindle *A* of the 12-inch trimming

lathe which was used for machining these caps. The extension is held to the spindle by means of a collar *C* and the other end of the extension is equipped with a locking collar *D* which carries the hardened tool-steel levers *E* pivoted on pins *F*. When the hand lever *L* is thrown over, the levers *E* push the expander rod *G* against the expanding mandrel *H*, which grips the work ready for the trimming operation. The cone-shaped member *I* which actuates the levers *E* is a sliding fit on the extension spindle *B*, and is moved by means of the fork *J* connected to the hand lever *L* by the link *K*. The fork *J* is supported from the lathe bed by means of a cast-iron bracket *M* and two slots *N* are cut in the lathe bed to allow the link *K* and handle *L* to move freely, the arrangement being clearly shown in the plan and cross-sectional views.

The expander *O* is screwed onto the front end of the expander rod *G* so that different sized mandrels may easily be used. The chuck *H* is made of machine steel and provided with five 1/16-inch slots. A spring *P* forces the rod *G* back to the idle position when the cone *I* releases the levers *E*. The throw of the expander rod *G* can be adjusted by means of two nuts, *Q* and *R*. The chuck is so designed that it will not interfere with the regular work for which the machine is used. This method of trimming caps proved to be decidedly economical and might readily be applied on a variety of trimming operations. J. S.

TURRET LATHE FIXTURE FOR MACHINING BEVEL GEARS

In the factory where the writer is employed great difficulty was experienced in securing accurate machine work on cast-steel bevel gears. As it was necessary to produce a large number of these gears at a low price, a simple turret lathe fixture of the form illustrated herewith was designed. One of the gears for which this fixture was designed is shown in place. The machine work consists of boring and facing the



Turret Lathe Fixture used for boring and facing Cast-steel Bevel Gears

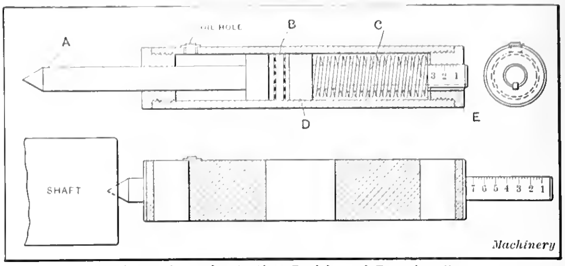
hub, it being necessary to have the bore very accurately located in relation to the pitch circle.

The fixture was designed to enable it to be clamped onto the faceplate of the turret lathe. Three taper pins are placed in the fixture at the angle of the gear teeth, the taper of the pins being such that they will fit accurately into spaces between the teeth. These pins provide a three-point bearing for the gear and locate it so that the hole can be bored in exactly the required position. The work is clamped to the fixture by means of the bolts and caps shown in the illustration. The boring and facing bars used for machining the gears are piloted into the 3-inch bore in the fixture, thus insuring the required degree of accuracy. M. W. W.

END-THRUST GAGE

The accompanying illustration shows a gage for measuring the end thrust of a shaft. In use, the point of the spindle *A* is inserted in the center of the shaft, after which pressure is applied by hand until the shaft is pushed into its desired location, the pressure which is applied being read on a graduated spindle at the opposite end of the gage. An instrument of this kind can be made with a spring and graduations which adapt it for the particular service for which it is intended.

The design of this instrument is clearly shown in the cross-sectional view. Referring to this illustration, *A* is the revolving spindle; the end of this spindle bears against the ball bearing *B* and transmits pressure to spring *C*. It will be evident that this spring is held between the collar *D* and the end *E* of the gage. The graduated plunger may be keyed into the end *E* to prevent the possibility of its turning. It will be found advisable to knurl the outside of the gage to



End-thrust Gage for testing Position of Rotating Parts

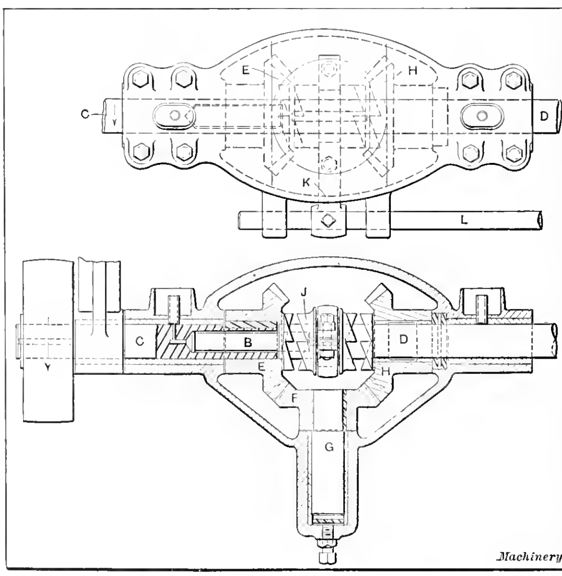
give it a neat appearance and also to afford a good grip when the instrument is used by a mechanic whose hands are covered with oil.

In the manufacture of electric motors it is found that there is a tendency for the armature to "hug" one bearing if it is not quite accurately balanced. This gage was designed for use in the testing department of a factory which had experienced trouble from this source. Gages were placed in the hands of the inspectors who were instructed to return to the assembling department any motor in which it was found that more than a specified pressure was required to bring the armature back to the central position.

RICHARD RUSSELL

REVERSE MECHANISM FOR FACING TRANSMISSION CASES

The executive head of one of the leading automobile factories of Indianapolis, upon taking charge of the work, found



Automatic Reverse Mechanism applied to Milling Machine, for Continuous Milling Operation

the aluminum transmission cases being faced on a milling machine which had been designed to work iron and steel. This proved to be a slow process. The first step taken toward increasing capacity was to change the spindle speeds from

one to five, to one to one, which increased the speed of the cutters five times what it had been. The next step was to add two more jigs for mounting the transmission cases on the milling machine table, making three jigs in tandem. As there was no mechanical return feed, the milling was all done during the forward movement of the table, which had to be returned to the starting point by hand. In order to operate the facing tools on both forward and return movements and also permit the operator to put on unfinished work and take off finished castings without stopping the machine, the feed shaft was made to reverse when the table had carried the third case past the cutters; then, on the return, the cases which the operator had put on while the first three were being faced were machined.

As the feed shaft reverse mechanism devised for this machine may be applicable to other milling machines, it will be described somewhat in detail.

The shaft *C* used to operate the feed table is driven from the side of the machine by belt. This shaft was cut and the drive end bored out to form a journal for gudgeon *B* set in the cut-off end of the feed shaft *C*. Miter gear *E* is keyed on shaft *C* and is provided with a clutch. A double-ended clutch *J* is splined to shaft *D* and miter gear *H* is journaled on shaft *D*. The gears *E* and *H* are connected by gear *F*. The two parts of the housing which enclose these gears terminate in bearings for shafts *C* and *D*. When the housings are bolted together, gear *F* is in proper mesh with gears *E* and *H*. The double-ended clutch *J* is provided with a yoke *K* which extends outward through an opening in the housing and is connected with a shifter bar *L*. When the machine is in operation, the shaft *C* and the belt pulley always run in the direction indicated by the arrow. If it is desired to feed the table forward, the clutch which is splined on shaft *D* is engaged with the clutch of gear *E*, whereas to operate the feed shaft in the opposite direction, the clutch *J* is moved into contact with the clutch of gear *H*. By attaching a rock lever to the shifter bar *L* and setting it to engage with stop arms at each end of the feed table, the reverse movement is obtained automatically, and the operator simply removes the finished parts and replaces them with unfinished castings after the cutters pass each piece.

Indianapolis, Ind. J. A. McAnulty

JIG FOR MILLING GIBS

It is the purpose of this article to describe a jig for milling dovetailed gibs of the type illustrated in Fig. 1. These gibs are about 18 inches long by 2 1/16 inches wide by 5/16 inch thick and are cored out on one side for a cam slot.

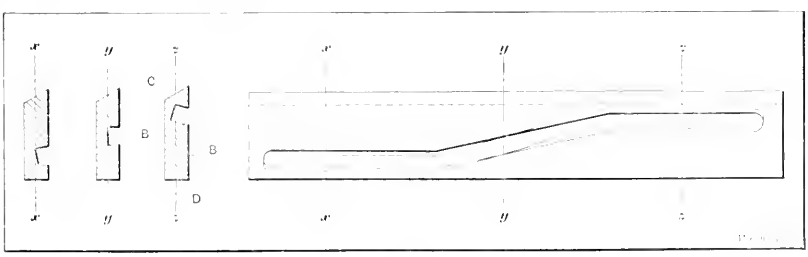


Fig. 1. Type of Gib to be milled

They are made in large quantities so that the time involved in handling the work becomes an important factor.

It was formerly the practice to plane these gibs owing to the impression that milling would not produce a straight enough job on such thin casti. gs. As the gibs were used on a cheap machine, no time could be spent in fitting, and consequently it was necessary to machine the work within the required limits of accuracy. In order to reduce the time required for this operation, the milling jig illustrated in Fig. 2 was designed. In machining the gibs on a milling machine, the surfaces *B* were first finished on a vertical milling machine, holding the work in a vise and using a face mill to avoid distortion. After this operation had been completed, the surfaces *C* and *D* were machined in the milling jig as illustrated in Fig. 2. For the first cut, only one pair of gibs was placed in the left-hand side of the jig. This pair of gibs was then transferred to the right-hand side of the jig and a fresh pair of blanks placed in the left-hand side, after which the jig was tightened up and ready for the second cut. A coarse pitch spiral cutter *A*, wide enough to span the four gibs was used, and it will

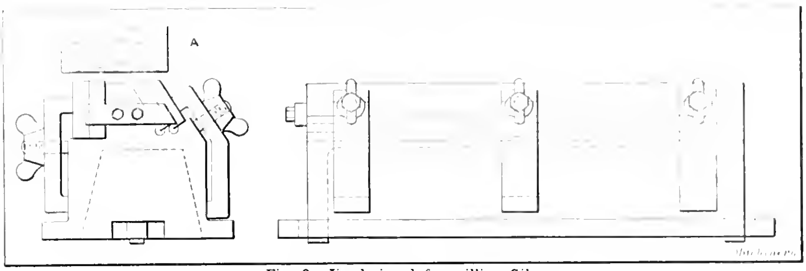

Fig. 2. Jig designed for milling Gibs

be evident that one pair of gibs was completed at each cut—except the first and last. Working according to this method, one operator was able to operate a vertical miller used for finishing the sides *B* and the horizontal miller used for finishing the sides *C* and *D*, thus effecting a material saving in production cost.

Cincinnati, Ohio. H. M. Bogart

STANDARD WIDTH AND THICKNESS OF KEYS

Realizing the advantages derived from interchangeability of machine parts, I am presenting in the following what we have found to be a satisfactory standard for the dimensions

DIMENSIONS OF STANDARD KEYS

Size of Shaft	Size of Key		Size of Shaft	Size of Key	
Diameter in Inches	Width in Inches	Thickness in Inches	Diameter in Inches	Width in Inches	Thickness in Inches
1 to 1 3/16	1/4	1/4	2 1/2 to 2 15/16	3/4	5/8
1 1/4 to 1 9/16	3/8	1/4	3 to 3 7/8	7/8	3/4
1 1/2 to 1 15/16	1/2	3/8	3 15/16 to 4 7/16	1	3/4
2 to 2 7/16	5/8	1/2	4 1/2 to 5 1/2	1 1/8	7/8

Machinery

of keys. It appears that by securing the experience of readers of Machinery along this line, a start might be made toward establishing a generally recognized standard.

The firm with which I am connected does general jobbing work in addition to manufacturing a line of machinery. When I came to the company in 1899 they were using square keys and continued to do so until several years later. These keys were usually made from square cold-rolled steel without any machine work except on the tapered keys, which were made with a taper of 1/8 inch per foot.

Complaints were occasionally received from customers in regard to the square keys. It was claimed that they weakened the shaft and hub unnecessarily, and worn and broken parts returned to the shop seemed to justify this conclusion. In 1903 it became easier to get cold-drawn steel in rectangular sections, and after careful consideration it was decided to adopt rectangular keys in place of the square ones previously used. The accompanying table sets forth the sizes which were adopted.

When taper keys were used, the shallow end of the keyway in the hub was made equal in depth to the keyway in

the shaft, the key being planed from square stock. These dimensions have proved very satisfactory and appear to be about right for general classes of service. As all sizes are in eighths of an inch, the keyways and keys can be made without requiring a large number of cutters and a variety of sizes of stock to be kept on hand. It will be noticed that the thickness of the keys is about three-quarters of their width, or as nearly this proportion as it is possible to make them without adopting smaller dimensions than eighths of an inch.

Orders are frequently received that call for "standard" key-seats and are filled from the dimensions given in the table without calling forth any complaint. It appears that many shops use standards of their own, most of which probably agree quite closely.

Watervliet, N. Y. MARTIN H. BALL

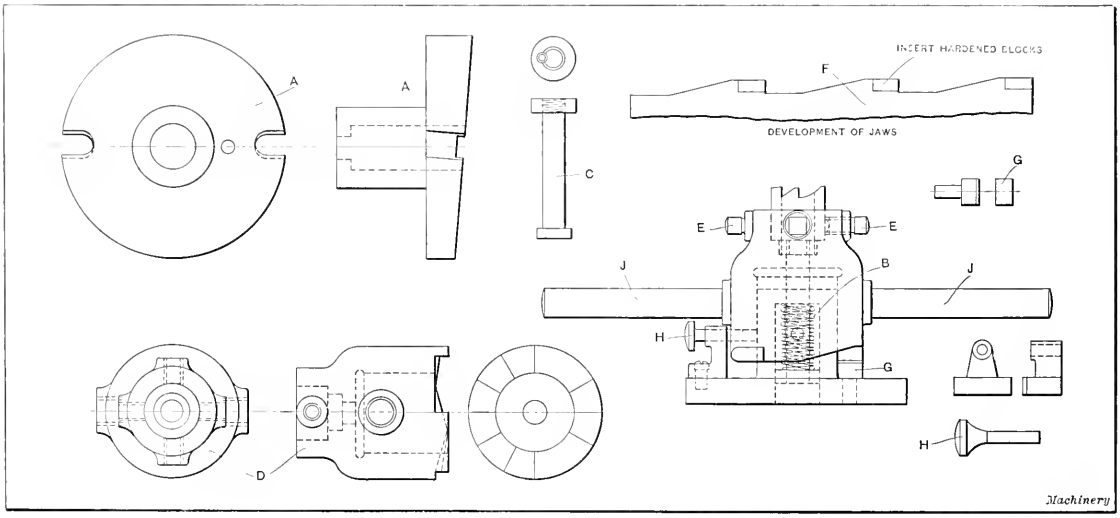
MILLING A THREE-JAW STARTING CRANK CLUTCH

A simple and efficient milling fixture for machining the jaws of a three-jaw starting crank clutch for an automobile motor is shown in detail in the accompanying illustration. In order to make clear the method of machining clutches by this means, the mechanism will first be described in some detail. The baseplate *A* of the fixture is finished at an angle on its under side in order to secure the desired angle on the clutch jaws. A keyway of the same size as the slots in the milling machine table is milled on the under side of the fixture, a key being used to prevent it from rotating. Two bolts fitting in the slots in the base of the fixture provide for securing it to the milling machine table. It will be seen that a pilot is provided on the upper side of the base, this pilot being counterbored to receive tension spring *B* and screw *C*.

The body of the fixture *D* is counterbored at its upper end to receive the clutch jaw which is held in position by means of four set-screws *E*. The lower end of the body *D* is machined to the form to which it is desired to finish the clutch jaw, the development of this cam surface on the lower side of the body being shown at *F*. Hardened steel blocks are inserted in this cam surface where the most severe strain takes place, and a hardened steel block *G* secured to the base of the fixture engages with the cam surface to give the body *D* the required motion. The spring *B* insures having the cam surface on the body of the fixture held in contact with the block *G* at all times.

In machining a clutch jaw on this fixture, the index pin *H* is inserted in one of the holes in the body *D* in order to locate the fixture in the starting position. An angular cutter is used which is 3 inches in diameter by ½ inch in width, and has the teeth cut in a surface inclined at an angle of 37 degrees. This cutter is fed into the work until its center is directly over the center of the clutch jaw which is to be machined. Owing to the angle at which the fixture is inclined, it will be evident that only that side of the cutter which is over the "high" side of the work will cut. After the cutter has been fed in as previously described, the index pin is withdrawn and the body of the fixture is rotated by means of the handles *J*. By so doing the cam surface at the bottom of the fixture runs over the hardened block *G* and guides the work in such a way that the desired contour for the clutch jaw is secured. The rotation of the fixture is continued until the cam drops off the hardened block *G*, indicating that one-third of a revolution has been completed. The fixture is then indexed by locking the index pin in the second hole in the fixture, after which the cutter is again fed in to the center of the work. By rotating the fixture as previously described the second clutch jaw is machined. The process is repeated a third time to machine the third clutch jaw. This fixture proved to be the means of producing very accurate work.

Cleveland, Ohio. E. H. PRATT



Fixture used for milling a Three-jaw Automobile Starting Crank Clutch

PREVENTING BLOW-HOLES FROM FORMING IN BRASS

Inexperienced mechanics sometimes have great trouble in preventing air- or blow-holes from forming at the joints of pieces which are being brazed together. This is generally due to the fact that the work is heated to too high a temperature, with the result that the brass begins to "boil." Brazing should always be done at as low a temperature as possible, and during the operation, the molten brass should be continually stirred to remove any air bubbles that may possibly form.

In cases where it is impossible to stir the brass, satisfactory results may be obtained by proceeding in the usual way, then allowing the work to cool to a dark red and heating it a second time, after which it is again allowed to cool. The second heating allows the metal to run into any blow-holes which may form, the air being driven out to the surface of the metal. It is of the utmost importance that the temperature be so regulated that the brass will not boil during the second heating. If this precaution is not taken, the metal will be in the same condition as it was before applying the heat the second time. In any kind of brazing the best results are obtained by heating the work just enough to cause the brass to melt, and taking care to have the temperature of the joints the same as that of the molten brass.

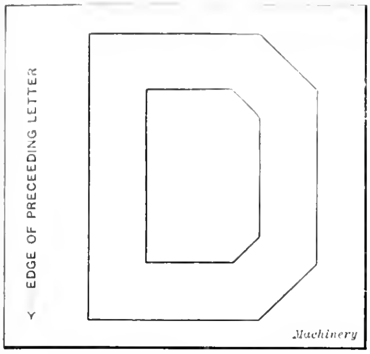
East Orange, N. J. GEORGE GARRISON

SHOP AND DRAFTING-ROOM KINKS

INGENIOUS MEANS AND SHORT CUTS FOR SAVING LABOR AND MATERIALS

AN EASY METHOD OF LAYING OUT BLOCK LETTERS

Block letters can be easily and quickly laid out by procuring a piece of quadrille paper and attaching a carbon sheet on the under side of it with the carbon surface facing the work. By laying out the first letter to the desired size and proceeding in the same space to lay out all the others, perfect lettering for a sign or drawing can be done in less than half the time required to construct the letters by the old method. The upper edge of the quadrille sheet may be folded so as to act as a guide for sliding the paper along the edge of a T-square or the board, to bring it into position for the next letter, thus saving the time required to line up each letter. The illustration shows a letter laid out by this method.

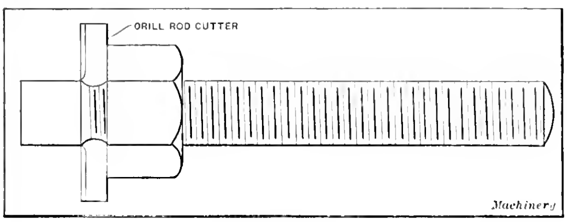


Method of laying out Block Letters on Drawings and Signs

West New York, N. J. William A. Kraus

A CHEAP COUNTERBORE

How many times have you tightened a bolt or nut upon a rough surface when you should have spot-faced to form a true seat for the nut—just because you did not want to stop to make a counterbore. Next time, take a cap-screw the size of the hole, cut the head off, drill a hole where the threads stop, stick in a drill-rod cutter, and screw a nut down against the cutter as shown in the illustration. You will find the cutter well supported by the nut, and the unthreaded end of the cap-screw acts as a pilot. The threads do not interfere with holding the shank in an ordinary drill chuck.



A Cheap Counterbore

Poughkeepsie, N. Y. H. W. Johnson

REMOVING RUST FROM STEEL

A quick method of removing rust from steel parts, which is not generally known to machinists, is outlined in the following: Rub the surface of the piece of work from which rust is to be be removed with muriatic acid. A convenient way to do this is to dip a match or other small stick into the acid and rub it over the surface of the work. This procedure is continued for several minutes, dipping the stick in as often as necessary to obtain a sufficient quantity of acid. After this treatment has been completed, the work should be washed with a solution of common washing soda and water and then dried in sawdust.

This will leave the work free from rust and scratches, but with a dull gray surface. The surface of the metal can be restored to its original color by a little rubbing I have used this method for the past three years and have not known a single case in which it failed to remove all the rust.

East Orange, N. J. George Garrison

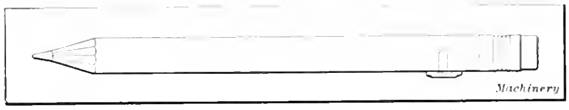
PREVENTING A SLIDE-RULE FROM STICKING

One of our draftsmen was troubled by his slide-rule sticking in damp weather. It was a Faber rule with a self-adjusting slide, but still had a tendency to warp and bind in damp weather so that it could not be used. I suggested gluing two small strips of wood—with the grain of the strips running across the grain of the wood in the rule on the under side of the rule at each end. The rule was first thoroughly dried and after the strips were glued in this way no further difficulty was experienced.

Mishawaka, Ind. Thomas J. Love

PREVENTING PENCILS FROM ROLLING

The accompanying illustration shows a very simple method of preventing pencils from rolling off the drawing board. The illustration makes the method clear without any detailed description being necessary, it being evident that the pencil is prevented from rolling by merely sticking a small sized thumb tack into it near the upper end.

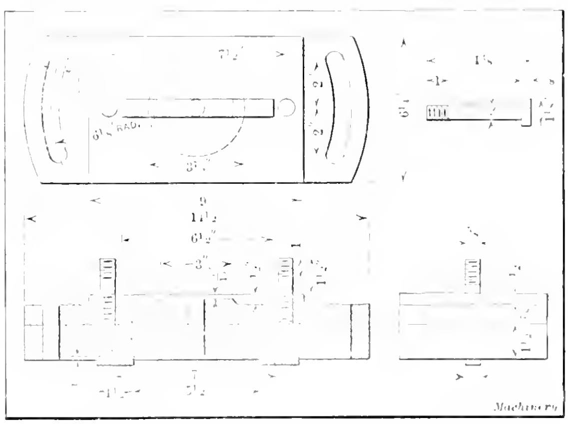


Use of a Thumb Tack to prevent Pencil from rolling

Cincinnati, Ohio. Edward Sobolewski

SWIVEL FILLER BLOCK FOR SPIRAL HEAD

The accompanying illustration shows in detail a simple milling machine attachment which will be found exceedingly useful for many other purposes than the one for which it was originally designed. As its name implies, the application of the attachment raises the spiral head and, at the same time, permits a limited amount of swiveling movement about a vertical axis. In the milling of bevel gears, it is a common practice to roll the spiral head. This, however, alters the shape of the resultant tooth to such an extent that the life of the gear is materially affected. With the attachment shown, the proper lines can be retained.



Swiveling Raising Block for Spiral Head of B. & S. Milling Machine

The construction is simple. A cast-iron plate is machined to suit the milling machine table and its upper surface is counterbored $3\frac{7}{8}$ inches diameter and $\frac{1}{2}$ inch deep. A second cast-iron plate has a boss which fits into the hole in the lower plate, and its upper surface is grooved to receive the spiral head. Both plates are bolted to the machine table with two $\frac{5}{8}$-inch square-head bolts which are shown in detail.

Hamilton, Ohio. A. M. Lount

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

ANNEALING MOLYBDENUM

G. G. Can any reader of MACHINERY give us the details of a method by which molybdenum can be annealed sufficiently to permit of being drilled?

DRAWING BRASS TUBING ON STEEL RODS

G. W. A. Can any reader of MACHINERY give me information regarding the drawing of tubing onto shafting? Some pump rods are made of steel and covered with sleeves of brass which are drawn tightly onto the rod. I wish to perform a similar operation but would much prefer to roll the outer member upon the inner to a perfect fit. Some methods analogous to that of expanding boiler tubes into the sheets, but the reverse process, of course, would fit the case in hand much better than drawing.

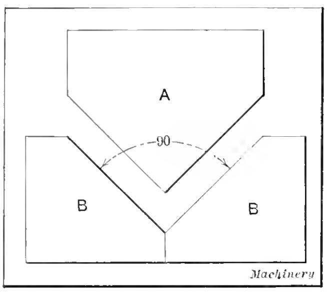
FLUX FOR OXY-ACETYLENE WELDING

A. B.—Are fluxes required for welding cast iron, steel, brass, copper and aluminum by the oxy-acetylene method?

A.—Steel ordinarily requires no flux for welding but a sealing powder is used advantageously on cast iron. Aluminum castings and thick aluminum sheets may be welded without flux but a flux is necessary for very thin aluminum sheets. Brass, bronze and copper require fluxes. The makers of oxy-acetylene apparatus furnish fluxes suitable for all these materials.

ANGLES OF ANGLE BEAM SHEAR BLADES

J. D. Y.—The accompanying illustration shows the upper and lower blades of an angle beam shear. Should the upper blade *A* be made with an included angle of 90 degrees the same as the vee in the lower blades, or should it be of a different angle? If so, what angle should be used?



A.—The relative shapes of the blades depend on the kind of shearing required. If the beams are to be sheared with a minimum of distortion, the angles of the upper and lower blades should be about the same. The question is submitted to readers who have had experience with this class of tool work.

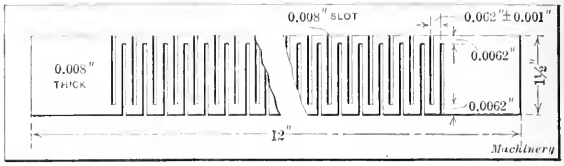
POWER OF WINDMILLS

H. A. W.—Would it be practicable to run a small machine shop with a windmill where the wind is fairly steady for days at a time? How large a windmill would be required to run a small machine shop?

A.—It would not be practicable to run a small machine shop with a windmill, for two reasons. In the first place, the speed would fluctuate so much that it would be difficult to run the tools at the proper speed, and in the second place, you could not get power enough in all probability. The power requirement of a "small machine shop" is indefinite but assuming that it is, say, five horsepower, a windmill motor would need to be very large to produce this amount of power steadily. The work done by a twelve-foot windmill of the most efficient make in a strong wind was shown to be but a fraction of a horsepower by tests conducted in 1895 and 1896 by E. C. Murphy. The results of these tests were published in the *Kansas University Quarterly*, April, 1897. The useful work done in a twenty-miles-an-hour breeze was 0.332 horsepower; in a twenty-five-miles-an-hour breeze, 0.379 horsepower; and in a thirty-miles-an-hour breeze, 0.417 horsepower. A sixteen-foot mill generated only 0.644 horsepower in a thirty-miles-an-hour breeze.

SLOTTING "NI-CHROME" STEEL RIBBON

W. C. H.—I would like to find out how we may successfully slot "ni-chrome" steel ribbon. The dimensions of the ribbon and slots are shown in the accompanying illustration. We have spent over one-and-a-half year trying to make a die that will slot this ribbon successfully but so far have not succeeded. Three different dies have been made and the last one is the best, but it is far from being satisfactory. The cutters break quickly. With a brand new sharp die, we can run about forty



feet of ribbon and then the corners of the cutters give way and wedge into the die, causing the cutters to break on the up-stroke. If we could get a die that would run one hour without breaking or grinding, it would be considered very satisfactory. "Ni-chrome" steel ribbon is the toughest material to work in a die that we have ever seen. Any information that the readers of MACHINERY can give will be thankfully received.

* * *

MANNING, MAXWELL & MOORE, INC., ACQUIRES PUTNAM MACHINE CO.

Manning, Maxwell & Moore, Inc., New York City, has purchased the entire capital stock of the Putnam Machine Co., Fitchburg, Mass. The Putnam Machine Co. is a pioneer tool manufacturer of America. It was started in a small way in 1836 by Salmon W. and John Putnam who were geniuses in tool designing and building. They were the originators of a number of improvements which have become commonly accepted features of machine design. Among these may be mentioned the feed-rod for operating the carriage of engine lathes, the adjustable lathe tailstock and the universal adjustable box and hanger for lineshafting. They produced the first set of hardened steel ring and plug gages made in America and were the first to bring out an upright drill with a revolving table and an adjustable arm swinging around the column of the drill. Their early experimental development work in gear-cutting blazed the way for the present gear-cutting machines. They were also the originators and builders of the famous Putnam steam engine.

The company has grown from a small beginning until its plant covers about fourteen acres of the most valuable land in Fitchburg; it is one of the leading builders in the world of heavy railroad machine tools, such as locomotive driving wheel lathes, coach wheel lathes, axle lathes, hydrostatic wheel presses, planers and lathes.

Of the old stockholders of the Putnam Machine Co., S. W. Putnam, son of the founder and himself a designer of wide reputation, and his son S. W. Putnam, 3d, will retain their connection with the company which will continue to be known as the Putnam Machine Co. By the purchase, the old officers and directors automatically ceased to hold office and the following are the new directors of the company: Salmon W. Putnam, Alfred J. Babcock, John N. Derby, Percy M. Brotherhood and George D. Branston, the last four mentioned being executive officers of Manning, Maxwell & Moore, Inc.

* * *

Tests have been made on the 5000-ton testing machine of the U. S. Bureau of Standards at Pittsburg to determine the strength of large brick piers. The tests were made on two piers four feet square by twelve feet high. The bricks of one pier were laid up in one-to-one cement mortar and of the other in one-to-three lime mortar. The tests developed a strength of 757 pounds per square inch in the lime mortar pier and 2917 pounds per square inch in the cement mortar pier. The fact that a strong bond increases the compressive strength of brick nearly four times that of the same bricks in a comparatively weak bond is not generally appreciated.

EIGHTH ANNUAL EXHIBIT OF THE FOUNDRY AND MACHINE EXHIBITION

The eighth annual exhibit of the Foundry & Machine Exhibition Co., which was held in the International Amphitheater, Chicago from October 10 to 17 inclusive, was very largely attended by foundry and machine tool manufacturers and those interested in modern machinery and supplies. The building selected was ideal for this purpose, there being no lack of light and power facilities. Machines were set up and in actual operation, which helped greatly to increase the general interest in the various exhibits. One hundred and seventy-four individual concerns were represented this year, which was a considerable increase over the number that exhibited last year at the convention in Buffalo. Among those exhibiting were the following:

Acme Machine Tool Co., Cincinnati, Ohio. "Acme" geared head combination flat turret lathe with complete bar and chucking equipment, driven by five H. P. constant speed motor; "Cincinnati-Acme" eighteen-inch geared head universal turret lathe.

American Tool Works Co., Cincinnati, Ohio. "American" high-duty lathe, with eight speed geared head for motor drive with miscellaneous tools, bars of material, etc., for testing purposes; "American" triple-geared plain radial drill; "American" back-geared plain radial drill; "American" single-geared crank shaper.

aloxite products, carborundum wheels; carborundum rubbing bricks; carborundum disks; aloxite wheels, etc.

Cincinnati-Bickford Tool Co., Cincinnati, Ohio. "Cincinnati" twenty-four-inch high-speed shaft-driven upright drill with patent geared tapping attachment, gear box and motor drive; "Cincinnati-Bickford" four-foot regular plain radial drill, variable speed motor drive; "Wizard" chucks and collets.

Cincinnati Milling Machine Co., Oakley, Cincinnati, Ohio. Vertical high-power, motor-driven milling machine in operation; universal high-power milling machine; universal cutter grinder, in operation.

Cincinnati Planer Co., Oakley, Cincinnati, Ohio. Thirty-six inch by thirty-six-inch by eight-foot heavy pattern, "Cincinnati" planer, with four heads equipped with "Triumph-Monitor" reversible motor drive.

Cincinnati Pulley Machinery Co., Cincinnati, Ohio.

Clipper Belt Lacer Co., Grand Rapids, Mich. "Clipper" belt lacer; "Clipper" belt hooks, etc.

Cowan Truck Co., Holyoke, Mass. Cowan all-metal transveyors.

Davis-Bournonville Co., Chicago, Ill. Portable and stationary oxy-acetylene apparatus; acetylene generator; oxygraph cutting apparatus.

Diamond Machine Co., Providence, R. I. Disk grinding machine complete with sliding table and ring wheel chuck; steel disks; cementing press and accessories.

Flexible Steel Lacing Co., Chicago, Ill. "Alligator" steel belt lacing and "Turtle" belt fasteners.

Gardner Governor Co., Quincy, Ill. Vertical self-oiling and horizontal self-oiling air compressors.

Gardner Machine Co., Beloit, Wis. Disk grinders; setting-up

View of the Eighth Annual Machine & Foundry Exhibition in the Amphitheater Bldg., Chicago

E. C. Atkins & Co., Inc., Indianapolis, Ind. Saws for all purposes; metal cutting saws, circular metal saws, metal band saws, hacksaw blades, hacksaw frames, machine knives, band saws, circular saws, saw fitting tools, power hacksaw machines.

Automatic Transportation Co., Buffalo, N. Y. Electric trucks built and used exclusively for interior trucking; electric trucks equipped with lifting platform, intended for machine shop work and equipped to raise a load from four to five feet, converting the truck into a tiering machine.

Baird Equipment Co., Chicago, Ill. Time stamps and electric clocks.

Baker Bros., Toledo, Ohio. High-speed, high-power drilling machine with compound table, motor driven; gear box showing arrangement of gears and method of shifting for high speed; high-power drill, motor driven; and keyseater for internal keyseating, motor driven.

Barnes Drill Co., Rockford, Ill. All-geared drill, complete with motor drive; sliding-head all-geared drill and tapper, with motor drive, self-oiled; all-steel geared manufacturing drill with motor drive.

Benjamin Electric Mfg. Co., Chicago, Ill. Benjamin safety devices for punch presses, installed on press in operation.

Charles H. Besly & Co., Chicago, Ill. Besly horizontal disk grinders; Besly disk grinders; direct-connected patternmaker's disk grinder; "Helmet" spiral circles; oil, taps, etc.

Bullard Machine Tool Co., Bridgeport, Conn. Bullard vertical turret lathe, "New Era" type, complete with cutting lubricant system, motor drive, etc., in operation on various classes of work.

Carborundum Co., Niagara Falls, N. Y. Carborundum and

wheel presses; roll sanding machine; ball bearing polishing lathes; ring wheel chucks; complete line of disk grinder supplies.

General Electric Co., Schenectady, N. Y. Induction motor-driven and turbine-driven centrifugal air compressors.

Gisholt Machine Co., Madison, Wis. "Periodograph" (time registering system).

Goldschmidt Thermit Co., New York City. Samples of roll repairs; samples of work done, with equipment for doing same; demonstration showing intense heat produced by the chemical reaction of thermit.

Gould & Eberhardt, Newark, N. J. Twenty-eight-inch "Invincible" type shaper with direct-current variable-speed motor drive with automatic starter and dynamic brake; twelve-inch gear hobber with direct-current motor drive, and automatic starter.

Greaves, Klusman & Co., Cincinnati, Ohio. Greaves-Klusman all-geared head, heavy, quick-change screw cutting engine lathe and heavy standard screw cutting engine lathe.

Hannifin Mfg. Co., Chicago, Ill. Air-operated chucks; countershafts; clamping fixtures; vises and mandrels; air-operated firedoors; collapsing taps.

Hoskins Mfg. Co., Detroit, Mich. Hoskins electric furnaces; Hoskins thermo-electric pyrometers including portable, wall, illuminated-scale and recording types; Hoskins electric hot plates for laboratories.

Hunter Saw & Machine Co., Pittsburg, Pa. Inserted tooth saw grinder; saw sharpening and beveling machine; inserted tooth saw blades; high-speed friction saw.

Independent Pneumatic Tool Co., Chicago, Ill. "Thor" pneumatic chipping hammers; calking hammers; flue beading hammers; riveting hammers; sand rammers; piston air drills; reversible wood boring machines; flue rolling machines; tapping machines; pneumatic grinders; and electric drills.

Ingersoll Rand Co., New York City. Air compressors, single and two-stage, electric driven; pneumatic chipping hammers; pneumatic riveting hammers; pneumatic scaling hammers; pneumatic motor hoists; stationary motors; piston drills; sand rammers.

International Machine Tool Co., Indianapolis, Ind. "Libby" heavy-duty turret lathe with tool equipment for gear blanks.

Kempsmith Mfg. Co., Milwaukee, Wis.

Landis Machine Co., Inc., Waynesboro, Pa. Double-head bolt cutters; stationary pipe die heads; automatic die heads; solid adjustable die heads.

La Salle Machine & Tool Co., La Salle, Ill. La Salle No. 1 plain and surface grinder with micrometer adjustment.

Lodge & Shipley Machine Tool Co., Cincinnati, Ohio. Eighteen-inch by eight-foot selective head engine lathe; sixteen-inch by six-foot universal new model tool-room lathe with selective head.

Manufacturers' Equipment Co., Chicago, Ill. Turret lathe in operation demonstrating "Aero" chuck and collapsible tap; complete line of "Aero" chucks and collapsible taps.

Modern Machine Tool Co., Cincinnati, Ohio. "Modern" turret lathes.

Norma Company of America, New York City. Norma annular ball thrust, roller and combination bearings, Hirth minimeters.

Norton Co., Worcester, Mass. Grinding demonstrations on swing frame grinding machine, on flexible shaft grinding machine and on new model two-inch Norton floor stand; exhibit of Norton alundum and crystolon grinding wheels.

Oliver Machinery Co., Grand Rapids, Mich. Full equipment of patternshop machinery, including universal wood milling machine; saw bench; jointer; band saw; sander, oilstone grinder; lathes; comb; surfacer; knife grinder, band saw filer; band saw setter; circular saw sharpener; fitting-up wheels; brazer; circular saw set; knife balance; etc.

Oxweld Acetylene Co., Chicago, Ill. Oxweld cutting and welding apparatus; supplies for oxy-acetylene welding.

E. O. Partridge, Chicago, Ill. Emery grinders.

Pawling & Harnischfeger Co., Milwaukee, Wis. Five-ton electric crane; three-ton hoist and single-line grab bucket in operation; crane motors; controllers; I-beam trolleys.

Rockford Drilling Machine Co., Rockford, Ill. Four-spindle vertical chucking gang drilling machine, complete with jigs and special tools for machining pinions.

Rock Island Mfg. Co., Rock Island, Ill. Vises for machine shop and foundry use.

William Sellers & Co., Inc., Philadelphia, Pa. Universal tool grinding and shaping machine; improved drill grinding machine; centrifugal sand mixing machine, all motor driven; centrifugal sand mixing machine, belt driven.

Shepard Electric Crane & Hoist Co., Montour Falls, N. Y. Cage controlled monorail electric hoist; pulpit-controlled single I-beam electric hoist; crane trolleys; foundry controllers.

Springfield Machine Tool Co., Springfield, Ohio. "Ideal" engine lathe with friction geared head; rapid change gear device; Fox monitor turret lathe with friction geared head, chasing bar and taper attachment.

Tabor Mfg. Co., Philadelphia, Pa. Molding machines.

Titanium Alloy Mfg. Co., Niagara Falls, N. Y. Ferro carbon-titanium and titanium alloys for use in ferrous and non-ferrous metals.

United States Electrical Tool Co., Cincinnati, Ohio. Electric drills and grinders.

Vulcan Engineering Sales Co., Chicago, Ill. Pneumatic jolt rammers with pattern drawing mechanism; electric jolt rammers; power and hand squeezers; split pattern machines and vibrators; pneumatic riveters; shakers and electric riddles and oscillators; pneumatic punches; mold dryers; cold metal saws; shop saws; hacksaws; etc.

Warner & Swasey Co., Cleveland, Ohio. Screw machines and turret lathes.

West Haven Mfg. Co., New Haven, Conn. "Acme" high-speed power hacksaw machine; "universal" hacksaw frames; "universal" hacksaw blades.

Willard Machine & Tool Co., Cincinnati, Ohio. Gap bed lathe; tool-room lathe with compound geared taper attachment and draw-in collet attachment, hexagon turret on carriage and square turret on carriage.

Wilmarth & Morman Co., Grand Rapids, Mich. Wilmarth & Morman wet surface grinder and "New Yankee" drill grinders, motor driven; combination cutter, reamer and drill grinder, motor driven; "New Yankee" drill grinders, belt driven; lathe center grinder; water tool and drill grinder.

Wright Mfg. Co., Lisbon, Ohio. Chain hoists, electric hoists, trolleys and traveling cranes.

All machines shown in the exhibit in operation were motor-driven and of the latest design. Several of the machines exhibited were strictly new and incorporated some radical improvements in machine design and construction. The general feeling among the exhibitors and visitors was that the convention was a pronounced success. An even better and more largely attended exhibition is expected next year.

* * *

NEW YORK ELECTRICAL SHOW

The Electrical Exposition and Motor Show of 1913 was held in the Grand Central Palace, New York City October 15 to 25 inclusive. A great variety of exhibits showed something of the part that electricity now plays in the activities of modern industry and home life. They ranged from an electric cow-milker to a full-sized section of one of the Consolidated Telegraph and Electrical Subway Co.'s electric underground cable conduits including manhole and vault. The U. S. Government exhibited a working model of a section of the Mint, all machines, furnaces, presses, etc., required for coining, being in operation. The process of coining $20 gold pieces was illustrated, the coins produced being bronze medals of the exact size of double-eagles. The Government also showed Agriculture, Panama Canal, Navy and Army exhibits. Electro-therapeutical apparatus claimed considerable space, but the commercial and industrial exhibits, of course, were the most important. The variety of office appliances and domestic machines now furnished with electric motors would surprise anyone who had not kept closely in touch with the applications of electric drive during the past few years. Among the many concerns exhibiting were the Bell Electric Motor Co., General Electric Co., H. W. Johns-Manville Co., New York Edison Co., Rhineland Machine Works, Twinvolute Pump & Mfg. Co., and Westinghouse Electric & Mfg. Co. The educational value of the show was appreciated by many students who embraced the opportunity to see the latest electrical apparatus and applications, and something of the activities of the Government department with which comparatively few are familiar.

A. S. M. E. MEETING IN WORCESTER

About two hundred members of the Boston branch of the American Society of Mechanical Engineers met with the Worcester branch of the society in Worcester October 17. After partaking of luncheon at the Worcester Institute of Technology, tours of inspection of engineering work and local industries were made to Holden where the hydraulic laboratories of the W. P. I. are located, to the Quinsigamond Works of the American Steel & Wire Co., to Worcester Electric Light Co., to Reed & Prince Mfg. Co., Graton & Knight Mfg. Co., Crompton & Knowles loom works, United States Envelope Co., etc. Prof. David L. Gallup read a paper on aeroplane propellers at the W. P. I. hydraulic laboratories, and a demonstration on an electrically-driven aeroplane propeller mounted on a revolving boom was made.

The party then reassembled at the Norton Co.'s works where the following papers were read: "Modern Abrasives, Their Manufacture and Use" by Aldus C. Higgins; "How the Best Abrasive Wheels are Made" by Carl F. Dietz; "Efficiency Grinding" by Charles H. Norton. The engineers then inspected the works of the Norton Co. and the Norton Grinding Co. The inspection was followed by a banquet at the new Hotel Bancroft, President Hollis acting as toastmaster.

* * *

TARIFF LAW OF 1913

The so-called Underwood-Simmons tariff bill was passed by Congress and became a law October 4. Substantial changes and reductions were made in all schedules. The free list was added to; the tariff on machine tools was reduced from thirty per cent to fifteen per cent; wool will be admitted free beginning December 1, 1913; and new rates on woolen manufactures will apply January 1, 1914. Sugar and molasses will be admitted free beginning May 1, 1916. The loss of revenue collected on imports will, in a measure, be made up by an income tax which provides for taxing the incomes of individuals, companies, corporations, associations, etc. The law provides for taxing all incomes more than $3000 annually except those of married persons which are exempted up to $4000.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

POND THIRTY-INCH RAPID REDUCTION LATHE

The illustrations show a new lathe which has recently been developed at the Pond Works of the Niles-Bement-Pond Co., 111 Broadway, New York City. This machine is intended for handling the heaviest roughing work of the kind met with in steel and forge shops. To adapt it for such severe classes of service, the machine is of particularly massive construction and steel gears are used throughout. The spindle is driven by a direct-connected 35-horsepower, variable-speed motor, which is capable of supplying a pressure of 26,000 pounds to the tool when it is working at a speed of 50 feet per minute. The motor pinion and the gear which it drives have herringbone teeth, which insure quiet operation. Two mechanical changes of speed can be made in the headstock by means of a convenient lever. The lower speeds of the faceplate are obtained by means of a pinion which drives the faceplate gear. The design is such that any tendency for the resistance of the tool or the power applied to the pinion to lift the main spindle in its bearings is eliminated. The higher speeds are obtained by driving direct through the faceplate spindle, thus obviating the necessity of running the faceplate pinion at an excessively high speed. The end thrust on the main spindle is taken on hardened steel and bronze washers.

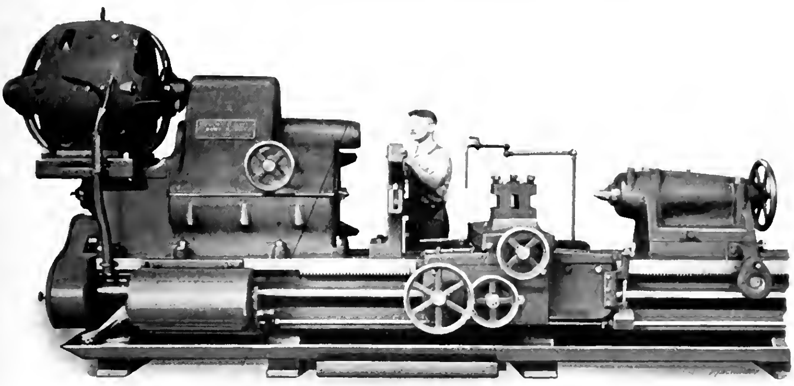

Fig. 1. Front View of Pond Rapid Reduction Lathe

The gearing in the headstock, in connection with the variable-speed motor, gives forty faceplate speeds ranging from 13 to 174 revolutions per minute. By means of a handle on the carriage, the faceplate may be started, stopped or reversed, and any of the motor speeds may be obtained without requiring the operator to leave his position at the front of the machine. The faceplate is made of steel and fitted with radially adjustable drivers. All the rotating shafts in the headstock are mounted in bronze lined self-oiling bearings provided with large oil reservoirs. All of the bearings and gears are entirely enclosed and furnished with a continuous supply of oil from a tank in the headstock. This tank is kept filled by a geared pump which draws oil from a tank located in the bed of the machine. All surplus oil drains back into this tank, the oil being filtered before it is used a second time.

The tool carriage has a bearing on the bed for its full length at both the front and back. It is gibbed underneath the track on both the inside and outside. The edges of the carriage are raised, drains being provided to prevent the lubricant from running onto the floor, and as the drainage surface is below the tool-slide guides, the latter are protected from chips and water. The tool-slide travels on a wide bridge, which is of such length that the sliding surface on the carriage is not exposed when the largest diameters for which the lathe is adapted are being turned. The tool-block or carrier is secured to the top of the tool-slide by means of four heavy bolts and a cross-key. It has two open-side slots and one closed central slot, which are large enough to receive tools 1¼ by 2½ inches in size. Each slot is provided with a hardened, serrated plate and three clamping screws. Cutting lubricant is supplied to the tool by means of a geared pump located at the headstock, and telescopic piping at the back of the bed conducts the lubricant to the tool carriage, from which it is returned to a tank at the head end of the lathe. The apron is of ribbed box construction, and the feed gear shafts are supported at both ends, all rotating shafts running in bronze bearings. The center-rest is of heavy construction, and provided with three adjustable jaws with large wearing surfaces.

The tailstock is especially heavy, but may be readily moved by gearing engaging with the steel feed rack. A graduated set-over is provided for turning small tapers. The tailstock can be rigidly clamped to the bed of the lathe by four large bolts, and a tail-brace engages a rack in the bed, thus preventing the possibility of the tailstock slipping under heavy loads. The bed is wide and deep, and has flat tracks tied together at short intervals by heavy box section ties. The bed is mounted on short legs in a deep steel pan which entirely surrounds the machine and extends beyond the sides a sufficient distance to prevent the cutting fluid from dripping onto the floor. The pan is also mounted on legs, thus providing space underneath it for a wheeled tank which is placed at the head end to collect the lubricant.

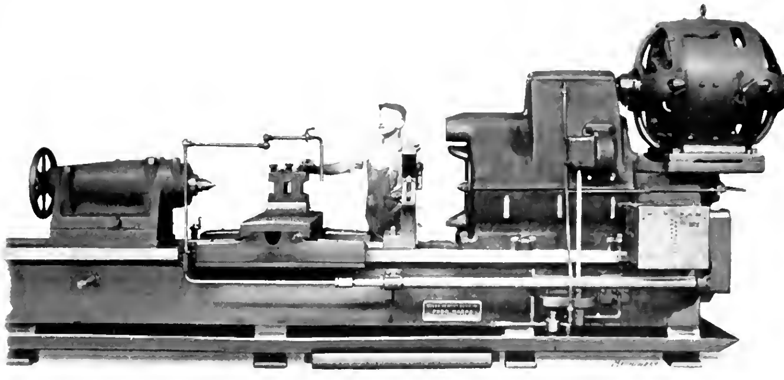

Fig. 2. Rear View of Pond Rapid Reduction Lathe

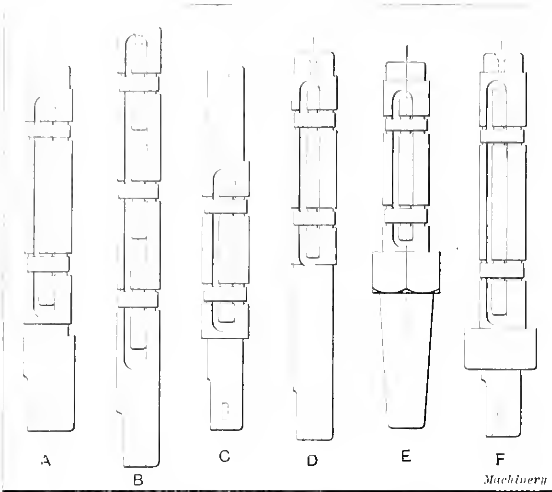
ALERT ROLLER MANDRELS

Six styles of roller mandrels which are now being manufactured by the Alert Tool Co., 221-223 N. 23 St., Philadelphia, Pa., are illustrated herewith. These mandrels are particularly suited for various classes of second-operation work, and their use enables the work to be set up with the greatest possible dispatch. Referring to the illustration, it will be seen that a

longitudinal groove is milled in each mandrel, the position of this groove being slightly off center. One or more hardened rollers—according to the style of mandrel—are carried in this groove. By having the groove off center the roller drops below the circumference of the mandrel at one side of the groove, but when the mandrel is turned to the left the roller moves over and binds the work securely in place. From the preceding description it will be evident that the principle upon which this type of mandrel operates is similar to that of the roller clutch. Transverse grooves are machined around the mandrel, and spring collars fit in these grooves to hold the rollers in place.



Six Different Types of Alert Roller Mandrels

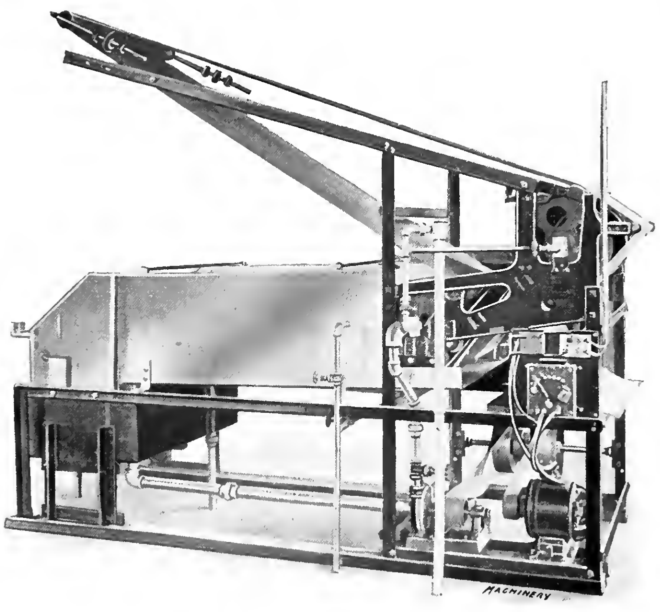
The following gives a brief description of the classes of work for which the different styles of mandrels shown in the illustration are intended: The mandrel shown at *A* is the standard type which is intended for the work of the tool-room, jobbing shop and similar purposes. A multiple roll type of mandrel is shown at *B*. This is intended for grinding or turning more than one piece of work at a single setting. Mandrels of this kind are made with any required number of rolls that is consistent with good practice, and effect a great saving of time in the production of duplicate work. The double facing type of mandrel is shown at *C*. This mandrel is intended for turning, facing, grinding or forming operations, and both faces of the work can be finished without requiring it to be removed from the machine. A double facing tool can be used to advantage with this mandrel. A single facing type of mandrel is illustrated at *D*; this is similar to the double facing type except that it is made shorter. It is used for facing one end of a piece of work at a setting and can also be used for turning, forming or grinding. The taper shank stub type of mandrel shown at *E* is intended for use in a turret lathe, engine lathe, milling machine or any other type of machine having a taper spindle. It is adapted for turning, facing and grinding operations. A special turning and facing type of roller mandrel is shown at *F*. This mandrel has a stop for locating the work longitudinally, and is particularly convenient for turning and facing duplicate parts, without altering the position of the tool. It will be noted by referring to the illustration that five of these mandrels have a flat ground on them to provide for the use of a driving dog, while the taper shank mandrel is driven in the usual way. It will be readily appreciated that the facility with which work can be set up on these mandrels effects a material saving in the cost of machining.

AUTOMATIC BLUEPRINT FINISHER

The automatic blueprint finisher illustrated herewith is a recent production of the Technical Supply Co., of Scranton, Pa. This machine facilitates the speed with which blueprints can be dried, and also turns out the prints perfectly smooth so that they occupy less space in the filing cabinets. In using this machine, the blueprint, as it comes from the printing frame, is placed upon a traveling belt which carries it under a series of pipes that spray water upon it. In this way the print is washed and made ready to be passed on to the drier. The wash water is delivered by a series of pipes which run the entire length of the belt. These pipes are equipped with spray nozzles which deliver water over the entire width of the belt, and after flowing over the blueprint, the water runs down into the tank, from which it is pumped back to the pipes. Before leaving the wet belt, fresh water is sprayed onto the blueprint. About fifteen or twenty gallons of fresh water is used per hour.

After being washed according to the method described in the preceding paragraph, the blueprint is taken up by a dry belt, which carries it over a stationary drier where the preliminary drying takes place. The print is then transferred to a heavy canvas belt which holds it in contact with a revolving drum that is heated by gas or electricity, as desired. The print remains in contact with this drum during one complete revolution and is then passed out of the machine onto a table or stand placed in position to receive it. The contact with the drum has completely dried the print, and also "ironed" it, so that it emerges from the machine perfectly smooth. The only manual labor connected with the operation of this machine is to place the print in position on the first belt; after this has been done the operation is entirely automatic.

An idea of the rapidity with which blueprints may be finished on this machine may be gathered by the following.: A print 15 by 20 inches in size can be passed through at the slowest speed of the machine and completely washed, dried and ironed in about two minutes and twenty seconds. With the machine operating at its highest speed, the same print would be completely washed, dried and ironed in one minute and ten seconds. Prints may be finished at the rate of $4\frac{1}{2}$ to $7\frac{3}{4}$ square feet per minute, and in a ten-hour working day a 42-inch machine will wash, dry and iron 7000 square feet of blueprints. The machine is of simple construction and the design is very compact. It is manufactured by Benjamin Levi, 355 West Broadway, New York City.



Automatic Machine for washing and drying Blueprints

PRATT & WHITNEY DISK GRINDER

There are certain classes of work finished by grinding, in which it is preferable to have the finish lines circumferential, instead of having the radial lines which result from the use of a cupwheel. To meet the requirements of such work, and especially for circular grinding where the surfaces to be ground are at various heights, the Pratt & Whitney Co., Hartford, Conn., has brought out a new grinder, front and rear views

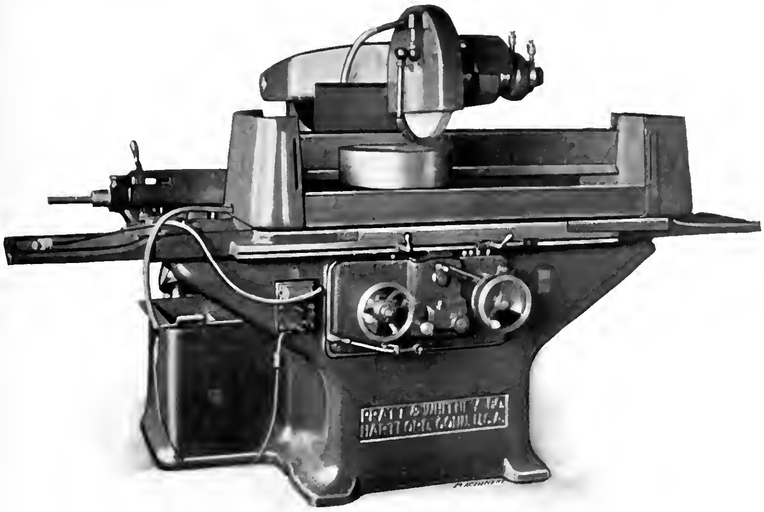


Fig. 1. Front View of Pratt & Whitney Disk Grinder showing Control Mechanism

of which are illustrated in Figs. 1 and 2. This machine has also been found very satisfactory for grinding thin hardened disks, as there is relatively little heat generated during the grinding processes, so that the work may be finished without distortion. Another application is the grinding of large piston rings and similar classes of work, the large wheel used on this machine handling such pieces without perceptible wear.

The bed, table and table feed mechanism are similar in design to the 14-inch vertical surface grinder of this company's manufacture. The machine is adapted for using a large size wheel, which is adequately supported and powerfully driven. Referring to the illustrations, it will be seen that the wheel is mounted at right angles to the work and provision is made for delivering a liberal supply of water during the grinding operation. The bed is massively proportioned and internally braced in a manner that insures ample rigidity and permanent alignment; it is of compact design, and the various units are located in a way that makes them easily accessible. Wide bearing surfaces of the vee and flat types are provided, and oil reservoirs for automatically oiling the ways are located in the bed. The pan which surrounds the rear of the bed for collecting the water and chips is of liberal proportions and easily accessible for cleaning.

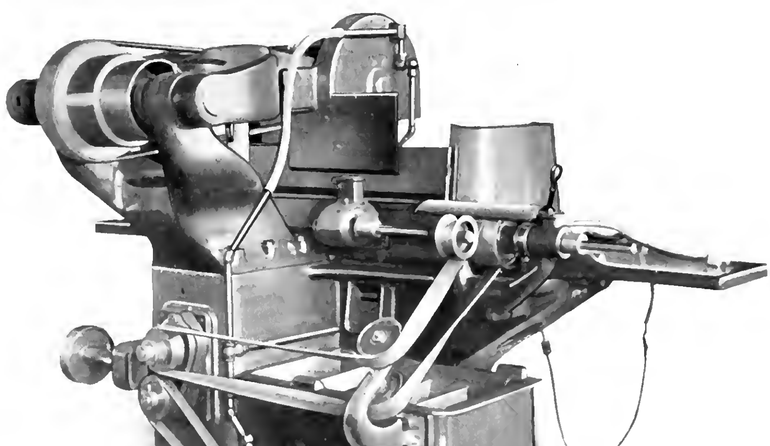

Fig. 2. Rear View of Pratt & Whitney Disk Grinder showing Wheel Support and Arrangement of Drive

The table is of heavy construction and powerfully ribbed to prevent warping and resist torsional strains. Both the bed and table are finished to masters, which insures perfect accuracy; the table is slightly longer than the bed and the traveling action keeps the bearings perfectly true. Guards are provided at each end of the table, which cover the bearings and protect them from injury. A pan is cast integral with the table for controlling the water. The work-holding problem is simplified by the use of a rotary magnetic chuck which forms part of the equipment of this machine. The features of these chucks were discussed in connection with the description of this company's 22-inch vertical surface grinder, which was published in the September number of MACHINERY. At this point it may be stated that they combine accuracy, durability and a low power consumption; they are also absolutely waterproof, the drive units being located outside of the water guard, thus making it impossible for water to get into the chuck. Lubrication is effected by means of large self-feeding reservoirs.

The table is provided with an automatic reciprocating motion, the desired length of stroke being obtained by means of adjustable table dogs. The table feed mechanism is designed as a simple and compact unit, which is easily accessible. Two table feeds are provided, both of which are instantly controlled by means of a lever located at the front of the machine. When adjusted to the central station, this lever serves as a means for stopping the table; when placed in the upper position, the slow feed is engaged; and when located at the lower station, the fast feed is brought into action. The table is driven through a vertically located rack and pinion, the construction being such that the possibility of vibrations commonly called "tooth marks" showing in the work is eliminated.

One of the important features of this machine is mounting the wheel on an arm, which entirely eliminates the use of a slide construction. The arm is accurately fitted on an arbor, which, in turn, is supported by an upright at the rear of the machine. Both the arm and arbor are of ample proportions to insure absolute strength and rigidity. With this construction, the wheel is supported without overhang, and the control of the vertical wheel feed is also made a simple matter. Referring to the rear view of the machine, shown in Fig. 2, the arrangement of this method of supporting the wheel will be readily apparent, and it will also be seen that the arm has a liberal bearing upon the arbor, the bearing surfaces being dust- and water-proof. Both hand and power vertical wheel feeds are provided. The feed mechanism operates a screw, which engages the under side of the arm upon which the

wheel is mounted, thus adjusting its position as desired. Both the elevating screw and nut are of liberal proportions and made easily accessible; the power feed is obtained by means of a ratchet wheel and pawl which act in connection with the elevating screw. Provision is made for automatically disengaging the power feed and the feed may be accurately gaged by means of a large dial, the periphery of which is graduated to thousandths of an inch. The feed operates at the end of each stroke when the wheel is entirely clear of the work.

The wheel spindle is made of tool steel and is first carefully heat treated, and then ground and lapped to obtain the highest possible efficiency for this important member. The bearings are bronze bushed and mounted in conical seats; they are mad · and located in such a way that they are easily accessible for adjustment and absolutely dust- and water-proof. Particular care has been taken to obtain proper lubrication, large self-feeding oilers being provided for this purpose. The wheel-mount is self-contained and constructed in a way that insures having the wheel held securely and perfectly true. The end of the spindle is made conical to receive the wheel-mount, which is positively driven by means of a key. The machine is designed to use wheels up to 18 inches in diameter by 2 inches in width, but suitable packing rings are provided to permit the use of wheels down to a face width of 1 inch. The wheel spindle drive is of liberal proportions so that there is no question as to whether the wheel will have power for the most severe classes of service for which the machine is intended. Two speeds are provided by means of a two-step cone pulley so that when the diameter of the wheel is reduced by wear, its speed may be proportionally increased.

It is well known that in order to keep a grinding wheel cutting freely and to prevent the work from heating, a liberal supply of water is absolutely necessary. This point has been given careful attention and the pump that is used is made and located in a such a way that it entirely dispenses with the use of the customary type of idler pulleys. The pump is capable of delivering an abundant supply of water, which is drawn from a tank located at the back of the machine, where it is readily accessible for cleaning. The arrangement is such that the water is returned to the tank without being carried through pipes. This is characteristic of the design of the machine throughout, care having been taken to guard against the possibility of dirt or grit collecting in inaccessible places.

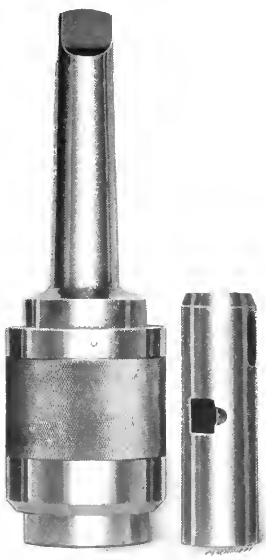

Fig. 2. The Wiard Chuck

The pipe through which the water is conveyed to the wheel, is attached to the guard and may be quickly adjusted or removed according to the requirements of different classes of work. Both the table and wheel are provided with guards to prevent water from being thrown onto the floor.

WIARD CHUCK

The Wiard chuck was originally made for the use of the Wiard Mfg. Co. This firm is engaged in contract work on automobile parts and the chuck was designed with the view of reducing the cost of various machining operations so that a profit could be made on contracts taken at a low price. The chuck proved to be so satisfactory that Mr. F. Wiard, 724 Ford Building, Detroit, Mich., recently decided to place it on the market. One of the larger sized chucks is illustrated in Fig. 2; the parts of the chuck are shown in Fig. 3, and Fig. 1 shows a cross-sectional view from which the construction will be readily apparent.

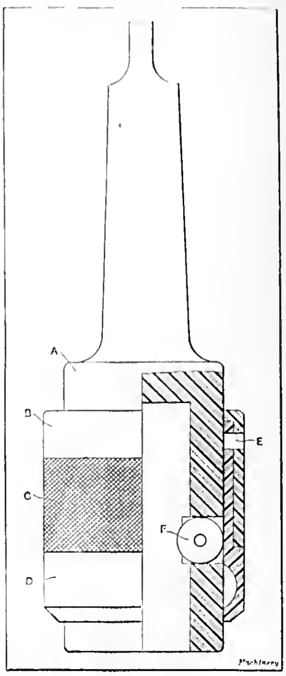

Fig. 1. Sectional View of the Wiard Chuck

Referring to the cross-sectional view, it will be seen that the body of the chuck *A* has a taper shank which fits into the drill press spindle. Surrounding this body is a sliding sleeve which is held in position by means of a pin in the body of the chuck which extends into a slot in the sleeve. The sliding sleeve is built up of three members, *B*, *C* and *D*; the parts *B* and *D* are secured together by means of a pin *E* while the knurled collar *C* is free to rotate around the chuck body. Two hardened steel disks *F* are held in place in the body of the chuck by means of pins which slide in transverse slots. This arrangement will be better understood by referring to the detail of the chuck body which is shown in Fig. 3. The purpose of these disks is to hold the collet in which the drill or other tool is mounted in position in the chuck and also to afford a positive drive. In order to set up a tool in the chuck, the operator takes hold of the knurled ring *C* with his thumb and finger and raises the sliding sleeve

Fig. 3. Parts of the Wiard Chuck

so that the hardened disks *F* are free to move back into the recesses in the sleeve. The collet is then pushed up into the socket in the chuck and when the sliding sleeve is pushed down, the disks *F* are forced into the recesses which are machined in the collet, thus providing a positive drive.

The chuck and collet are numbered according to the taper number of the drill. For instance, the No. 2 chuck takes drills up to 29/32 inch, which is the No. 2 taper limit. The shank of the No. 2 chuck is a No. 3 taper or one size larger than that of the drill; this standard is adhered to in all different sizes of the Wiard chuck. All of the wearing parts of the chuck and collet are hardened and ground to special gages. During a recent test, twenty-five holes were drilled in a cast-iron block 2¾ inches square by 1 inch thick. Two ¾-inch drills were mounted in collets and the operator used alternate drills for drilling successive holes. The twenty-five holes were finished in four minutes and 21½ seconds which shows the rapidity with which tools may be changed in this chuck.

WATSON-STILLMAN HYDRAULIC SHEAR

A horizontal hydraulic shear with a capacity for cutting 4½-inch steel cables has recently been placed on the market by the Watson-Stillman Co., 192 Fulton St., New York City. The machine is also capable of shearing a variety of large sizes of rolled steel, and its general arrangement will be readily understood by referring to the accompanying illustration.

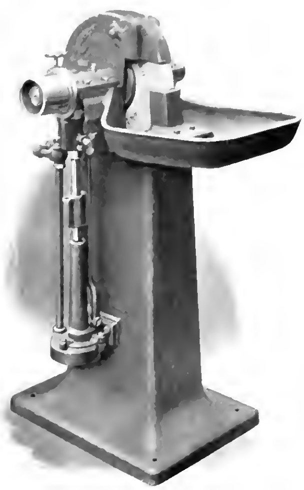
Watson-Stillman 175-ton Hydraulic Shear

It will be seen that the shear is mounted on a truck, upon which it may be conveniently moved about the shop to any position where shearing operations are to be performed.

The pump is entirely independent of the cylinder, and the valves and pump parts are easily accessible. In shops equipped with a hydraulic system, the hand pump may be eliminated and direct connection made with the high pressure pipe line. The ram and cutter are guided by a slide which runs in a groove machined in the frame of the shear. After the ram has completed its cutting stroke, the pressure is released by turning the handwheel on the pump, after which the ram is returned by a rack and pinion. The lever which actuates this rack and pinion movement is seen in the illustration extending out to the left. A spring is provided which absorbs the shock of the sudden jump forward which the ram makes at the instant of rupture, and thus protects the teeth of the rack and pinion from excessive strains. A gage is connected with the pipe line which supplies the machine in order to indicate the operating pressure at all times.

BLOUNT WET TOOL GRINDER

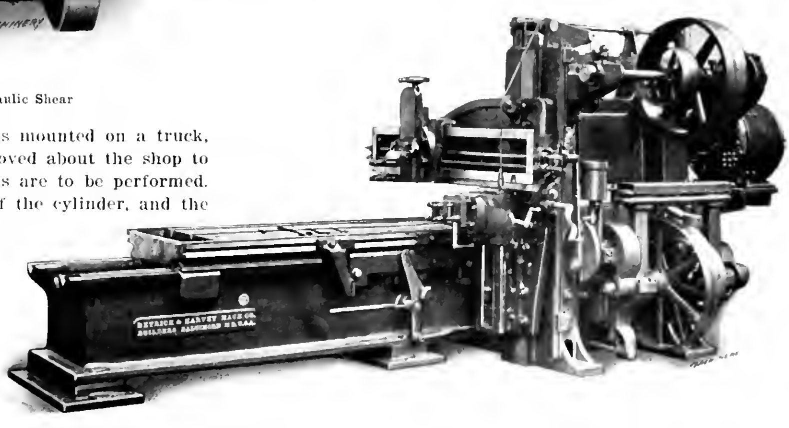
The accompanying illustration shows a 14-inch wet tool grinder, the design of which is similar to the machine equipped with a 30 by 3-inch wheel which was referred to in the July 1912 number of MACHINERY. The present machine, however, is of lighter construction and is intended to meet the requirements of shops having work for a smaller sized machine. It will be seen that a vertical centrifugal pump is provided which furnishes a constant supply of water the volume of which may be regulated to meet the requirements of different classes of work. The pump is driven by a friction pulley which engages a flange on the inner side of the main driving pulley. A sleeve covers the pump and encircles the pump shaft, extending above the water line. The purpose of this sleeve is to prevent water from leaking onto the floor without requiring the use of packing. The tank is located in the column of the machine and holds an ample supply of water; an opening is provided through which the tank may be cleaned if necessary. This grinder is a recent product of the J. G. Blount Co., Everett, Mass.



Blount 14-inch Wet Tool Grinder

DETRICK & HARVEY OPEN-SIDE PLANER

A 36-inch by 24-inch by 8-foot open-side planer which was recently built by the Detrick & Harvey Machine Co., Baltimore, Md., for use on the U. S. repair ships *Vestal*, *Panther* and *Culgoa*, is shown in the accompanying illustration. It will be seen that this planer is driven by an individual motor, a Morse silent chain being used for connecting the motor to the machine. The cross-rail is provided with one head which has horizontal, vertical or angular feeds by hand or power. A side head is also provided which has vertical hand and power feeds, and horizontal hand adjustment.



Detrick & Harvey 36-inch by 24-inch by 8 foot Open-side Planer

The bed is provided with substantial cross girts at frequent intervals and suitable lubricating devices for oiling the table vees. The vees are 21 inches between centers and each vee is 1½ inches wide at the top. The included angle of the vees is

90 degrees. The bed is 12 feet 8 inches long between the end pockets, and the bearings for the driving shaft are cast integral with the bed and provided with bronze bushings. The table is 32 inches wide by 8 feet long between the end pockets. Three T-slots are planed in it and a number of rectangular cored stop holes are also provided to facilitate securing the work in place. The table is gibbed down on both sides to prevent the possibility of its lifting.

The post is of box section and reinforced by extensions at the front and rear which extend to the full height of the post. The cross-rail is an L-shaped casting with the leg bearing on the face of the post, 11 1/4 inches wide by 51 inches long. The length of this vertical support of the cross-rail is about 1 1/3 times the length of the overhanging arm in order to give the necessary rigidity, and the horizontal portion of the cross-rail is cast integral with the vertical leg. The cross-rail is further supported by a triangular brace secured to the rear surface of the overhanging arm and extending to the inner face at the rear of the post. That part of the vertical leg of the cross-rail which projects downward from the horizontal slide-way, has a slide-way on its front face upon which the side-head is mounted. This reduces the distance from the cutting tool to the ultimate point of support, and does away with the use of a sliding saddle, when the side-head is mounted directly upon the post.

The feed mechanism is of the positive friction type, and only consumes power when in use. The drive is of the Sellers worm-gear type, the machine being driven by a 10 horsepower constant-speed motor which is direct-connected to the countershaft on the planer post by a silent chain drive. The countershaft revolves in a line parallel to the line of travel of the table and is belted to the planer pulleys. Power is transmitted through a pair of bevel gears to a diagonal shaft on which the multiple threaded worm is mounted, which engages the rack under the table. The cutting speed is 50 feet per minute and the return speed 90 feet per minute. The planer occupies a floor space not over 9 feet wide by 20 feet long, and weighs 21,000 pounds.

PAWLING & HARNISCHFEGER HOIST

The intensive methods of manufacturing that are used in modern industrial plants make efficient methods of handling material and product a matter of the greatest importance. Various systems have been developed for this purpose, among which different forms of cranes, hoists and trucks may be mentioned.

The accompanying illustrations show three forms of hoists which have recently been brought out by the Pawling & Harnischfeger Co., Milwaukee, Wis. Referring to these illustrations, it will be seen that the hoist shown in Fig. 1 is arranged for hook suspension; Fig. 3 illustrates a hoist with the truck operated by a hand chain; and Fig. 2 shows a hoist which is motor-driven and provided with controllers which may be operated from the floor. The frame of these hoists is of symmetrical design, the drum being located at the center and surrounded by a frame of cast steel. The motor of the hoist shown in Fig. 2 is secured to one side of the frame and the gear case is located at the opposite side.

The wire rope is of plow steel and proportioned to give a factor of safety of 5. The drum is flanged and provided with grooves of a depth equal to the diameter of the rope, so that the rope is not apt to jump out of the grooves even if the pull is in a sidewise direction. The standard lift of these hoists is 15 feet. The load brake runs at a moderate speed and is located so that a minimum number of parts is interposed between it and the drum. The load is automatically held at all times and cannot be dropped through carelessness of the operator or the interruption of current. In order to let the load down, the motor must be reversed.

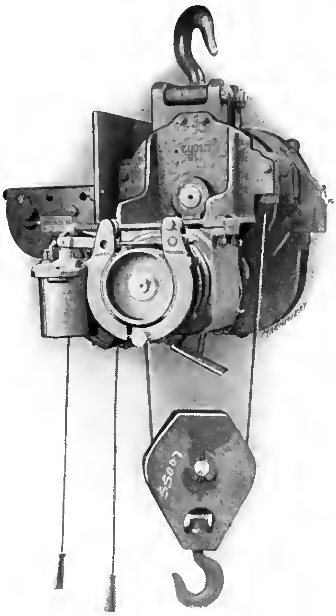


Fig. 1. Pawling & Harnischfeger Hoist arranged for Hook Suspension

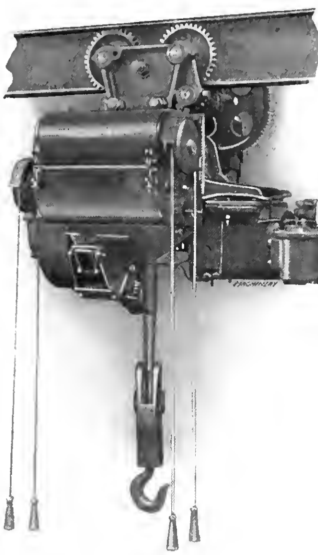

Fig. 2. Motor-driven Pawling & Harnischfeger Hoist

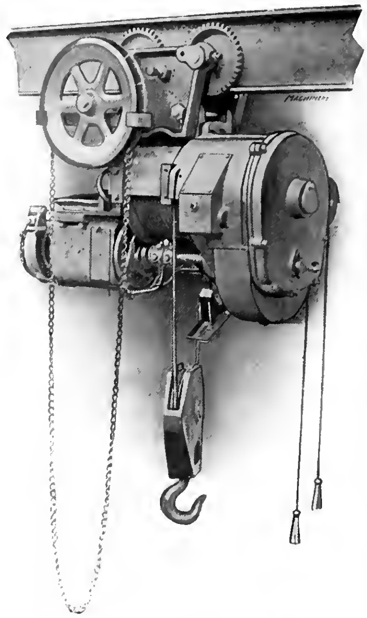

Fig. 3. Pawling & Harnischfeger Hoist operated by a Hand Chain

All of the gears are of cast steel and the pinions are of forged steel, both gears and pinions being hardened. The hoist gears and the load brake are enclosed in a dust- and oil-proof case and thoroughly lubricated by the splash system which gives them a high transmission efficiency and long life. Spur gears are used exclusively, as experience has shown them to be the most satisfactory for this class of service.

The truck is bolted to the cast-steel drum frame and the truck wheels are drop-forgings. The chain wheel, which is used on the hand-driven truck, is provided with a chain guard; and on the motor-driven truck the four truck wheels are driven to facilitate running over short curves. The motor used on the hoist shown in Fig. 2 is provided with a substantial asbestos lined solenoid brake, which will stop the motor promptly after the controller has been moved to the off-position. When the bottom block reaches the highest position, it strikes a limit switch which shuts off the current and brings the motor to a stop by means of the motor brake. A load cannot be hoisted any higher but it can be lowered in the usual way, and as soon as the load is let down, the limit switch re-sets itself automatically. Direct-current motors manufactured by the Pawling & Harnischfeger Co. are used on these hoists. These motors are especially designed for crane

service and run at a moderate speed. Alternating-current motors can be furnished if so desired.

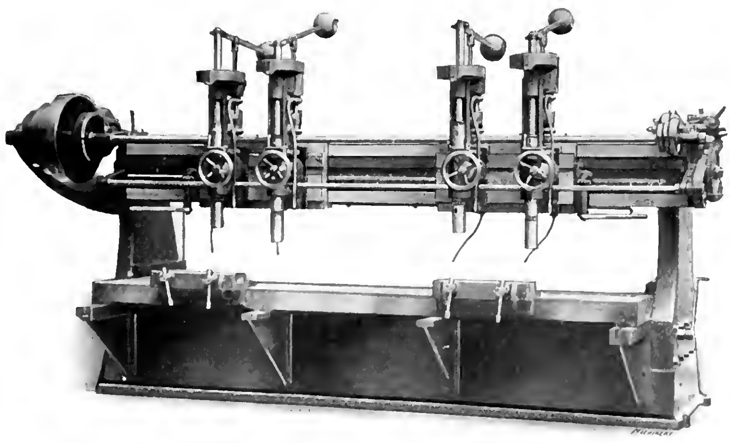
The controller used on these hoists is of the drum type and is provided with a large number of speed points. The use of single-speed controllers is not recommended as they do not permit of any speed regulation and are out of the question where any degree of precision in handling the load is required. They have the further draw-back that the contact points burn off rapidly, and in the long run repairs and renewals cost more than the original cost of a multi-speed controller.

The combination of a multi-speed controller, a substantial solenoid motor brake and a liberally proportioned load brake gives an efficient speed control to these hoists. Particular care has been taken throughout the design, to make all parts of the mechanism readily accessible for adjustment. The motor, gear case and controller are separate units and can be removed independently. The load brake or any of the gears can be removed without disturbing other parts of the hoist.

FOOTE-BURT FLUE SHEET DRILL

The four-spindle drilling machine illustrated herewith is an addition to the line of machines manufactured by the Foote-Burt Co., Cleveland, Ohio. This machine is styled a No. 2 mud-ring and flue-sheet drill and is particularly suited for the requirements of railroad locomotive boiler shops and general boiler shops, for use in drilling the rivet holes around a mud ring or for cutting out the flue holes in a flue sheet. The spindles are of the independent feed type, each spindle being provided with an automatic knock-off for the power feed and quick return of the spindle by a handwheel located at the front of the head. Each spindle is also provided with a clutch for starting and stopping, and an interlocking mechanism, so that the feed cannot be thrown in with the spindle stopped or *vice versa*. With this independent feed mechanism it is possible to have some of the spindles drilling while the operator is setting the other spindles so that a high efficiency of both the machine and operator is obtained.

The spindles are arranged in pairs which are mounted on auxiliary cross-rails, and the spindles are adjustable on these cross-rails to a minimum center distance of 8 inches. The advantage of this feature is that it is possible to set the spindles to the proper spacing of the rivet or flue holes and then adjust two spindles along the main rail of the machine, thus maintaining the proper spacing and eliminating the

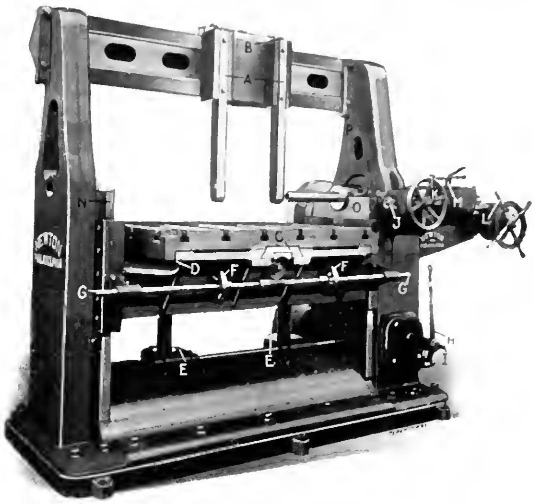


Foote-Burt No. 2 Mud-ring and Flue-sheet Drill

necessity of spacing each spindle individually. The spindles overhang the front edge of the base 8 inches to take care of the mud ring work, and the table is provided with chucks for holding the mud rings. The table has an in and out movement of 36 inches and is supported under the spindles by bracket slides on the front of the base. Three changes of power feed are provided, any one of which is instantly available by simply shifting a lever at the right-hand end of the machine. Six changes of speed are provided by means of the three-step cone and throw-out back gears. The weight of the machine is approximately 21,000 pounds.

NEWTON TOOL-ROOM BORING MACHINE

The accompanying illustration shows what is known as a tool-room boring machine, which has recently been added to the line of the Newton Machine Tool Works, Inc., Philadelphia, Pa. This machine is intended for boring operations on jigs and fixtures, and for other classes of work where a high degree



Newton Tool-room Boring Machine

of accuracy is required. One of the noteworthy features of the design is the "aerial" cross-rail which is provided with an adjustable slide on which the boring bar supports *A* are mounted. These supports are interchangeable, and they are made in a number of irregular shapes to provide for supporting the bar in positions which would otherwise be inaccessible. In addition to the side bearings in the slide, an end stop is provided to insure accurate alignment.

The cross adjustment of the table is provided by a narrow guide *C* which has a double taper bearing in the saddle, and end locking gibs *D* are employed to hold the work table securely to the saddle. The knee is raised or lowered by screws *E*, and the bearings for these screws are exceptionally long to provide the necessary rigidity. The cross movement of the table is obtained through a worm and worm-wheel and a fine pitch screw controlled by means of handwheels *F*, while a more rapid adjustment is obtained with a wrench on the square ends of the spline shaft *G*.

Power elevation of the knee is controlled by the lever *H* and hand elevation and fine hand adjustments are obtained by a wrench on the square end of the shaft *I*. The feed motion of the spindle is engaged by the arm *J*; slow hand adjustment of the spindle is obtained by means of wheel *K* and fast hand adjustment through the wheel *L*. The gear feed changes are controlled by the latch lever *M*, which operates the movable sleeves on which the gears are mounted and gives the changes without requiring the removal of gears. The alignment of the knee supporting the table is insured by four side bearings on the uprights, one of which is shown at *N*, and the end thrust is taken on bearings *O* on the upright. It is, of course, understood that the rail support *P* is independent of the spindle cap.

The following gives a brief description of the mechanical features of this machine: The spindle is 3 inches in diameter

and has a No. 5 Morse taper. it is driven by a sleeve having a bearing on each side of the driving worm-wheel, and is arranged to drive cutters or a boring bar with a broad faced key. The length of the boring bar is 6 feet 8 inches and the length of the continuous feed which may be obtained is 24 inches. The spindle sleeve is driven by a steep pitch bronze worm-wheel provided with ball thrust bearings. The spindle speeds vary from 12 to 120 revolutions per minute. Power is supplied by a General Electric $5\frac{1}{2}$ horsepower motor running at from 375 to 1125 revolutions per minute. A double step cone pulley for a 4 inch belt is used to transmit the power to the machine. The work table is 60 by 48 inches in size and provided with the customary T-slots to facilitate clamping and to accommodate parallels. In addition to the T-slots shown in the illustration, there are four additional T-slots in the table running parallel with the spindle of the machine. The maximum distance from the end of the spindle to the outer upright is 72 inches; the minimum distance from center of the spindle to the top of the table is $1\frac{3}{4}$ inch and the maximum distance is 24 inches. The net weight of the machine is 22,000 pounds.

ACME FLAT TURRET LATHE

The illustrations show what is known as a combination flat turret lathe, that is a recent product of the Acme Machine Tool Co., Cincinnati, Ohio. The term "combination" is applied to this machine because it is adaptable to both bar and chucking work. A complete view of the machine arranged for chucking operations is shown in Fig. 1, while Fig. 2 shows the head end of the machine provided with a collet chuck to adapt it for bar work. The maximum capacity for bar stock is $3\frac{1}{4}$ inches in diameter by 36 inches in length, while all classes of chucking work up to 16 inches in diameter can be handled. The actual swing over the bed of the lathe is 22 inches. The bed is of deep and heavy section and is strongly ribbed to withstand the cutting strains when the maximum pulling power of the all-geared head is being utilized. The pan blocks and tank are cast integral with the pan, which is of unusual depth and capacity. A perforated cover serves as a strainer which allows the oil to drain off the chips and flow back into the tank. A geared pump provides an ample supply of oil when the machine is running.

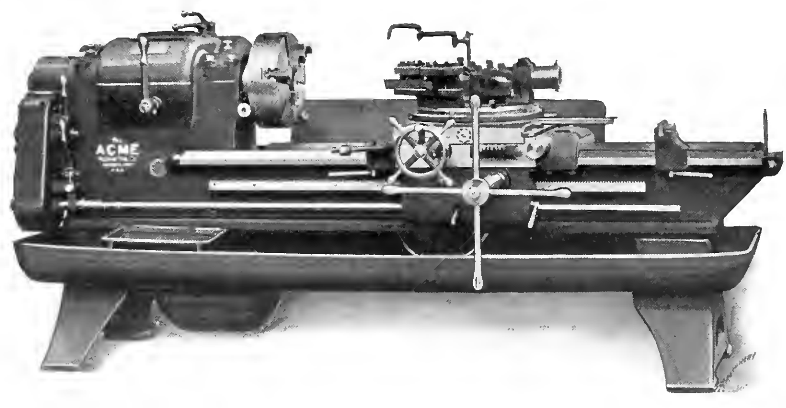


Fig. 1. Acme Flat Turret Lathe arranged for Chucking Operations

Nine changes of speed are provided by the geared head which is of simple construction. The available speed range is from 14 to 285 revolutions per minute, the changes being quickly obtained by means of two levers located at the front of the head. The head is cast integral with the bed which simplifies the construction and also insures the permanency of the alignment of the spindle with the vees upon which the carriage travels. The spindle is made of high carbon crucible steel and may be instantly started, stopped or reversed by means of a double cone friction operated by a lever at the front of the head. The drive is taken from a single pulley 12 inches in diameter, which runs at 600 revolutions per minute and carries a $3\frac{1}{2}$ inch belt. The positive automatic chuck for holding bar work is illustrated in Fig. 2; it can be opened and closed while the machine is running, by means of the long lever at the front of the head. The distinctive feature of this chuck is that the work does not have end motion while the chuck is being closed so that accurate shoulder lengths can be produced. The master collet parts which hold the jaws are secured against the closing ring, which prevents dirt or chips from getting between them. The jaws do not collapse and extremely short work can be held

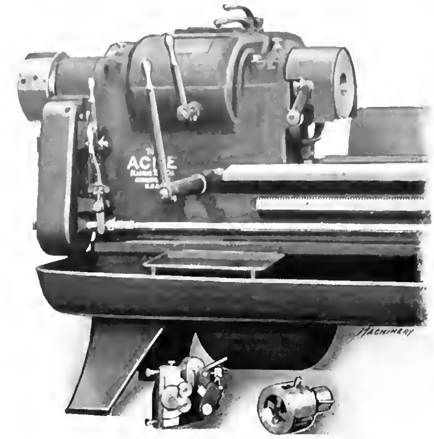

Fig. 2. Acme Flat Turret Lathe for Bar Work

without tilting; adjustment for variations in diameter 1/16 inch larger or smaller are provided. The jaws can be easily removed without dismantling the chuck, and to insure accuracy and long life all working parts of the chuck are hardened and ground. The simplex roller feed is extremely simple in design and operation, only one adjustment being necessary. By adjusting the jaws to the required size with a spanner wrench and then releasing them slightly, the rollers will be given the proper tension. The roller feed is operated by the same lever which actuates the automatic chuck.

The cross-sliding turret revolves on a hardened and ground stem of large diameter and is automatically locked in position by a hardened and ground taper plunger located directly underneath the cutting tool. This plunger enters hardened taper bushings in the turret, and the turret is further held down at the extreme outer edge by means of circular clamps. The oiling arrangement is such that lubricant can be delivered to each individual tool. The cross-slide moves on a long narrow dovetailed guide with flat bearing surfaces on each side and has an adjustable gib to compensate for wear. A hardened center stop is also provided. The cross-feed, which is operated by hand or power in either direction, is provided with a graduated pilot handwheel to facilitate the production of duplicate work. The saddle has a continuous bearing on two vees of the bed and the swinging stock stop is attached at the front of it. One independent stop is provided for each turret face and there are also six auxiliary stops which are operated by a knob on the front of the saddle. These can be used in any desired combination with the independent stops. Eight stops are provided for the cross-feed, which are controlled by a knob on the front of the slide; these can be used to advantage in conjunction with the graduated pilot wheel. The stops are arranged to trip the power feed in either direction and when chuck work is being handled, as many as seven different lengths can be turned without indexing the turret. Safety stops are provided to trip the power

feeds in all directions and all working parts are protected from dirt and chips. The feed for both the longitudinal and cross movements is of the all-geared type; and all feed changes are instantly obtainable by means of the lower lever on the head-stock, while the upper lever provides for reversing the feeds. The feeds can be changed or reversed without stopping the machine.

The apron is of the double-wall construction, with all shafts and studs supported at both ends. It is securely bolted and keyed to the bottom of the saddle and provides a double bearing support for the feed-rod which is driven by a knuckle-joint coupling at the head end. By referring to the illustrations in connection with the preceding description, it will be readily seen that all of the operating levers on this lathe are located in positions where they may be conveniently reached by the operator. In this way, the time between operations is reduced to a minimum. Similarly, all oil holes are easily accessible and of a type which makes it impossible for dirt to find its way into the bearings. The machine is driven by a 5 H. P. constant speed motor which is operated at from 1200 to 1800 revolutions per minute. A convenient arrangement is to mount the motor on a sliding base on the floor and belt it directly to the driving pulley on the machine.

BRADFORD EIGHTEEN-INCH LATHE

In the March, 1912, number of MACHINERY, a motor-driven lathe built by the Bradford Machine Tool Co., Cincinnati, Ohio, was illustrated and described. The accompanying illustrations show a lathe of similar design which has been brought out by this company, the distinctive feature of the present machine being the application of single pulley drive through the geared head. Where the lineshaft is suitably located, a single pulley on this shaft affords a satisfactory arrangement for transmitting power to the machine. The regular equipment, however, consists of the usual double friction countershaft having both belts driving forward, or if more convenient having one belt for reversing. In some cases, a triple friction countershaft is used which affords sixteen forward and eight reversing speeds for the machine.

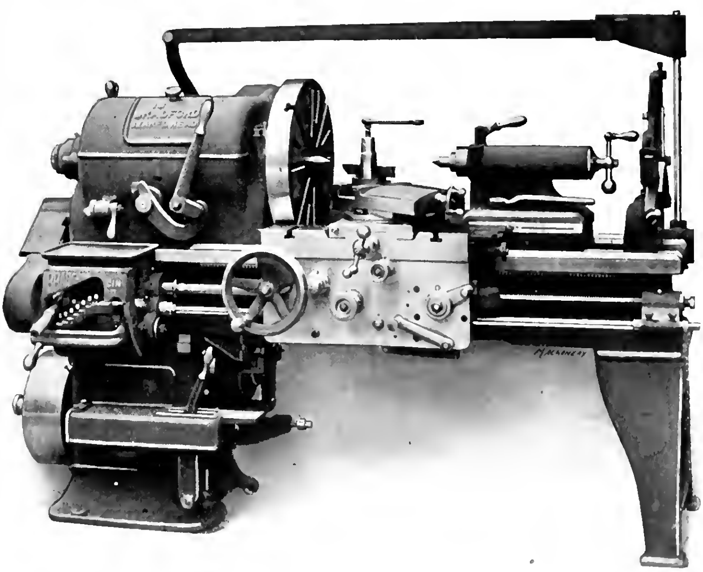

Fig. 1. Bradford 18-inch Lathe with Single Pulley Drive through Geared Head

An end view of the lathe is shown in Fig. 2, in which the arrangement of the single pulley drive is clearly shown. Referring to this illustration, it will be seen that the driving pulley is provided with a friction clutch which is controlled by a shifter pole running the full length of the lathe. This affords a convenient means of releasing or engaging the clutch on the initial driving pulley when making changes. A lever on the head is used for stopping or starting the lathe when it is required to make inspections or remove the work. The idler pulleys are mounted on a frame which may be adjusted downward and this adjustment provides for regulating the tension of the endless driving belt which is employed.

A selective type of speed box is used which consists es-

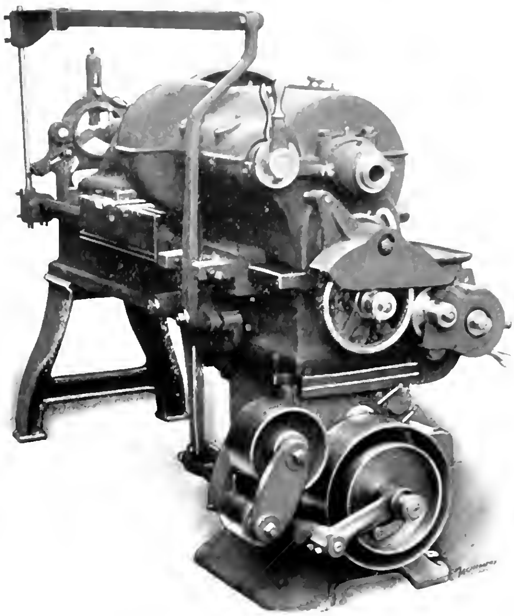

Fig. 2. End View of Bradford Lathe showing Arrangement of Single Pulley Drive

sentially of two shafts and eight gears, so that four changes are provided. Four gears are mounted on each shaft, those on the lower shaft being arranged in two groups, each containing two gears. Each of these pairs is made to slide independently of the other pair, by means of a single lever and two shifting forks. The shifting lever is so arranged that it is impossible for two gears to be engaged at the same time, and the gear shifting mechanism is positively and automatically locked when the lathe is running. This makes it impossible for the gearing to be damaged by a careless or inexperienced operator. The lower speed box shaft is extended to the left to carry the initial driving pulley, while the upper shaft in the speed box extends to the right and has a Morse silent-chain wheel mounted on it for transmitting power to the lathe head. The available spindle speeds are clearly marked on the speed plate opposite the four positions of the speed box lever. These four changes in connection with the right- and left-hand positions of the lever on the head, give all of the spindle speeds that may be obtained.

The lathe head is illustrated in Fig. 3 with the cover removed in order to show the arrangement of the gearing. It has already been stated that power is transmitted from the speed box to the head by means of a Morse silent chain drive. The Morse chain wheel is mounted on a short shaft upon which there is a gear which transmits the power to a friction driven gear on the main spindle. This spindle gear meshes with the first gear on the back shaft and the second back shaft gear transmits power to a positive clutch driven gear on the spindle. A lever on the head controls both the friction and positive clutches which engage the high and low speed gears on the spindle.

The change gears are of the standard Bradford type and give an ample range of feeds. All standard and pipe threads

can be cut and only one lever is required for making the changes. When not in use, the worm-wheel on the chasing dial may be swung out from the lead-screw to an inoperative position, so that unnecessary wear is avoided. The feeds are all positive geared through the feed-rod and any desired feed can be instantly engaged. The lathe has friction cross feed and also friction transverse feed for the carriage. An automatic stop is provided which may be placed in any position on the feed-rod. When required, a lead-screw and change gears to conform to the metric system may be provided on this lathe. The lead-screw is cut from a master-screw and is not splined, as a feed-rod is employed to save wear on the lead-screw and nut. The nut is made of phosphor-bronze and is tapped in a way which provides a high degree of accuracy.

The spindle is made of high-carbon crucible steel and is bored straight through from one end. The outside of the spindle is then turned parallel with the hole, after which it is finished by grinding. The tailstock is of the overhanging pattern which permits the use of the compound rest at right angles when turning between short centers. The tailstock can be set over for taper turning and the clamping arrangement is of a design which insures ample rigidity. The base of the compound rest is graduated in degrees and the wearing

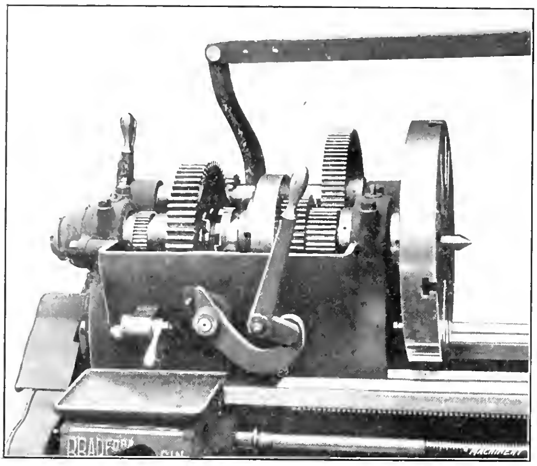

Fig. 3. Head of Bradford Lathe with Cover removed to show Arrangement of Gears

surfaces are liberally proportioned. The carriage has a full bearing on the vees for its entire length and is gibbed front and back. The apron is of the double-plate pattern and is provided with a non-interfering device so that the feed-rod and lead-screw cannot be engaged simultaneously.

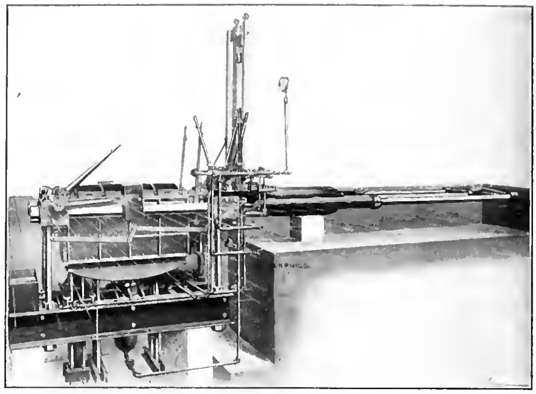
HYDRAULIC BALING PRESS

The horizontal baling press shown in the accompanying illustration constitutes a recent addition to the line of the Hydraulic Press Mfg. Co., 84 Lincoln Ave., Mt. Gilead, Ohio. It will be seen that this press is hydraulically operated; the machine is intended for baling scrap sheet metal and is capable of exerting pressures up to 200 tons. It can be used on scrap metal up to No. 10 gage.

The press is installed so that the top of the box is flush with the floor line. This makes it an easy matter to fork the scrap into the press without having to lift it. The box is 60 inches long by 20 inches wide by 30 inches deep, and the normal size of the bales produced in the press is 10 by 12 by 20 inches. The cast-steel door which forms the top of the box is counterbalanced and can be easily moved with the hand lever provided for that purpose.

The press is equipped with two hydraulic cylinders for pressure purposes, one of these cylinders being used for compressing the material against the top of the box and the other for compressing it against the end of the box. Two auxiliary cylinders are connected with the horizontal pressure cylinder for use in returning the horizontal ram. After the platen which constitutes the bottom of the box has completed its forward movement, it is locked in position by two hydraulically operated bolts which enter each end of the platen. These bolts prevent the platen from tilting while the horizontal pressure platen travels across it to compress material against the end of the box.

In the head end of the lower platen which forms the bottom of the box, there is a small ejecting platen operated by a 4-inch ram. The ram works in an ejecting cylinder located on the sills in the head end of the press. As the lower platen



Horizontal Hydraulic Press for baling Sheet Metal Scrap

travels upward, it carries the ejecting platen and ram with it. This permits the 4-inch cylinder to fill from the pump reservoir by gravity. As soon as the scrap metal has been pressed into a bale, the door constituting the top of the box opens automatically and pressure is then applied to the ejecting cylinder. This causes its ram and platen to rise and lifts the bale out of the box to the level of the floor line so that it can be easily moved.

The valve equipment required for operating all of the members of this hydraulic baling press is controlled by an interlocking device which compels the operator to throw each lever in its proper order. It is impossible to operate the machine in any other way. There is also a "tell-tale" board with an indicator governed by cables attached to the moving part of the press, which enables the operator to see the positions of the vertical and horizontal pressure platens at any moment during the period of operation.

ONEIDA DRILL CHUCK

Two styles of ball bearing drill chucks which have recently been added to the line of the Oneida National Chuck Co., Oneida, N. Y., are illustrated in Figs. 1 and 2. The general arrangement of these chucks is similar to that of a chuck which

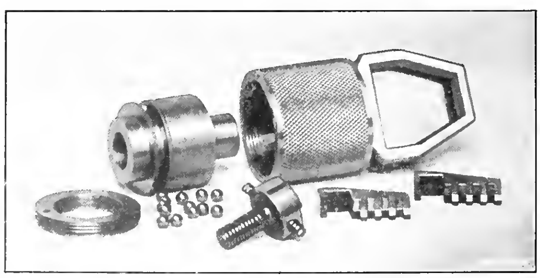


Fig. 1. Parts of the Oneida Ball Bearing Drill Chuck

this company has been manufacturing for several years. The improvements in the present design consist of having the jaws tightened on the shank of the drill through the resistance of the cut, instead of using a wrench for this purpose; and in having a ball bearing between the chuck body and the outer sleeve, so that the chuck may be readily opened by hand. Fig. 2 shows the style of chuck which is made for handling 1/4, 3/8 and 1/2-inch drills, while the parts of the open-body type of chuck for handling 3/4 and 1-inch drills are illustrated in

Fig. 1. Both the open- and closed-body chucks operate on the same principle.

In mounting a drill in this chuck, the drill is slipped into place between the jaws, and the knurled sleeve is then turned to bring the jaws into contact with the shank. A loose grip is secured in this way and the drill press is then started. As the drill begins to cut, the resistance continues the tightening of the jaws so that an adequate grip is secured. One of the features of this arrangement is that the grip on the drill increases with the resistance offered by the cut, so that the grip is proportional to the severity of the service. The chuck is opened by turning a knurled sleeve in the reverse direction.

Fig. 2. Oneida Drill Chuck

It will be evident from the illustration that the operation of the chuck jaws is effected by turning a screw which fits in the chuck body. The flange at the lower end of this screw fits into slots at the upper ends of the chuck jaws, and raises or lowers them in contact with the tapered surfaces of the chuck body. In tightening the chuck, the flange is lowered and the jaws forced down on the taper, causing them to close on the shank of the drill. When the knurled sleeve is turned in the reverse direction, the flange and chuck jaws are raised and at the same time forced out of contact with the drill by means of the two coiled springs shown in Fig. 1.

LANDIS STATIONARY PIPE DIE-HEAD

A stationary pipe die-head which is made in 4- and 8-inch sizes by the Landis Machine Co., Inc., Waynesboro, Pa., is shown in the accompanying illustration. This die-head consists of four essential parts which are: the body or the head that carries the chaser-slides; the chaser-slides; the operating ring which imparts the oscillatory movement of the handle to the chaser-slides to give the chasers a radial movement to or from the center; and the chasers.

It will be seen that six chasers are employed which are inclined to the work to agree with the pitch of the thread that is required. The chasers are milled from flat bar steel

Landis Stationary Die-head made in 4- and 8-inch Sizes

and are hardened for their entire length. They have line contact with the work which reduces friction to a minimum and permits the use of high cutting speeds. When dull, the chasers are ground on their front ends and then moved forward in their holders the necessary amount, the correct cutting position being determined by means of a small hook gage. The rake can be ground to suit the nature of the material that is being threaded. The throat is permanent, allowing close shoulder work to be handled.

Each chaser is gripped in its holder by a clamp that engages the upper side of the dovetail on the back of the tool and draws it down onto a solid seat. The chasers are removed for grinding by loosening the two screws which tighten each of the clamps. The head is manually operated by means of a bell-crank lever which moves the chaser holders to or from th center on radial lines. The holders are incorporated in the head, thus limiting their use for either right- or left-hand threading. The head is made of steel and graduated for all sizes of pipe within its range.

During a recent test of one of these die-heads, a cutting speed of 40 feet per minute was maintained on pip s varying in size from ¾ inch to 2 inches. An important feature of this die-head is that one set of chasers covers the entire range of pipe sizes for a given pitch, so that it is unnecessary to remove the chasers from their holders except for the purpose of grinding. Another feature which tends toward economy is that one or more chasers can be replaced without requiring an entirely new set to be purchased. This die-head is suitable for threading all kinds of pipe such as iron, brass, steel or copper.

DAVIS-BOURNONVILLE RAILAGRAPH

The Davis-Bournonville Co., 30 Church St., New York City, has added to its line, the oxy-acetylene rail cutting machine shown in the accompanying illustrations. This equipment is known as the "railagraph" and is made for cutting different forms of electric traction and steam railroad rails. It can be used on a rail in position in the road bed.

The machine consists of a stand which is clamped on the rail to be cut by means of a hand lever that actuates an eccentric binder. On each side of the rail, a bracket is provided in

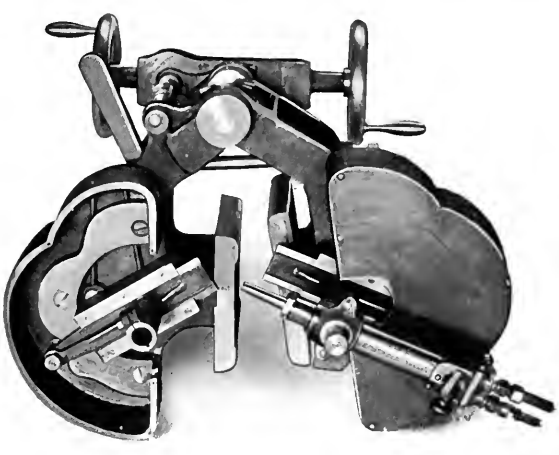

Fig. 1. Davis-Bournonville Rail Cutting Machine

which the cutting torch can be mounted. This bracket is secured to a slide which has a roller attached to it; and the roller is held in contact with a cam by means of a tension spring. Different forms of cams are provided for cutting different styles of rails, the purpose of the cam being to regulate the position of the slide so that the point of the torch is held at a distance of about ⅛ inch from the work while it is being fed over the line on which the rail is to be cut off.

The machine is driven by hand, the small handwheels at the top being used for this purpose. The power is transmitted through a pair of bevel gears, a worm and wheel, a second pair of bevel gears and then through a pair of spur gears to the shaft upon which the torch-slide is mounted. By rotating the handwheel, the torch is made to travel over the rail and as previously stated, the cam and slide arrangement holds the ends of the torch at the required distance from the work.

In operation, the torch is first applied at one side of the rail and fed over the line on which it is to be cut, one half of the base, the entire web and one half of the rail surface being cut by this operation. The torch is next removed from the holder and mounted at the opposite side of the rail; it is then passed over the work the second time in order to cut the remaining halves of the base and rail surface. An idea

of the rapidity with which this cutting-off machine operates may be gathered from the fact that during a recent exhibition, a 9-inch electric traction rail was cut off in a few seconds over three minutes, with a consumption of 2 cubic feet of acetylene and 5½ cubic feet of oxygen. A comparison between this time and the time required to cut off such a rail with a hand hack-saw will readily show the desirability of using an

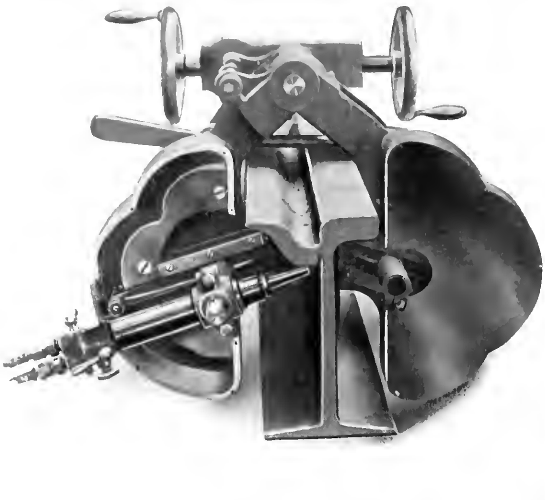

Fig. 2. Davis-Bournonville Machine in Position for Cutting

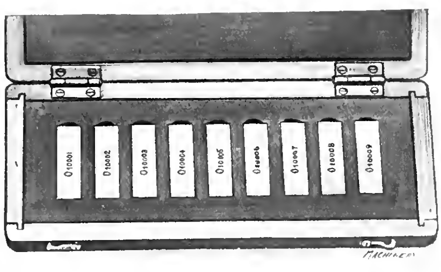
oxy-acetylene equipment for work of this kind. The standard Davis-Bournonville machine cutting torch is used on this machine, except that for rail cutting the torch is made about 2 inches shorter than the standard dimension. In using this equipment, the oxygen is used at a pressure of 50 pounds per square inch.

JOHANSSON GAGES

The Johansson Swedish gages are widely used in this country as a standard for use in tool-rooms and for other classes of work where accuracy is required. As most mechanics know, these gages are made in series, the sizes of which differ by ten thousandths, thousandths and hundredths of an inch. A new set of gages has just been brought out, consisting of a series of nine blocks ranging in size from 0.0201 to 0.0209 inch;



Special Set of Johansson Gages varying in Size by 0.00001 inch

a series of nine blocks, ranging in size from 0.021 to 0.029 inch; and a series of nine blocks ranging in size from 0.010 to 0.090 inch. By using different combinations of blocks, every size from 0.03 inch can be obtained.

The extreme accuracy with which these gages are finished by the processes which Mr. Johansson developed for their manufacture is shown by the fact that several special sets of gages have recently been made with a variation of 0.00001 inch between each of the nine blocks in the series. It has been stated by Mr. Johansson that these blocks were accurate within 0.000001 inch of the required dimension. Such a degree of accuracy is not required in most shops where Johansson gages are used, but it illustrates the perfection of the method by which all of these gages are finished and is consequently a strong recommendation for their use in cases where the greatest accuracy is required. The Johansson gages are being distributed in the United States by the Gronkvist Drill Chuck Co., 20 Morris St., Jersey City, N. J.

PORTER-CABLE UNIVERSAL MILLING ATTACHMENT

For several years, the Porter-Cable Machine Co., Syracuse, N. Y., has been manufacturing a No. 3 belt-driven universal milling attachment. The results obtained with this tool have been entirely satisfactory, but for heavier classes of work a positive driven attachment is required. To meet the requirements of such classes of service, a No. 4 gear-driven attachment, shown in the accompanying illustrations, has recently been placed on the market. The attachment is shown set in vertical and horizontal positions in Figs. 1 and 2 and a partial cross-sectional view is shown in Fig. 3, from which the arrangement will be readily understood.

The attachment is mounted on the milling machine by means of a driving arbor inserted in the spindle. This arbor

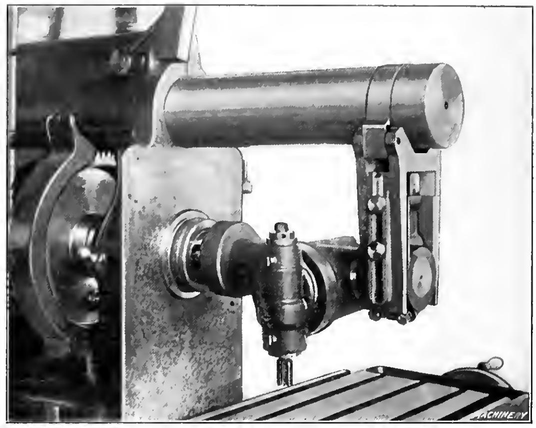


Fig. 1. Porter-Cable Universal Milling Attachment set in Vertical Position

has either No. 9, 10 or 11 B. & S. taper as desired. The driving gear is mounted on the arbor and meshes with a pinion on the countershaft contained in the frame of the attachment. This arrangement is shown in the partial sectional view. After the arbor has been placed in the spindle of the milling machine, the outer end is supported and held in place by means of a telescoping clamp and flexible steel strap which passes around the overhanging arm. This clamping mechanism is made ad-

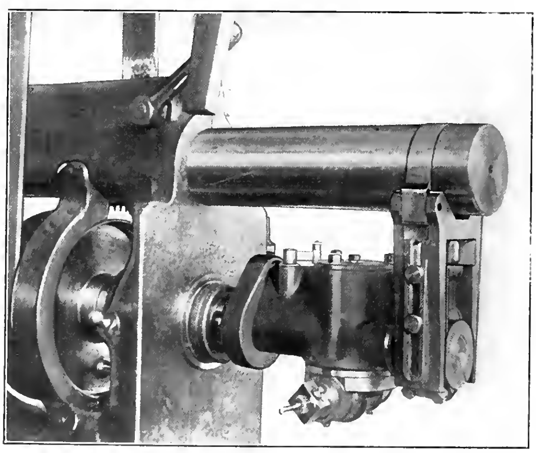

Fig. 2. Universal Milling Attachment set in Horizontal Position

justable to provide for the varying distances between the centers of the spindle and overhanging arm of different sizes of milling machines, so that the attachment can be used on more than one size. This means a considerable economy, as

one attachment may be used on several machines which may have an occasional job for which it is required.

Referring to the illustrations, it will be seen that the attachment is universal in that it may be operated at any angle in any plane. The required setting is obtained by means of graduated dials on the spindle housing and main frame, which read to 90 degrees on either side of the zero mark. Bosses or lugs are also located on the front of the spindle housing; these bosses are accurately machined in line with the center of the spindle and by using a square or protractor, a very accurate setting may be obtained.

A particularly valuable feature of this attachment is the reversing mechanism which is clearly shown in Fig. 3. The

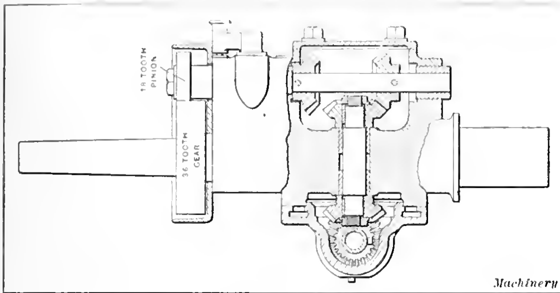

Fig. 3. Partial Sectional View of Porter-Cable Universal Milling Attachment

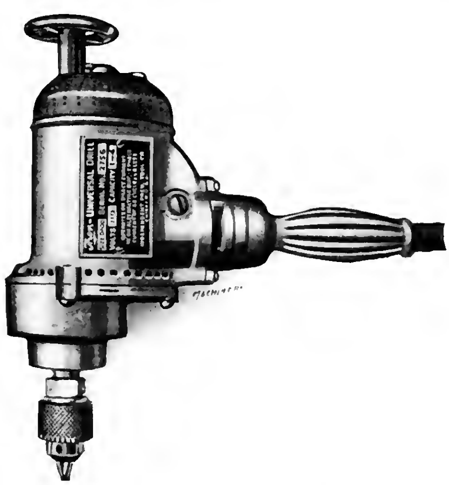
control of the position of the shaft is effected by a bronze sleeve which forms the inner bearing for the shaft. This sleeve has rack teeth cut on its upper side which mesh with a pinion that is integral with the stem of a small locking lever shown in the illustration. By this means, either of the bevel gears may be engaged to adapt the attachment for using either right- or left-hand mills, without regard to the direction in which the milling machine is running. All of the gears in the attachment are of steel and the miter gears which operate the cross shaft and spindle have planed teeth. The countershafts and spindle are hardened and ground and the spindle bearings are carefully scraped to an accurate fit. This attachment has a capacity for end mills up to $1\frac{1}{4}$ inch in diameter.

THOR PORTABLE ELECTRIC DRILLS

The Independent Pneumatic Tool Co., Thor Bldg., Chicago, Ill., has recently brought out two sizes of portable electric drills, one of which is shown in the accompanying illustration. The principal feature of these drills is that they are equipped with universal motors so that they can be attached to an



Thor Portable Electric Drill made with a Grip Handle

ordinary incandescent lamp socket of 110 or 220 volts, direct current, or single phase alternating current of 60 cycles or less. The drills are made with a hand grip of the type shown in the illustration or with a breast plate.

The spindle and armature shaft is supported on roller and ball bearings and the revolving parts are carefully balanced so that there is no vibration at the high speed for which the tools are designed. The brush holders are self adjusting and the commutator may be easily removed for cleaning by simply unscrewing one nut. The motor is air cooled by a fan which draws air in through the holes in the cover. The air passes around the motor and is ejected through the small holes which will be seen at the bottom of the case. Drills of this type are made in two sizes which have capacities for drilling holes up to $\frac{1}{4}$ and 5/16 inch in steel.

SMITH & MILLS CRANK SHAPER

In the issue of MACHINERY for February, 1909, a crank shaper built by the Smith & Mills Co., Cincinnati, Ohio was illustrated and described. The machine shown in the accompanying illustration is a more recent product of the same company and is constructed along the general lines of the preceding type of shaper referred to, the improvement consisting of a single pulley drive and change gears which have been applied in place of the cone pulley. This speed changing mechanism is simple and efficient, the control being located within convenient reach of the operator who is able to make any required changes without moving from his position at the front of the machine. The changes in cutting strokes are obtained by four pairs of gears, which are thrown into mesh by the aid of suitable shifting levers. The four changes

Smith & Mills Crank Shaper with Single Pulley Drive and Change Gears

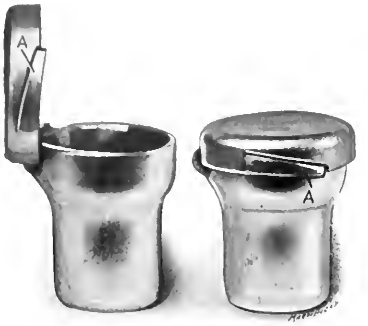
obtained in this way are supplemented by the back gears located inside the column of the machine. The back gears are engaged or disengaged by a conveniently located handle, and in connection with the change gears give a total of eight changes to meet the requirements of different classes of work.

The main driving shaft runs in a bearing which is bolted to the back of the column of the machine, as shown in the illustration, and the friction driving pulley is located at the opposite end of this shaft from the change gear box, where it is out of the operator's way. The speed box has three shafts, two of which carry sliding gears that are shifted by the levers shown in the illustration, one at the back and the other to the left of the handwheel. The handwheel provides for revolving the gears by hand when making changes. The gears run in oil so that both the gears and bearings in the speed box are thoroughly lubricated at all times. This speed box arrangement makes the machine particularly well suited for motor drive. The motor may be either bolted to the floor behind the machine and belted to the friction pulley, or a pad can be attached to the base of the machine, upon which

the motor is mounted and connected to a gear on the driving shaft by means of a rawhide pinion. Plain crank shapers of this type are built in 12, 14 and 16-inch sizes, while back-geared crank shapers—one of which is shown in the illustration—are built in 16, 20 and 25 inch sizes.

CONUS OIL CUP

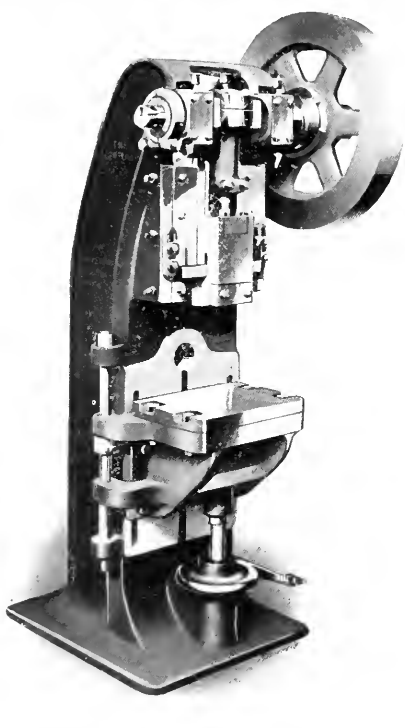
A simple form of oil cup manufactured by G. A. Lindstedt & Co., Stockholm, Sweden, and distributed in the United States by the Buckeye Churn Co., Sidney, Ohio, is shown in the accompanying illustration. The body and cover of this cup are stamped from sheet steel. The body is not threaded, but is simply driven into the oil hole, and as there is no obstruction of any sort on the inside of the cup, it has the maximum capacity for lubricant. In order to adapt these cups for use on rotating parts, the flange on the cover is split, as shown at *A*, in order to provide a spring lock for keeping the cover closed. These cups are easily kept clean and the flanged cover effectually prevents dirt from getting into the oil channels.



The Conus Oil Cup

CLEVELAND HORNING AND WIRING PRESS

The horning and wiring press illustrated herewith is a recent product of the Cleveland Machine & Mfg. Co., 4938 to 4952 Hamilton Ave., Cleveland, Ohio. The construction of this machine embodies the following features: bronze bushings for the shaft bearings are provided in the frame of the machine; there is a safety latch on the clutch pin; the crank pin is of ample proportions; a hinged brake band is provided that has a compensating spring for wear and expansion; and the machine is equipped with a quick-adjusting knock-out device.

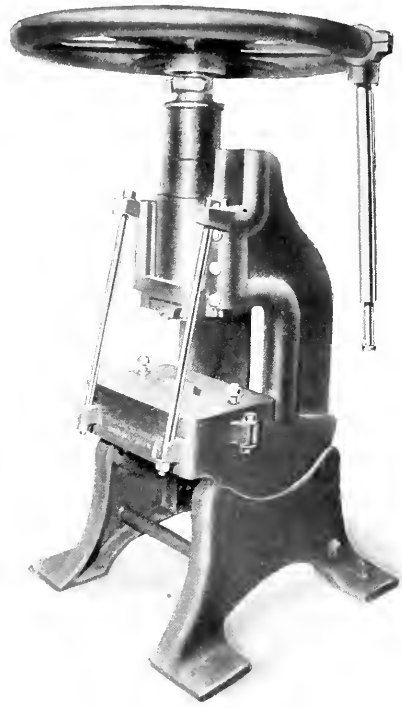


Cleveland Horning and Wiring Press

The machine is intended for the operation of wiring dies that are used for wiring the edges of pails, cups, reflectors and similar classes of work. Referring to the illustration, it will be seen that the frame of the press is bored for a horn. A plain horn for holding piercing or riveting dies or a horn of duplex construction for folding and locking the side seams of pails, tubs, furnace pipe and other articles made out of sheet steel, may be used on this press. The screw adjustment under the knee provides for setting it to any desired height so that the machine may be adapted for wiring dies of different depths. In using the press with a horn, the screw is lowered and the knee is swung around to a position where it is out of the operator's way. Machines of this type are made in four sizes. The machine shown in the illustration will close seams in a length up to 12 inches or in a diameter up to 24 inches; it will wire work up to 10 inches in diameter or 12 inches in length; the floor space occupied is 38 by 30 inches and the weight of the machine is 1850 pounds.

STANDARD SCREW PRESS

The hand screw press illustrated herewith is a recent product of the Standard Machinery Co., 7 Beverly St., Providence, R. I. The machine is designed for various operations on sheet metal and is capable of operating blanking dies up to 16 inches in diameter. It was built for operating dies used for punching armature disks, but is capable of application on a variety of other classes of work. The machine is operated by a quadruple threaded screw of $1\frac{3}{4}$ inch lead. This screw is $3\frac{1}{2}$ inches in diameter and made from a steel forging; it is turned by a handwheel 4 feet in diameter which has 500 pounds of metal in its rim.



Standard Hand-operated Screw Press

The machine is fitted with tie-rods to provide accurate alignment and the nut in which the operating screw turns is secured to the lower part of the frame by four bolts. The screw is held in the ram by means of a split collar. It will be seen that the frame is set on legs in such a way that the press can be inclined. The principal dimensions of this machine are as follows: thickness of bolster plate, $2\frac{1}{2}$ inches; maximum

distance from ram to bolster plate, 14½ inches; distance from lower end of ways to bed, 12 inches; distance between gibs, 10¾ inches; distance between uprights at rear of machine, 14½ inches; distance from the center of ram to back of rod, 6½ inches; weight of machine, 3000 pounds.

HJORTH DRILL GAGE

In shops where it is the practice to grind drills by hand, satisfactory results cannot be expected from the drill unless both of its lips are ground equally, so that each does its proper share of the work. Figs. 1 and 2 show two styles of

Fig. 1. Hjorth Gage for Drills up to 1 Inch in Diameter

gages which are made by the Hjorth Lathe & Tool Co., 27 School St., Boston, Mass., for testing the accuracy of a drill after it has been ground. The gage shown in Fig. 1 has a capacity for drills up to 1 inch in diameter, while the gage shown in Fig. 2 will take up to 2-inch drills.

It will be seen that the general arrangement of both gages is similar except that the larger one is provided with a stand.

Fig. 2. Hjorth Gage for Drills up 2 Inches in Diameter

Both gages have a V-slot in the handle in which the drill to be tested is laid. The gage proper has a 59-degree angle and may be adjusted vertically to bring it in line with the axis of different sizes of drills. In using such a gage, the drill is held firmly in place in the V-slot; the gage is next adjusted to bring it to the proper height; and the operator then observes whether the lips of the drill are parallel with the edges of the gage. If any discrepancy is found, further grinding must be resorted to until satisfactory results are obtained.

NEW MACHINERY AND TOOLS NOTES

Dividers: Welles Caliper Co., Milwaukee, Wis. A pair of dividers with inserted steel points which are held in place by binding screws.

Offset Bench Shear: Welles Caliper Co., Milwaukee, Wis. A machine designed for use on sheet steel up to 3/16 inch in thickness. The weight of the machine is 35 pounds.

Oil Heater: Hauck Mfg. Co., Brooklyn, N. Y. A portable steel tire-heating outfit for use in roundhouses. Crude petroleum, fuel oil or kerosene may be burned in this heater.

Double Spindle Engine Lathe: J. J. McCabe, New York City. This machine has been provided with improvements and special features which make it especially well adapted for use in street railway and other repair shops.

Die-stock: Nye Tool & Machine Co., Chicago, Ill. A taper-threading die-stock with long pipe handles for turning the die. The chasers fit into guiding slots and are kept from dropping out by the pressure of spring backed pins.

Hydraulic Press: United Engineering & Foundry Co., Pittsburg, Pa. A high-speed, hydraulic forging press for use on gun forgings. The machine was built for installation at the Watertown Arsenal and is capable of exerting pressures up to 800 tons.

Ring and Tire Welders: Toledo Electric Welder Co., Cincinnati, Ohio. One of these machines is designed for butt-welding harness rings and similar classes of work; the other is a similar machine except that it is designed for welding heavier work such as tires.

Steel Belting: Flexible Steel Belting Co., Bridgeport, Conn. A flexible steel belting of unit construction, designed as a substitute for double leather belting. Each unit is composed of four sheet metal parts and a pin. These belts may be taken apart and assembled in new lengths, if so desired.

Boring Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. A machine for finishing gas-engine liners or bushings which has a capacity for boring bars up to 9½ inches in diameter by 6 feet long. The machine is provided with clamps which are adjustable to enable bushings of various diameters to be held.

Cold Saw: Newton Machine Tool Works, Inc., Philadelphia, Pa. This machine was designed to meet the requirements of a shop where 1⅜-inch heat-treated stock was to be cut off at the rate of 900 pieces in ten hours. Ten bars are held at a time in a special work-holder. The machine is motor-driven.

Electrical Welder Switch: Toledo Electric Welder Co., Cincinnati, Ohio. A hand switch for use on spot welders. The use of this switch adds materially to the convenience with which the machine can be operated, making it possible for one man to handle large sheets and control the machine without assistance.

Power Press: Cleveland Machine & Mfg. Co., Cleveland, Ohio. A line of straight sided, single crank geared power presses. These machines are designed for blanking, forming and drawing light and heavy sheet metal parts. All sizes can be fitted with drawing attachments and also a bar knock-out in the slide.

Machinists' Hammer: Westfield Plate Co., Thompsonville, Conn. A machinists' hammer with a composition metal head for use on machine tool and automobile work. The head of the hammer is made of a mixture of lead and antimony, and may be readily removed from the handle which is made of tinned, malleable iron.

Combination Punch and Shear: Henry Pels & Co., 90 West St., New York City. This machine has a capacity for punching holes 3 inches in diameter in a 2-inch steel plate, and it will shear a 2½ inch plate 60 inches in width. The machine has this company's steel plate frame construction and is operated by a Cameron steel lever.

Hacksaw: Racine Tool & Machine Co., Racine, Wis. A hacksaw adapted for cutting structural steel and various materials used in the machine shop. An automatic mechanism lifts the saw on the return stroke and the machine is equipped with a quick change vise. Work can be cut off either square or at an angle.

Wire Straightening Machine: Sleeper & Hartley Co., 98 Beacon St., Worcester, Mass. A wire straightening machine, especially adapted for straightening piano wire. This wire is rolled in relatively small coils and a machine of special design is necessary to straighten it ready for feeding to an automatic wire-forming machine.

Die Handling Crane: Toledo Bridge & Crane Co., Toledo, Ohio. A special crane, especially adapted for handling work in drop-forge plants. The hook of this crane is at the end of a counterbalanced arm and swings into a vertical position when the load is removed from it. An auxiliary hook is provided which enables the crane to be used for a variety of other classes of service.

Power Hammer: Fairbanks Co., New York City. This hammer is arranged so that it can be driven with either a slanting belt from above or with a horizontal belt from either side. This makes it possible to set the hammer up in places where there is very little overhead space. These hammers are made in sizes ranging from 25 to 300 pounds capacity and are equipped with either belt or motor drive.

Automatic Turret Lathe: Gisholt Machine Co., Madison, Wis. The design of this machine has been carefully worked out to provide for the safety of the operator. It is easily adjusted and of rigid construction to adapt it for severe service. All of the operations are automatic except the setting up and removal of the work, and in some cases the work may be automatically removed from the machine by an air chuck. This machine is built in two sizes of 15 and 20 inches.

SELLING GUARANTEES WHAT ARE SAFE LIMITATIONS?*

BY G. O. GRIDLEY†

In presenting an article on the subject of "Selling Guarantees, What are Safe Limitations?" I have considered that "safe limitations" means limiting the guarantee in favor of the seller, or stating it in another way, the title might be "How Broad a Guarantee is it Safe for the Manufacturer to make to a Prospective Customer?"

This question of guarantees has troubled mankind for many generations, in fact for ages, and to-day it costs us not an inconsiderable amount of money as well as time and trouble to maintain our guarantees, notwithstanding our endeavors to put in "safe limitations." Why is this? Why have we gone on and on, generation after generation, making guarantees that have cost us so much money and trouble? Is it because we have deliberately misrepresented our machines? Is it through a misunderstanding of the language used in our guarantees? Is it from the lack of good judgment on our part as to what we can perform? Or is it from a desire on our part to so word our guarantee that the purchaser must keep the machine even though he does not want to do so?

Let us consider what the object is in making a guarantee. Is it to help us make a sale? Is it to safeguard the interests of both the manufacturer and the purchaser? Is it to assure the purchaser he will get that which he thinks he is buying? Or is it to assure him he is to get that which will best serve his purpose? I believe it should be the latter.

No transaction between seller and buyer is satisfactory, and no business is, nor can it be, successful if the relation between the seller and buyer is not satisfactory to both. Neither is any guarantee satisfactory unless it safeguards the interests of both parties to the transaction. Therefore we must draw our guarantee carefully and see that its language is such that it means to the one to whom we are giving it the same that it means to us.

In the case of the builder of a machine which is designed especially for the purchaser, your guarantee should be drawn very clearly and definitely so as to safeguard both parties, because there are many elements over which the other has no control that enter into and influence the decision of the purchaser as to whether he will accept or reject the machine. With the manufacturer of a standard line of tools which he builds in lots and which are not built especially for each individual customer it is different, and it is not necessary to have the guarantee so definite as in the case of the builder of the special machine, because if one customer does not want the machine the maker can sell it to another.

There are, of course, cases where a definite guarantee of performance is necessary, and it should be given, as, for instance, where the question of costs of a new product is being considered or where a change of methods is being taken up; but where only an increase in product is to be made without change of method, the limited guarantee should not be given. *Make your guarantee broad and short and without limitations.* It is better for your customer and for yourself, because it will cost you less to maintain such a guarantee than any in which there are limitations so drawn that you may feel that you have met your guarantee and that your customer should keep the machine even though he does not want to do so.

Your guarantee should be such as to assure your customer that he is getting that machine which will best serve his purpose.

This does not necessarily mean that he is getting the best machine of its kind, because the most accurately made machine and the one which will do more work than others, and necessarily cost more than others, might not be best for the purchaser, as he might perhaps need and could use to better advantage that extra money which the best machine would cost; therefore, we should not try to force onto him this high-priced machine. In fact, we should not try to sell it to him, because a cheaper machine would be better for him to purchase. If, however, you have been so fortunate or so unfortunate as to have taken his order for the high-priced machine, and after getting it into his shop, he realizes that there is only a little work for it, and that the work need not be accurate and that a cheaper machine would have been better for him to buy, what do you do if he comes to you and states the case clearly and honestly; do you take it back or not? If you take it back your guarantee with safe limitations has not been of any financial benefit. If you do not allow him to return it what happens? If he is honest with himself, he pays the account when it is due, and then when he requires more machinery he will probably go to your competitor and place his order with him.

Can your loss on this order placed with your competitor under these conditions be charged to anything other than the cost of maintaining your limited guarantee? I say it cannot and that it can be and should be charged against that account. Open an account in your books under the heading "Cost of Maintaining Limited Guarantees" also one under the heading "Cost of Maintaining Unlimited Guarantees" and see which costs you the more. You will find that the unlimited guarantee costs less than the other.

The company with whom I am associated has made a great many limited guarantees, as well as broad ones, and I am frank to state that the limited guarantees cost us the more to maintain. It costs us less to secure an order with the limited guarantee than one with the broad and unlimited one. This is because it takes a higher degree of salesmanship to get an order that way, although it seems on first consideration that it should be the opposite. To secure an order with the broad unlimited guarantee you must first convince your prospective customer that you have the best machine for his purposes. When you have done that, your guarantee of performance, which is a limitation, is of secondary consideration, and the question of whether or not the machine will make four or forty-four pieces in a given unit of time is not made the main issue, as it should not be, but consideration is given to the question of whether or not the machine is the best machine for the purpose. If it is the best for the buyer, all things considered, your guarantee has not cost you anything to maintain; neither will it cost you anything on future sales. The cost of getting future sales will be greatly reduced, and you can, therefore, credit the saving in securing these sales to the "Cost of Maintaining Unlimited Guarantees."

It will cost the manufacturer a considerable sum to make a limited guarantee of performance, as one with experience and judgment must give his most careful attention to each proposition if the guarantee is anything more than perfunctory, and even with the most careful attention given to a detailed guarantee mistakes will happen—mistakes that will cost considerable money either through overestimating the capabilities of your machines or through underestimating them and thereby losing the order. In this case you should make another charge against the "Cost of Limited Guarantees." This, however, is not the greatest objection to guarantees of performance.

The greatest objection in my mind to making guarantees of performance is that your customer too often loses sight of everything except the stated guarantee of performance and does not give due consideration to the machine—that is whether it is the best for his purpose—whether it will continue to perform that which it was guaranteed to do after having accepted it, or whether or not it will be useful in the future, if his work changes.

There is a big advantage in using the broad unlimited guarantee, in addition to its primary advantage. It will make you improve your machines faster than you otherwise would; it will make your representatives more careful in their statements of performance, and thus create a reputation for your machines, your ability to perform and your honesty, all of which reduce the cost of maintaining selling guarantees.

What are the objections to an unlimited guarantee other than that the purchaser can, if he is so disposed, take advantage of you and return the machine without just cause? On the other hand, if he wishes to do so, he can question this or

* Paper read at the National Machine Tool Builders' Association Convention, New York City, October 22

† General Manager, Windsor Machine Co., Windsor, Vt.

that, justly or not—it matters not which—and make you a great deal of trouble and expense, usually ending by your taking the machine back. However, during a period covering about ten years and many broad unlimited guarantees, our company has not had such an advantage taken of it except in two cases, and I believe others who have sold those two parties machines on limited guarantees have had fully as much trouble and been to greater expense and then had their machines returned. Therefore, that need not be given serious consideration, as few of your customers are dishonest.

Do not make guarantees with "safe limitations" because you are working in the wrong direction and because it will cost you more to maintain such guarantees. Start on the basis of the right machine for your customer, and then make your guarantee broad and short and without limitations, such as: "We guarantee this machine satisfactory to you."

* * *

NATIONAL MACHINE TOOL BUILDERS ASSOCIATION CONVENTION

The twelfth annual convention of the National Machine Tool Builders Association was held in New York City October 22, 23 and 24 at the Hotel Astor, E. P. Bullard, Jr., presiding. In his opening remarks, Mr. Bullard referred to the need of greater efficiency in building machine tools. The production of the tariff had made better methods imperative. The textile manufacturers had already taken steps to meet foreign competition. There was no reason in his opinion why our makers could not maintain the supremacy of American machine tools. Improvements all along the line, a broader outlook, closer cooperation in committee work would put them on more than an even footing in the world's markets.

C. L. Taylor, chairman of the patent committee, in his report referred to the dangerously broad scope of a law passed by Congress to protect foreign manufacturers at the Panama-Pacific Exposition. This law imposes a fine of $1000 or one year's imprisonment for imitating a foreign maker's patented machine or his copyright, without providing that the foreign patent or copyright shall be legitimate. The practical effect might be to prevent some American makers from building their own machines for four years, because of the notorious practice abroad of copying American models. Steps are to be taken to so amend the legislation as to prevent such an outrageous outcome.

D. M. Wright offered a resolution in regard to the nomenclature of machine tools to change the name of the National Machine Tool Builders Association to the Metal Working Machine Makers' Association. Action on the resolution was put over until the next meeting. Mr. Wright also reported on the standardization of machine tools and accessories, stating that little progress had been made. He recommended the appointment of sub-committees composed of men competent to exhaustively investigate those details with which they are thoroughly familiar with the view of bringing about agreement on vital essentials which could not be handled effectively by the general committee.

C. H. Alvord reported on the Panama-Pacific Exposition, stating that the railroads have promised every facility for the transportation and care of machine tools, etc., to be exhibited. The exposition management has offered various inducements, but the machine tool builders have evinced little interest, so far, in the exposition.

The association now numbers 175 members; no new members were admitted at this meeting.

The following excellent papers were read but available space at this date will not permit reproducing them in full in this number:

"Cost Accounting Practice with Special Reference to Machine Hour Rate," by Clinton H. Scovell of the Clinton H. Scovell Co., Boston, Mass.

"Selling Guarantees—What are Safe Limitations?" by George O. Gridley of the Windsor Machine Co., Windsor, Vt.

"Automatic Features on Machine Tools—To What Extent Are They Commercially Profitable?" by Edson R. Norris, director of the manufacturing operations at the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa.

"The Development of Cutting Tools," by B. F. Waterman of Brown & Sharpe Mfg. Co., Providence, R. I.

"The Use of Heat-treated Gears in Machine Tools—From the Standpoint of the Material Manufacturer," by J. Heber Parker, metallurgist of the Carpenter Steel Co., Reading, Pa.

"Carbonizing and Heat-treating of Shafting—Methods and Materials Used," by J. G. Weiss, works manager of the Hyatt Roller Bearing Co., Newark, N. J.

The following officers were elected: President, William A. Viall, Brown & Sharpe Mfg. Co., Providence, R. I.; first vice-president, J. B. Doan, American Tool Works, Cincinnati, Ohio; second vice-president, D. M. Wright, Henry & Wright Mfg. Co., Hartford, Conn.; treasurer, A. E. Newton, Reed-Prentice Co., Worcester, Mass.; secretary, C. L. Taylor, Taylor & Fenn Co., Hartford, Conn.

The question of abandoning the semi-annual or spring meeting was taken up and decided in favor of continuing to have two meetings a year. The place of the next meeting was not fixed. Three cities were suggested, namely, Buffalo, Atlantic City and Worcester. A letter ballot will be taken to decide in which city the spring meeting will be held.

STABILITY IN FLYING MACHINES

Prof. Albert A. Merrill, founder of the Boston Aeronautical Society and lecturer on the subject of aeronautics, presented a paper "Stability in Flying Machines" at the monthly meeting of the American Society of Mechanical Engineers Tuesday evening October 14, in New York City. Prof. Merrill analyzed the forces acting on an aeroplane in flight. The movements are translation and rotations about the center of gravity. The rotations are about the three axes of the machine, *viz.*, vertical, longitudinal and lateral. He showed that existing machines are for the most part badly designed and have little or no inherent stability. A strong plea was made to mechanical engineers to take up the design of flying machines and correct the present faults. Prof. Merrill intimated that cut-and-try methods had been the rule and rational design an exception. He saw little commercial future for the flying machine until the faults of existing design had been corrected and machines built having inherent stability.

Elmer E. Sperry, the designer of gyroscopes for U. S. naval vessels and Curtiss aeroplanes, denied that great inherent stability was desirable in flying machines. He pointed out that the great modern ocean steamers like the *Olympic* and *Imperator* had very low metacentric heights, that of the former being only sixteen inches. In other words, if the center of gravity of the *Olympic* were raised only sixteen inches, the vessel would roll over. The inference was that marine designers have discovered that a low metacentric height was favorable to speed and fuel efficiency. Mr. Sperry referred to the very satisfactory results following the application of his gyroscopes to Curtiss aeroplanes and showed lantern slides illustrating the mechanism.

The members of the society and members of the two New York aeronautical societies present displayed keen interest in the paper and discussion. A comparatively new scientific field has been opened, worthy of the best thought of the physicist and mechanical engineer.

AMERICAN MACHINIST THEATER PARTY

The *American Machinist* gave a theater party at Cohan's Theater to the members of the National Machine Tool Builders Association and their friends, Thursday evening, October 23. The play was "Potash and Perlmutter" adapted from the stories by Montague Glass, published in the *Saturday Evening Post*. It is advertised as "trimmed with a thousand laughs," and judging from the effect produced on the machine tool builders, this is in no sense an exaggeration. The play depicts Jewish characteristics in a broad, sympathetic and amusing manner not, however, without pathos and glimpses of the high ideals which may inspire the Jew in great crises.

AUTOMATIC FEATURES ON MACHINE TOOLS*

TO WHAT EXTENT ARE AUTOMATIC FUNCTIONS COMMERCIALLY PROFITABLE?

BY EDSON R. NORRIS†

In recent years machine tool builders have been active in taking advantage of the many improvements that have been suggested in the way of special devices, attachments and accessories for machine tools for the purpose of increasing the usefulness of the tools, lessening the cost of production and in some cases reducing the skill necessary to operate. It is the object of this article to consider some of these special features from the standpoint of the large user of machine tools, yet giving due consideration to the demands of others whose requirements are different and whose lines of work are also often diversified in nature. The subject cannot be discussed without taking into account to some extent the designs of the tools; and what might appear as adverse comment in the illustrations of apparently faulty designs is merely offered in the way of constructive criticism.

It may be said that ordinarily the following reasons and conditions prompt the machine tool user to purchase equipment:

1. To take care of an immediate increase in business.
2. To provide for anticipated increase in business and at the same time to reduce the cost of manufacture by replacing existing tools with more efficient ones.
3. To replace worn-out tools with tools of the same design.

All large progressive concerns expect to and generally do expand, either by increasing their business along existing lines of manufacture or along similar lines, and frequently this increase occurs so suddenly that immediate action must be taken in purchasing the necessary tools to take care of the extra requirements. When this condition arises the purchaser must quickly decide what machines will be required, and endeavor to purchase those that can be delivered promptly and which will do the work intended in an efficient and economical manner.

It is often found, however, that while the machines offered for prompt delivery will perform the work desired in a satisfactory manner from a time standpoint, they are also designed and equipped to do a still larger class of work, and if installed the investment is greater than it should and would be for the work intended, if time would permit the installation of special machines. The fact that the fully-equipped general-purpose tools are valuable and a good investment both for the large and small manufacturer, when the work is brought through in small quantities and the machining requirements vary, has no doubt a tendency to encourage the machine tool builders in some cases to carry only as their standards fully-equipped tools (or nearly so) capable of doing a wide range of work, feeling that as long as this situation exists the demand will warrant such a policy and that it would not pay to carry a line of cheaper and simpler tools.

When machines are considered to take care of an anticipated increase in business and to improve manufacturing conditions by replacing existing tools, the purchaser generally has the time to give the proper attention to the design and character of the machines needed and it is almost unnecessary to say that he frequently decides to install special or single-purpose tools when the machine tool builders have nothing else to offer but expensive general-purpose tools.

The history of the automobile business in regard to machine tool requirements, if reviewed, will show that when the business first started machine tool builders had no difficulty in selling standard tools for this service, but as the business reached a sounder footing and time permitted giving more attention to the methods of manufacture, it was found advisable in a great many cases to demand machines capable simply of performing particular operations or similar operations to those for which they were intended.

* Paper read at the National Machine Tool Builders' Association convention, New York City, October 22.

† Director of manufacturing operations, Westinghouse Electric & Mfg. Co., East Pittsburg, Pa.

This has prompted some machine tool builders so to design their tools that they can now supply not only this demand but also the demands made upon them for tools equipped to do a wider range of work. The attention of the writer was recently called to an instance where this had been done in the re-designing of a horizontal boring and drilling machine so that it could be offered simply for boring operations, and not as a high-class precision tool. The machine was arranged with a reasonable number of changes in feeds and speeds, and as a jig would be depended upon for accuracy of the work and duplication of parts the spindle of the machine merely acted as a driver and feeder. The machine was designed for either belt or motor drive.

What has been said regarding the tendency of automobile builders in ordering tools, is also true of other large manufacturing companies, but possibly not to so marked a degree, because their products are not so well standardized or defined. This condition was very apparent in placing about $100,000 worth of medium sized machine tools in a new factory for a line of work which is manufactured in large quantities. It was advisable for several reasons to provide direct motor drive for all of these tools, and an effort was made to do so, but it was soon found that this could not be accomplished with all the machines that were considered desirable to use on the work and could be supplied promptly. For instance some of the engine lathe and milling machine operations necessary in this work are of a light and simple nature, which can be done economically on stud lathes or cone type millers; in most cases, therefore, the standard lines of motor-driven engine lathes and high-power milling machines were considered too expensive to install, which, of course, prevented carrying out the idea of motor driving all of the tools as originally desired.

It can readily be seen that it is not generally considered desirable or profitable to use so-called "standard or fully-equipped tools" on a line of standard apparatus. While it is appreciated that it is to the machine tool builders' interests to make their standard lines of tools serviceable for as many purposes as possible, in order to be able to meet the different requirements of a majority of their customers, they should also aim to make the designs so that the tools can be sold without the attachments and special features if not required for the work intended. They should either do this or else they should carry a line of machines of simpler design, which can be used on the general run of commercial work.

Machine tool builders very often show machine tool users by time studies or actual demonstrations in connection with a special piece of work that the time taken can be lessened by the use of their particular tools, and in such cases from the machine tool builders' standpoint, there is no reason why advantage should not be taken of this gain. With the user, however, this is not the entire proposition, especially if his production will permit him to use the machine in question continuously on such a line of work, which is very often the case. Under this condition any special features or attachments other than those actually needed for the work in question are of no value to the user and on account of the high purchase value, the saving in time does not warrant the extra investment. Cases of this sort are very common and are discouraging to those endeavoring to be progressive by aiming to take advantage of some of the new machine tools offered, and while machine tool builders deserve a great deal of credit for the great advancement made in the designs of their tools for the purpose of producing work rapidly and accurately, it seems that in their efforts to do this they have overlooked the fact that in some lines of manufacture these tools are too expensive to use. Simpler designs embracing some of the modern features will often do just as well.

These points can probably be made clearer by referring to a certain machine the Westinghouse Electric & Mfg. Co. has

found very useful for its needs, and of which it has about two hundred in operation. The builder of this tool has, however, more recently developed a fully-equipped tool with all of the modern attachments, making it very advantageous in some instances, but which naturally is higher priced. He intends to discontinue the manufacture of the old machine, yet it is very evident that on certain classes of work the older type is just as desirable, and on other classes the advantage of the new tool is negligible, because of the difference in purchase price of the two machines. It would be to the interest of the user to have this old design of tool improved to some extent and it would likewise be profitable to the manufacturer, without in any way discrediting the value to both parties of the new type of tool.

In another case the machine tool builder in his effort to produce a simple tool for a certain line of work did not take advantage of some of the modern attachments which would have improved his tool from an operating standpoint. The changes in feeds were cut down to what was considered the required amount for the service intended, but to change the feed it is necessary to remove and replace change gears. It can readily be seen that a modern change feed attachment would have been far more desirable. The value of this machine to the user also could be increased if it were equipped with a rapid traverse for the carriage. Another tool recently installed to improve the quality of work and reduce the cost, lacks a certain modern feature, which makes the machine more laborious and more expensive to operate, and it will have to be equipped with this attachment to meet the cost of doing the operation under the old method.

These examples tend to show that attachments are valuable, and that a greater effort should be made to apply them to the simple line of machines, when they can be used to advantage.

The demand for motor-driven tools, especially by the larger manufacturers, is increasing as the value of the motor drive is becoming more fully recognized, but some tool builders do not seem to realize this fact, or to take it into account in their designs. Machine tools so designed that the only possible way to apply motor drive is by ceiling mounting and belting down to them, or by placing the motors on the floor some distance from the tools, are very unsatisfactory, and it is safe to assume that this type would not be considered if it were possible to find other machine tools to do the work which were better arranged for motor drive.

While this fault can be found with some machine tools of recent design, most of them, however, have been on the market for years, and in place of making them more suitable for motor application some builders have designed new lines of machines which are satisfactory as far as motor application is concerned, but which cost considerably more to install on account of the greater number of parts or attachments and higher power features. These new types of machines have a broad field of usefulness and are profitable on certain classes of work, but they do not entirely replace the old type; it is obvious therefore that users whose policy it is to motor drive must either drive some of their equipment with belts, or else do work on expensive tools which could be done as economically on cheaper and simpler tools.

To show what may be accomplished by a combined effort on the part of the machine tool builder and user an instance may be given of a small hand milling machine which has been arranged for adjustable speed motor drive in a very satisfactory manner by widening the column of the standard machine to receive the motor, and driving direct to the spindle by means of a sprocket chain. Ventilation is secured through suitable openings in the column. A semi-dustproof condition is obtained by covering these openings with a fine mesh wire screen. Saving in operating time and changes in speed are obtained by the use of a starting and speed adjusting rheostat so placed on the side of the machine that the operator does not have to change his position to start, change the speeds or stop the machine. This application requires no extra floor space, and it makes a self-contained portable unit which can be readily shifted from one location to another, making the tool available and desirable to those wishing motor application.

In making the change the tool builder was put to some additional expense and the purchaser was charged accordingly for the first machines, but on later purchases the price was about the same as the regular charge for the standard cone type. This is very uncommon, however, as machines sold for motor drive generally cost more, regardless of the fact that the full value of the parts not required seems more than those added for motor application.

A few years ago it was not considered advantageous to motor drive planers, but now the adjustable speed reversing motor drive for planers is generally accepted as a decided improvement over the usual method of belt drive. This is merely mentioned to call attention to the possibility of eliminating some of the mechanical speed changing features of other equally important machine tools by the use of the adjustable speed motor, and in so doing, of obtaining a more satisfactory range of speeds. On some types of machines the speed-changing features can be omitted without altering the designs to any great extent, but this is not true in all cases, clearly showing that adjustable speed drive was not considered when designing them.

In conclusion it may be said that on commercial lines of work the operations and methods are so planned that the operators are only required to perform a single operation, and can therefore be graded accordingly. It is not good policy consequently to use highly improved machine tools capable of doing a wider range of work than the operators are called upon to do, but the machines should be equipped with any automatic features which will decrease the skill necessary to operate them, or which will reduce the cost of performing the required operations.

CABLEWAY SEVENTY-FIVE MILES LONG

Henry D. Baker, on special commercial service in India, writes in the U. S. *Daily Consular Reports* that work will probably begin in 1914 on the longest aerial cableway in the world. It will be seventy-five miles long and will be built across the Himalaya Mountains from the plains of Punjab to the "Vale of Kashmir." The project is considered to be the only feasible means of providing rail communication over this mountainous district. Owing to the loose conglomerate soil which causes disastrous slips and falls of huge boulders whenever there is unusual rainfall, engineers who have studied the situation deem it impracticable to build even a light electric railway. The cableway will be constructed in spans of about 800 yards, each upheld by steel towers, some of which will be 100 feet high. In some places the spans will bridge gorges 1200 feet deep.

* * *

In a paper read by Mr. Thomas D. West before the American Foundrymen's Association at Chicago in October, Mr. West emphasized the importance of making notes of everything about the plant that might cause an accident. The supervisors of a plant should regularly make notes of everything they see or think of that might cause injury to employes. The recent expansion of accident liability in many states has increased the insurance rate of those works in which the hazards, on account of the indifference of the supervisors, are high. If the practice of recording all memoranda bearing on accident causes and prevention is followed, a great change will be noticed in the extra-hazardous plant.

* * *

The great Zeppelin dirigible L-2 exploded near Johannsthal, Germany, October 17, at a height of 3000 feet, and twenty-eight of the passengers and crew were killed. Only one escaped. This is the ninth serious accident that has befallen the Zeppelins, the eighth occurring September 9 in a storm. Fifteen lost their lives in this disaster. The huge bulk, the inflammability of the gas-holder and the close proximity of gasoline engines and electrical apparatus constitute a hazard that seems beyond the power of the German engineers to cope with. Storms and fire have wrecked these great costly structures, but until the last two were destroyed there had been no loss of life.

PERSONALS

D. De Vries, manager of the technical department of Stokvis & Zonen, Rotterdam, Belgium, arrived in the United States in October, having made a trip around the world. Mr. De Vries will leave for Rotterdam about November 10.

Thomas D. West read a paper before the American Foundrymen's Association in Chicago, October 15: "Recording Memoranda on Accident Prevention," prepared with special reference to the conditions of foundry practice.

S. O. Livingston, secretary and sales manager of the Wilmarth & Morman Co., Grand Rapids, Mich., manufacturer of grinding machines, sailed on the *Olympic*, October 25, for a business tour of England and the Continent.

Walter Deakin, managing director of H. W. Ward & Co., Ltd., machine tool builders, Birmingham, England, arrived in America on the *Mauretania* October 17. Mr. Deakin will spend about six weeks visiting American manufacturing plants.

The degree of Doctor of Laws was conferred upon Mansfield Merriman at the annual celebration of Founder's Day, Lehigh University. Dr. Merriman, who is well known as an author and teacher, was head of the civil engineering course at Lehigh for nearly thirty years.

The Worcester manufacturers are feeling very proud, and justly so, of their new hotel, the Bancroft. A good hotel has been needed for a long time in Worcester, and some of the public-spirited citizens, headed by Mr. C. L. Allen of the Norton Co., raised $800,000, and put one up that everybody says is equal to the best anywhere.

Joseph A. Anglada, consulting engineer with offices at 1790 Broadway, New York City, has sold his interests in the Anglada Co., Detroit, manufacturer of demountable rims and automobile accessories, and has resigned the presidency of the company. Mr. Anglada will devote his energies to a company which will manufacture a small motor car of his design.

The Technology Club of Syracuse, N. Y., on the occasion of its eleventh annual meeting, October 8, honored Prof. John E. Sweet, one of its founders and the first president, by establishing the John E. Sweet Lecture Fund. The fund is to be used in the maintenance of a lecture course in which distinguished speakers on both technical and popular subjects will be brought to Syracuse.

William L. Garcia, who has been with the Fairbanks Co., for the past eight years, as manager of the engineering and power transmission department, has resigned to take a similar position with Flint & Chester, Inc., New York City, beginning October 6. A complete engineering and power transmission department has been equipped and Mr. Garcia will have full charge of same.

Melville W. Mix, president of the Dodge Mfg. Co., has been nominated on the Democratic ticket for mayor of Mishawaka, Ind. This is the third time the honor has been conferred on Mr. Mix. He has been twice elected mayor by a large majority. Aside from being president of the Dodge Mfg. Co., Mr. Mix is also the head of the National Veneer Products Co., a large concern making trunks, traveling bags and leather novelties, and is interested in other local and national business activities.

* * *

OBITUARIES

Dr. Rudolph Diesel, the inventor of the Diesel internal combustion engine, was drowned September 30 by falling overboard from the steamer *Dresden*, sailing from Antwerp.

Heinrich Dreyer, a well-known machine tool dealer of Berlin, Germany, died September 14, in Neckargemünd, near Heidelberg. Mr. Dreyer was only thirty-nine years old, but during the last ten years had built up a large and successful machine tool business, handling American tools exclusively. For nearly two years he was incapacitated from business by illness, but the interests of his clients have been well taken care of by his brother-in-law, Mr. Schumann, an experienced Berlin banker, and also by Mr. Franz Böhm, who previously had a number of years' experience in the machine tool field with Messrs. Schuchardt & Schütte.

Edwin T. Moore, secretary and treasurer of the Coatesville Boiler Works, Coatesville, Pa., and director of the executive board of the Coatesville Foundry & Machine Co., died at his home in Coatesville, September 25, from a complication of ailments brought on by overwork, aged forty-six years. Mr. Moore entered the employ of the Coatesville Boiler Works at the age of twenty-one as a clerk, and ten years later he was made secretary and treasurer. His unusual grasp of the details of the business received recognition when he was made general manager about two years later. Under the able supervision of Mr. Moore, the company grew and developed into a very important industry. He was instrumental in organizing the Coatesville Foundry & Machine Co., which in five years has also grown into an important industry. He was prominently connected with several other local enterprises.

JAMES MILLS

James Mills, president and general manager of the Smith & Mills Co., Cincinnati, Ohio, died October 17, aged seventy-four years. He had been suffering from heart trouble for the past six months, but his death was unexpected. Mr. Mills was born in Oldham, England, and came to America in 1861. He settled in New York and later served in the Civil War. After the war was over, Mr. Mills located in Savannah, Ga., and moved from there to Cincinnati in 1868. He became associated with the John Steptoe Shaper Co., and was shortly afterward made superintendent. In 1888, Mr. Mills and Albert S. Smith organized the firm of Smith & Mills with a very small capital. The business prospered, but no capital was ever borrowed to expand it. The policy was to be free of all financial entanglements and to conduct a safe, conservative business of constantly growing volume. Contrary to the policy of many machine tool concerns, the plan of Smith & Mills was to carry a large stock of machines ready for shipment. Mr. Smith withdrew from the firm some time ago, when the business was reorganized as the Smith & Mills Co. Mr. Mills is survived by a widow, two sons and three daughters. The sons, Ernest and James E., are active in the management.

COMING EVENTS

December 3-6.—Annual meeting of the American Society of Mechanical Engineers. Headquarters Engineers Bldg., 29 W. 39th St., New York City. Calvin W. Rice, secretary.

December 11-20.—First International Exposition of Safety and Sanitation under the auspices of the American Museum of Safety, 29 W. 39th St., New York City. Dr. William H. Tolman, director. Safety and health in every branch of American industrial life—manufacturing, trade, transportation on land and sea, business and engineering, in all of their subdivisions, will be represented at this exposition. Exhibits from Europe and other foreign countries will be admitted free of duty by special act of Congress. European employers have cut their accident and death rate in half by a persistent campaign of safety. There are twenty one museums of safety in Europe, and all these will contribute to the American Exposition.

NEW BOOKS AND PAMPHLETS

Registration of Vital Statistics and Good Business. By Louis I. Dublin. 15 pages, 6 by 9 inches. Published by the Metropolitan Life Insurance Co., New York City.

List of Works Relating to the Development and Manufacture of Typewriting Machines. 18 pages, 7¼ by 10¼ inches. Published by the New York Public Library, New York City.

Technical Control of the Colloidal Matter of Clays. By H. E. Ashley. 118 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Technologic Paper of the Bureau of Standards, No. 23.

The Silver Voltameter—Part III. By E. B. Rosa, G. W. Vinal and A. S. McDaniel. 60 pages, 7 by 10 inches. Published by the Department of Commerce, Bureau of Standards, Washington, D. C., as Reprint, No. 201.

The Function of Time in the Vitrification of Clays. By G. H. Brown and G. A. Murray. 26 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Technologic Paper of the Bureau of Standards, No. 17.

Effect of Overfiring upon the Structure of Clays. By A. V. Bleininger and E. T. Montgomery. 23 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Technologic Paper of the Bureau of Standards, No. 22.

Analysis of Coals in the United States Part II. By N. W. Lord, J. A. Holmes, F. M. Stanton, A. C. Fieldner and Samuel Sanford. 1200 pages, 6 by 9 inches. Published by the Department of Interior, Bureau of Mines, Washington, D. C., as Bulletin 22.

Melting Points of the Refractory Elements—I. Elements of Atomic Weight from 48 to 50. By G. K. Burgess and R. G. Waltenberg. 14 pages, 7 by 10 inches. Published by the Department of Commerce, Bureau of Standards, Washington, D. C., as Reprint No. 205.

Diagram Giving Stresses in Beams. By H. R. Thayer. 9 by 12 inches. Published by D. Van Nostrand Co., New York City. Price 20 cents.

With the diagram, the designer can find a beam for given loads and stresses; a beam for given moments and stresses; the section modulus required for given loadings and stresses; the stresses caused in a given beam by a given load; and the stresses caused in a given beam by a given moment.

Laboratory Manual of Testing Materials. By William Kendrick Hatt, and H. H. Scofield. 135 pages, 5 by 7½ inches. Published by McGraw-Hill Book Co., New York City. Price $2 net.

The manual is the outcome of the operation through eighteen years of the laboratory for testing materials of Purdue University. It treats of materials stressed beyond the elastic limit, testing and testing machines, list of experiments, instructions for performing experiments, common formulas, specifications for steel and iron, standard forms of test pieces, strength tables, etc. The work is one that should be appreciated by students, engineers and others who have to conduct experiments in the strength of materials of all kinds.

Cranes and Hoists. By Hermann Wilda. Translated from the German and adapted to British practice by Charles Salter. 168 pages, 4½ by 6¼ inches. 399 illustrations. Published by Scott, Greenwood & Son, Ludgate, E. C., England, and D. Van Nostrand Co., New York City. Price $1.

The work treats on the elements of lifting tackle, comprising hemp and wire ropes; chains, rope and chain pulleys; rope and chain drums; grooved chain wheels and sprockets; capstans; hooks; holding gears; brakes; gearing; couplings; etc. The second chapter is on types of cranes and hoists, comprising pulleys and pulley connections; fixed and movable pulleys; block and pulley tackle; differential pulleys; screw or worm pulleys; winches; traveling crabs with electric drive; lifting jacks; wall swings, pillar and traveling cranes; derrick cranes, etc. The book contains a great deal of valuable information and condensed data.

Farm Gas Engines. By C. F. Hirshfeld and T. C. Ulbricht. 239 pages, 5¼ by 7½ inches. 188 illustrations. Published by John Wiley & Sons, Inc., New York City. Price $1.50 net.

This work differs from other works on the operation and care of farm gas engines in that it may be used as a guide by those contemplating the purchase of a farm gas engine. The author discusses the power problems, fuels, the internal-combustion engine, the construction of the engine, principles of operation, indicator diagrams, power of gas engines, cooling systems, valve systems, com-

parison of two- [illegible] four-cycle operation, carbureters, electric [illegible] apparatus, the governing systems, lubricat[illegible], desirable and undesirable features of construct[illegible], mufflers, power rates and speed and types of farm engines. The work is one that can be recommended not only to farmers but to [illegible] purchasers and users of small internal combustion engines.

Strength of I-Beams in Flexure. By Herbert F. Moore. 40 pages, 6 by 9 inches. Published by the University of Illinois Engineering Experiment Station, Urbana, Ill., as Bulletin 68.

The formulas commonly used by architects and structural engineers for determining the carrying capacity of structural steel shapes are, in general, based on the common theory of elasticity and the tensile strength of structural steel. In figuring the strength of I-beams under transverse loads, it is the usual practice to consider only the direct flexural action. Transverse tests of I-beams have not been numerous and the results of such tests have not been widely used. It is known that besides direct flexural action of I-beams there are also sidewise buckling action and stresses in the web. In this bulletin these secondary effects are discussed and tabulated summaries given of the results of tests of I-beams. From the results of tests, the conclusion is drawn that in considering direct flexural action of I-beams the yield point strength of the material must be regarded as the ultimate fiber stress for the beam.

Principles of Industrial Organization. By Dexter S. Kimball. 272 pages, 6 by 9 inches. Published by McGraw Hill Book Co., New York City. Price $2.50 net.

The author points out that as the industrial enterprises have grown in magnitude, the simple administrative methods formerly in use have long since been outgrown in modern plants. He discusses fundamental principles, factory systems, systems preceding present methods, the effects of the great inventions, etc. One of the effects of great inventions has been to separate the worker from the tools and to degrade labor. In order that national property may not suffer and the degradation of labor may not be allowed to go on, a discussion of means for elevating labor, providing for welfare work, etc., is given. The author takes up modern industrial tendencies, forms of industrial ownership, principles of organization, planning departments, principles of cost-keeping, the depreciation of wasting assets, the compensation of labor, purchasing, storing and inspection of materials, the location, arrangement and construction of industrial plants, and theories of management, etc.

The Science of Burning Liquid Fuel. By W. N. Best. 159 pages, 6½ by 9½ inches. Illustrated. Published by W. N. Best, 11 Broadway, New York City. Price $2.

This work is a treatise for practical men; it gives some of the twenty-five years' experience of a man who was among the first to use liquid fuel on locomotives and for industrial purposes. The contents comprise: Liquid Fuel, its Origin, Production and Analysis; Atomization; Oil Systems; Refractory Material; Locomotive Equipment; Stationary and Marine Boilers; Oven; and Furnaces. The chapter on furnaces is of the utmost direct and suggestive value to foremen of forge shops, etc. Various types of oil feed furnaces are illustrated, showing the construction in detail. The author refers to the fact that the fuel oils used in America are now being refined and are distilled by new processes which produce higher percentages of kerosene, gasoline, etc., and that therefore it has become necessary to utilize the heavy crude oils from California and Mexico. These fuels necessitate many changes in oil systems heretofore used, and practical hints as to these troubles are given. The author being a maker of oil-burning apparatus, is in close touch with the developments of oil-burning apparatus in all fields.

Hendricks' Commercial Register of the United States. 1668 pages, 7¼ by 10 inches. Published by the S. E. Hendricks Co., 74 Lafayette St., New York City. Price $10.

This well-known directory of manufacturers has just been issued in the twenty-second annual revised edition. It was established in 1891 and has been published annually since. It is one of the most complete works of its kind published. Its aim is to furnish complete lists of manufacturers for the benefit of those who wish to buy as well as those who have something to sell. It covers very completely the architectural, engineering, electrical, mechanical, railroad, mining, manufacturing and kindred trades and professions. The present edition is the largest so far issued. The twenty-first edition required 122 pages to index its contents while the twenty-second edition requires 138, or 16 additional pages. As there are upward of 400 classifications to the page, the 16 additional pages represent over 6000 additional classifications, none of which appeared in previous editions. The total number of classifications is over 55,000 representing the manufacturers or dealers of machines, tools, specialties or materials required in the architectural, engineering, mechanical, electrical, railroad, mine and kindred industries. An important feature of the register is the simplicity of its classifications. They are so arranged that the book may be used for either purchasing or mailing purposes. As an illustration, all manufacturers of a particular trade are classified under a general heading for mailing purposes. They are then sub-divided, each firm and corporation being placed under as many classifications as every variety of their products call for. The value of this arrangement for all classes of users is obvious. The work also gives information with the names of firms of value to the buyer. The trade names of products are included with the manufacturer's name whenever the product of a manufacturer is sold under a trade name. These trade names appear in parentheses between the names and addresses, under the classifications where they appear.

NEW CATALOGUES AND CIRCULARS

Mesta Machine Co., Pittsburg, Pa. Bulletin I on Mesta gas engines.

J. T. Slocomb Co., Providence, R. I. Leaflet on the Slocomb micrometer No. 26, with friction thimble.

Charter Gas Engine Co., Sterling, Ill. Catalogue No. 12 of "Charter" type "R" oil engines.

Industrial Instrument Co., Foxboro, Mass. Bulletin 81 on "Foxboro" electric pyrometers.

Pawling & Harnischfeger Co., Milwaukee, Wis. Bulletin 301 on the "P. & H." type "T" electric hoist.

Loew Mfg. Co., Cleveland, Ohio. Circular on the "Loew Victor" lathe bed pipe threading and nipple machine.

Schutte & Koerting Co., Philadelphia, Pa. Catalogue 6, Section C on Koerting air jet chimney ventilators.

General Electric Co., Schenectady, N. Y. Bulletin No. A4142 on the importance of operating lamps at the proper efficiency.

National Tube Co., Frick Bldg., Pittsburg, Pa. Circular of the "National" spring plug cock, suitable for working pressures up to 125 pounds.

Newall Engineering Co., Blackhorse Lane, Walthamstow, London, E., England. Catalogue of Newall gages, micrometers and measuring machines.

Oneida National Chuck Co., Oneida, N. Y. Circular of the "National" ball bearing drill chuck in which the jaws automatically tighten on the drill.

Charles H. Besly & Co., 118-124 North Clinton St., Chicago, Ill. Circular on the Besly patternmakers' disk grinder, illustrating its use on typical pattern work.

Electric Furnace Co. of America, Alliance, Ohio. Circular of the Baily electric furnace for heat-treating metal and for annealing, tempering and casehardening.

C. U. Scott, Davenport, Iowa. Folder illustrating Mr. Scott's plant for casehardening, carbonizing, heat-treating, brazing, blueprinting, tinning, galvanizing, etc.

Eugene Dietzgen Co., 218 E. 23 St., New York City. Circular of the Dietzgen economy box for storing blueprints, sketching, tracing and drawing paper, tracing cloth, etc.

B. F. Sturtevant Co., Hyde Park, Mass. Catalogue No. 225 on air washers for removing dust and soluble impurities from air supplied to plants where absolute purity of the atmosphere is required.

Sleeper & Hartley, Worcester, Mass. Bulletin 270 on torsion spring winding machines; bulletin 272 on music wire straightening and bundling machine; and bulletin 275 on No. 1 wire flattening mill.

Electric Controller & Mfg. Co., Cleveland, Ohio. Bulletin 1017 on automatic controllers for motor-driven machines, direct current; bulletin 1036 on the Youngstown safety limit stop for direct current motors.

Clinton Wire Cloth Co., Clinton, Mass. Report of a fire, load and water test made upon cinder, concrete, terra cotta and gypsum floor slabs at the Columbia Fire Testing Station, Greenpoint, Brooklyn, N. Y.

Lumen Bearing Co., Buffalo, N. Y. Booklets on machine tool and machinery bronzes and high tensile strength bronze. These little booklets, which are sent free to any address, contain valuable information on bearing metals.

Shaw Electric Crane Co.—Manning, Maxwell & Moore, Inc., 119 W. 40th St., New York City. Bulletins 82, 91 and 109 on portable electric single drum drag, type M trolley for steel mill service and crane motor, type Z.

National Tube Co., Frick Bldg., Pittsburg, Pa. Circular of the "Kewanee" air pump union which is largely used on the air lines of locomotives. The union is tested with 125 pounds compressed air under water before leaving the factory.

Covel Mfg. Co., Benton Harbor, Mich. Circular on automatic band-saw sharpener having a capacity for saws from 1 inch to 6 inches. This machine automatically sharpens all kinds of band-saws with any shape of tooth, within its capacity.

Alston Saw & Steel Co., Folcroft, Pa. Circular on the Alston process improved hacksaw blades for all purposes. The blade is made with a hardened edge and back and a soft center, a combination which is said to produce an extremely flexible saw.

General Electric Co., Schenectady, N. Y. Bulletin No. 4972 describing the KR system of voltage regulation which can be successfully employed on systems having such large fluctuations of voltage that the standard method is ineffective.

Porter-Cable Machine Co., 501 East Water St., Syracuse, N. Y. Circulars of No. 3 sensitive high-speed universal milling attachment for standard milling machines, and No. 4 positive drive universal milling attachment for standard milling machines.

F. Wiard, 724 Ford Bldg., Detroit, Mich. Circular on the Wiard drill chuck for rapid drilling, reaming, counterboring, etc. The chuck is made for use with collets fitting the Morse standard taper. Drills can be changed with the spindle in motion.

Ingersoll-Rand Co., 11 Broadway, New York City. Bulletin No. 8011 showing new line of "Little David" riveting hammers, sizes 50, 60 and 80, which are suitable for structural work, tank, steel or other similar work up to 1¼ inch diameter rivets.

Gisholt Machine Co., Madison, Wis. Catalogue of Gisholt adjustable reamers manufactured by the small tools department of the company. The manufacture of these reamers is the outcome of the demand for tool equipment by users of Gisholt turret lathes.

Metropolitan Museum of Art, New York City. Supplement to the bulletin on the relation of the Metropolitan Museum of Art to the public schools, showing how valuable an educational adjunct the museum may be made by teachers with their classes.

National Tube Co., Frick Bldg., Pittsburg, Pa. Bulletin No. 16 on "National" stationary and marine boiler tubes, containing illustrations showing the severe tests to which boiler tubes are subjected and which they must endure in order to be passed by the inspectors.

C. H. Cowdrey Machine Works, Fitchburg, Mass. Descriptive leaflet of the company's equipment for building special machinery. It is prepared to build textile machinery, celluloid machinery, shoe machines, paper bag machines, printing press feeders, jigs, fixtures, tools, etc., to order.

Raymond Foundry & Machine Co., Raymond, Wash. Circular on the Selby gearless reverse clutch for motor boats driven by gas engines. The claims are made that this clutch gives full speed in reverse direction, that its efficiency is 96 per cent in reverse and that it is noiseless in operation.

Davis-Bournonville Co., 30 Church St., New York City. Special price list No. 4 of oxy-acetylene welding and cutting supplies, comprising "Atlas" cast-iron welding rods, "Ajax" welding wire, "Atlas" sealing powder, "Marvel" flux powder for brass and bronze, "Peerless" aluminum welding powder, etc.

Toledo Bridge & Crane Co., Toledo, Ohio. Clearance dimension sheet for standard cranes, giving the dimensions for cranes of 3 tons to 150 tons capacity, inclusive, and having from 40 to 80 feet span. This list will be sent to consulting, contracting or mechanical engineers and plant superintendents, on request.

Curtis & Co. Mfg. Co., 1568 Kienlen Ave., St. Louis, Mo. Catalogue No. 61 on air compressors, air hoists, air cranes, pneumatic and hydro-pneumatic elevators, trolleys, trolley systems and sand blasts. The catalogue illustrates a wide variety of pneumatic appliances for manufacturing plants.

E. Horton & Son Co., Windsor Locks, Conn. Catalogue No. 12 of lathe chucks, faceplate jaws and drill chucks, including the Morrow ball-bearing self-tightening drill chuck. The catalogue lists the new lines of the S. E. Horton Machine Co. with those of E. Horton & Son Co., thus forming a complete line of chucks for all purposes.

General Electric Co., Schenectady, N. Y. Bulletin No. A4137 illustrating and describing Curtis steam turbines of 100 to 2500 K.W. capacity for driving 60-cycle generators at 3600 R.P.M. These generating sets are of the horizontal shaft rigid frame type, and either two or four impulse wheels are used, depending upon the capacity of the generator.

Universal Boring Machine Co., Hudson, Mass. Catalogue of No. 3-A "Universal" horizontal boring machine, containing illustrations showing head, post and operating levers; machine fitted with special table and equipment. The manufacturer makes a point of the fact that the "Universal" is "a right-hand machine for right-handed operators."

General Electric Co., Schenectady, N. Y. Bulletin A4115 entitled "Electricity on the Farm" constituting the most complete treatise on the subject that has yet been issued by any manufacturer. The bulletin treats of lighting systems for the farm and the uses of electricity in the farm home and contains a dissertation on the general advantages of electric drive.

James Clark, Jr. Electric Co., Louisville, Ky. Catalogue No. 22 of "Willey" electrically-driven portable drills in a large variety of styles, center grinders and hand grinders and buffers, surface and internal grinders, toolpost grinders, bench grinders, combined wet and dry grinders, jewelers' sensitive bench drills, electrically-driven hacksaws, friction-driven sensitive drills, notching presses, winding machines, locomotive turntable motors, etc.

Hollands Mfg. Co., Erie, Pa. Catalogue No. 22 of vises and tools comprising machinists' solid jaw parallel vises, filers' solid jaw parallel vises, machinists' offset jaw vises, machinists' swivel jaw vises, Penn woodworkers' vises, woodworkers' offset jaw vises, Walworth pipe vises, standard combination vises, Keystone woodworkers' vises, Keystone malleable pipe vises, Penn malleable hinged pipe vises, three-wheel pipe cutters, pipe reamers, taper reamers, pipe taps, etc.

National Tube Co., Frick Bldg., Pittsburg, Pa. Bulletin No. 17 on the manufacture and use of Shelby seamless steel tubing, containing extracts from an address to the U. S. Naval School of Marine Engineers by J. H. Nicholson and Emil Holinger. The article is illustrated with many drawings to show principles of operation. The bulletin should be of unusual interest to all concerned with the use of seamless tubing, seamless cylinders, hydraulic forgings, projectiles, etc.

New York Central Lines, Grand Central Station, New York City. Reprint from the "Outlook" of "A Nation's Neglect" by Marcus A. Dow, general safety agent New York Central Lines. The writer urges educational and legislative measures to prevent the unnecessary killing and maiming of thou-

RE-BLADING A PARSONS STEAM TURBINE

TOOLS, DEVICES AND METHODS EMPLOYED IN REPLACING BLADES OF A TURBINE ROTOR

BY N. I. MOSHER*

In a machine shop where the writer was a foreman, a Parsons steam turbine from one of the United States Navy destroyers came in to be rebladed. After dismantling the unit the first step was to test the cases and rotor, to determine if they had taken any permanent "set" or distortion from the

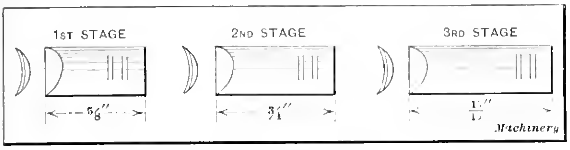

Fig. 1. Results of Successive Operations in forming the Turbine Blades

heat. A careful test showed the cases to be perfectly accurate, but it was found that the rotor had taken a permanent set that threw it 0.030 inch off center. This figure refers to the error that existed at the middle of the rotor, the error gradually diminishing until it was nil at each end. After careful consideration it was decided not to attempt to remedy this error until after the new blades had been set in the rotor. This line of action was adopted, because it was felt that

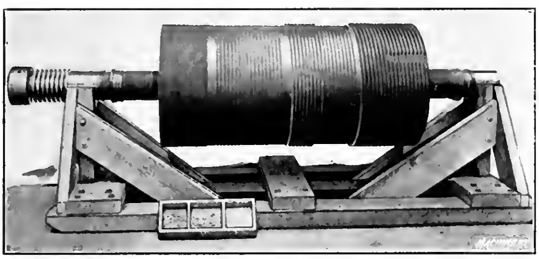

Fig. 2. Cradle in which the Rotor was supported to remove the Old Blades

further distortion would be sure to result from calking the blades in the grooves in the rotor. The method by which the error was finally eliminated will be described in a subsequent paragraph.

The next operation was to remove the old blades from the rotor and cases. In order to facilitate matters the rotor was mounted in a cradle of the form illustrated in Fig. 2, and the blades were removed with a hand chisel. A similar method

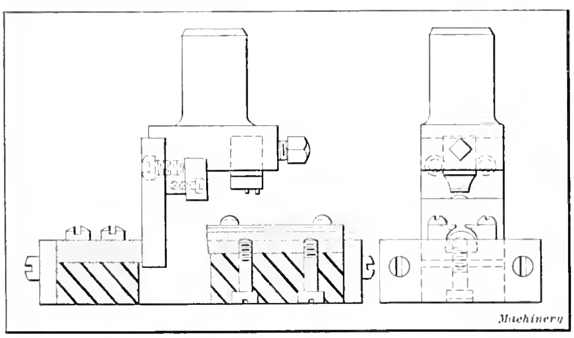

Fig. 3. Shear, Punch and Die used for cutting off and forming the New Blades

of procedure was adopted in removing the blades from the turbine cases. An idea of the magnitude of this task may be gathered from the fact that the total number of blades was in the neighborhood of 60,000.

The first step in preparing to re-blade the rotor and cases was to cut the blades and calking strips from the bar stock. This stock was purchased in lengths of 10 feet, and of the required form for the blades and calking strips. In preparing the blades the operations performed on the stock were as follows: First, pieces of the required length were cut off from the bar. Second, notches were stamped in one end of these blanks to provide for securing them in place in the turbine

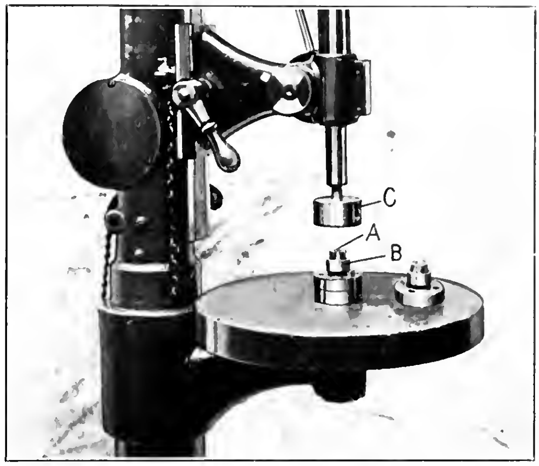

Fig. 4. Method used for milling the Ends of the New Turbine Blades

rotor and cases. Third, the opposite ends of the blades were then milled to the required form. The first and second operations were performed by the combination shear and die illustrated in Fig. 3. This die was used in a No. 18 Bliss power press operated at 90 revolutions per minute. At this speed

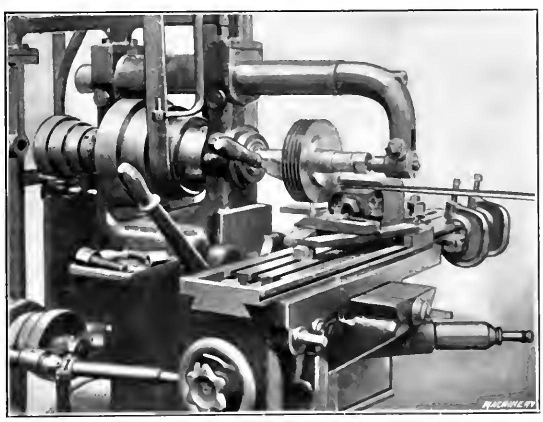

Fig. 5. Milling Machine Fixture used for cutting off Calking Strips

3600 blades could be cut off and grooved in an hour, and the total time required to perform these two operations on 60,000 blades was 18 hours. This does not include the time occupied in adjusting the die.

The ends of the blades were next milled to the required form by means of an end mill mounted in the drill press shown in Fig. 4. The workholder consisted of a pin *A*, 5/8 inch in diameter, around which five blades were held by means of a collar *B*. The hollow mill *C* was fed down over the ends

* Address: 15 James St., Winter Hill, Somerville, Mass.

of the blades, and about ten seconds was required to complete the operation. The blades were quickly removed from the holder by simply turning it upside down. Two work-holders were employed and two boys were engaged upon this work. One boy operated the machine and the other removed the finished blades from the holder and filled it with fresh blanks, while the milling operation was being performed on

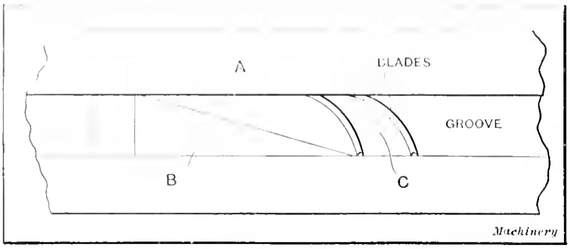

Fig. 6. View of a Groove in the Turbine Rotor showing Method of starting to replace the Blades

work held in the other holder. By this method, it was possible to mill about nine hundred blades per hour, and as long as the milling cutter was kept sharp, a perfectly smooth surface was produced. After washing these blades with gasoline, they were ready to be calked into the cases and rotor of the turbine.

The next operation consisted of cutting up the calking strips into pieces of the proper length. This material, like the stock

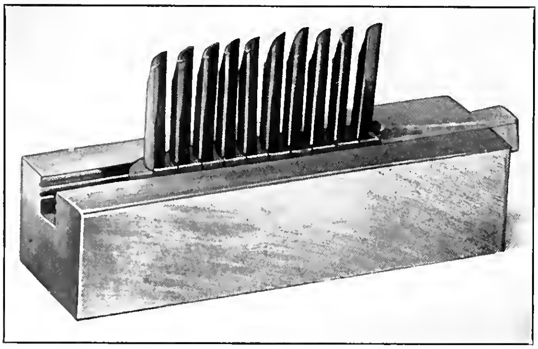

Fig. 7. Model of a Section of the Rotor Groove, showing Blades, Calking Strips and Wedges in place

from which the turbine blades were made, was purchased in 10-foot lengths and cut up by means of gang saws secured on the arbor of a Fox hand milling machine illustrated in Fig. 5. The saws were spaced on the arbor to cut off pieces of the required length and a stop was provided at the end of the fixture to enable the bar stock to be properly located in relation to the saw blades. By this means, six pieces were cut off at once and about 2400 pieces could be cut per hour.

With the blades and calking strips prepared, the work of installing the blades in the turbine was started. In order to make a start in filling a groove, two wedges *A* and *B* were driven into place as shown in Fig. 6. One end of the wedge *A* is formed to the required angle and shaped to enable the first blade to be properly located against it. A calking strip *C* is next placed in the groove and calked sidewise to secure it in small grooves cut in the sides of the grooves in which the blades are mounted. These small grooves may be seen in Fig. 7. Alternate blades and calking strips were then put in place and calked until the opposite side of the starting wedges was reached. The wedges were then removed and the remaining blades and calking strips put into place. A certain amount of manipulation was necessary to get the last few blades in, but after a little experience this part of the work was easily performed; and with one man putting the blades in place and the other calking them, it was possible to set five hundred blades per hour. After a groove had been filled in this way, it was necessary to go back over the same blades a second time and set the calking strips endwise to expand them into the small notches that were stamped in the blades in a preceding operation. A third man performed this work and was able to proceed with about the same rapidity as the two men who set the blades in place. Fig. 8 shows the tools used for

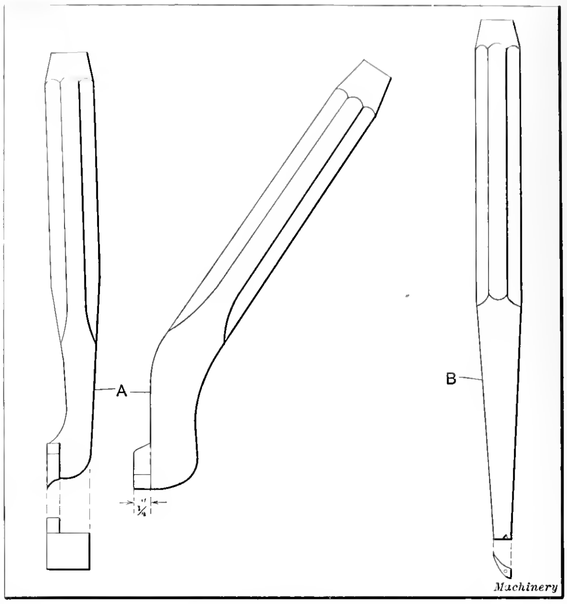

Fig. 8. Tools used for expanding the Calking Strips Sidewise and Endwise

calking. The tool shown at *A* was used for expanding the calking strips sidewise and a tool of the form *B* was used for setting the strips endwise. It will be seen that there is a small hole in the end of the calking tool *B*. This leaves a mark on the calking strip and shows at a glance whether the strip has been set. The blades were mounted in the grooves in the cases in the same manner, but owing to the awkwardness of the position much more time was required for this part of the work.

After both the rotor and cases had been re-bladed, the next operation was to true up the rotor and turn the blades down to a length that would give the desired clearance. The blades

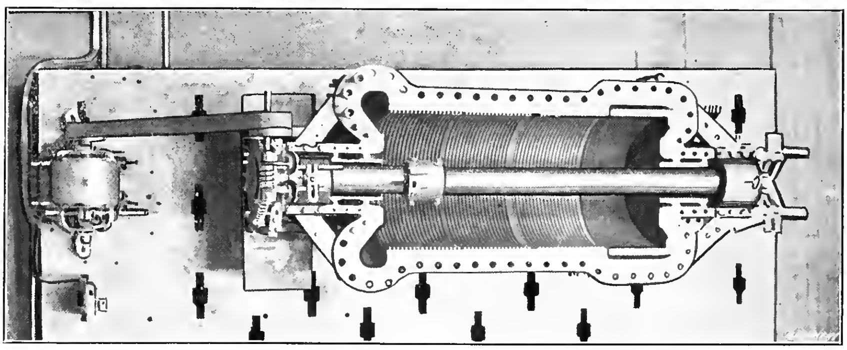

Fig. 9. Arrangement of the Boring-bar for machining the Ends of the Blades in the Cases

were turned in a lathe provided with a special tool which cut the ends off clean without leaving any burr. The journals were next ground, and it was then necessary to balance the rotor. For this purpose the rotor was set up in a lathe and trued between the blades, *i. e.*, the part that revolved close to the fixed blades in the cases. Truing up the drum in this way left one side 0.030 inch thicker than the other side—ac-

cording to previous measurements—and this naturally threw the rotor out of balance. To correct this error, the rotor was mounted on hardened steel knife-edges and allowed to roll until the thick part of the metal—the heavy side—reached the lowest point. The necessary amount of putty to exactly balance the rotor was then placed on the thin side of the drum. The weight of this putty was then determined and its weight in steel secured to the light side of the drum by means of screws. In this way, an accurate balance was secured.

The blades in the cases were finished to the required length in practically the same way that the cylinders of a reciprocating engine are bored. Fig. 9 shows the lower half of the case set up on a surface plate with a 6-inch boring bar fitted in the bearings and driven by an electric motor and belt. A special tool was fitted in the cutter head, the tool being set to about 0.010 inch smaller radius than the cases should have

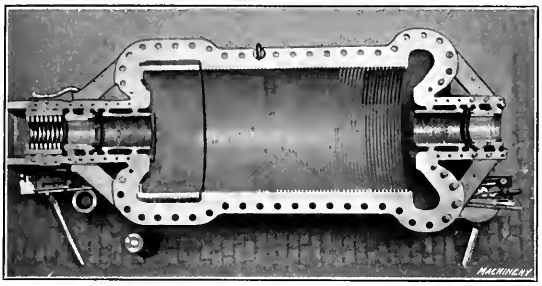

Fig. 10. Upper Half of the Turbine Case ready to be bolted in place for boring the Blades

when finished. The upper half of the case, shown in Fig. 10, was then lowered into place and securely bolted. In this way, the cases were in exactly the same condition as they would be if the turbine were in operation. After running the first cut through, the cutter head was drawn back to the starting point and a second cut was then taken with the boring bar expanded 0.010 inch, which machined the blades down to exactly the required length. The adjustment of the tool and the calipering of the bore was accomplished by reaching through the exhaust nozzle. The time required to bore the rotor cases was eight hours. About the same length of time was required to turn the blades in the rotor to the required length. A clearance of about 0.030 inch was left between the cases and the blades of the rotor. After the cases had been bored out, the bar was removed and the chips and dirt blown out. The bearings were then adjusted, after which the rotor was lowered into place and the cases bolted together.

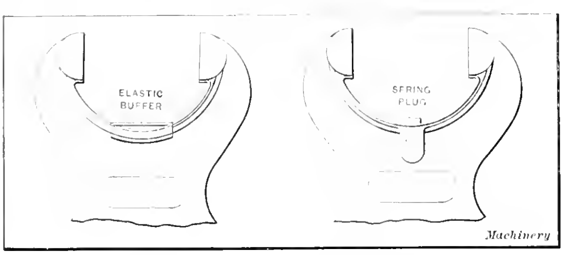
IMPROVED LIMIT GAGES

An improvement in snap limit gages of some interest has been patented by Ludwig Loewe & Co. and Otto Moratz of Berlin, Germany. The improvement is intended to give snap gages longer life. The claim is made that when gaging work, the effect of many pieces passed through the jaws is to peen



Ludwig Loewe & Co.'s Improved Limit Gages

the metal at the bottom of the slot of the "go" gage because of the slight shock caused when the part strikes it. The effect is to open the jaws and thus the wear on the jaw faces themselves is accelerated. The inventors interpose an elastic material or a spring plug in the center, which takes the impact of the work piece and thus stops the peening action.

CLUSTER DOUBLE-ACTION PUNCHES AND DIES*

BY BENJAMIN W. HURD†

The cluster double-action punches and dies shown in Fig. 1, although of a type familiar to many readers, should be of interest to others who have not had experience in this style of die construction. While this type of die has many advantages over the single construction, it is open to the objection that extreme care has to be taken in laying out the punch-block. The holes in the die-block are reamed approximately 0.005 inch larger than the collets and are transferred to the die-block through bushings fitted into the punch-block when the two members are clamped together. If the holes for the die-holders are not laid out accurately the tie or web between the blanked holes will be cut out as the metal feeds through, any error in spacing, of course, being multiplied as the work progresses. However, if the die-holder is properly laid out, it is possible to cut very close on scrap. On thin metal, in actual running, it has been found that the scrap averaged 18 per cent, while the estimated scrap was 18¼ per cent. These test runs were made on 0.017-inch metal, 90 Cu 102 N mixture, sixty- and sixty-five-pound rolls, averaging two strips to the roll. The difference between the actual and estimated scrap was due to the slight amount that the feed rolls squeezed the scrap back, making the webs slightly less than that estimated.

As a general rule, the punch- and die-block for this type of die is made from steel, and while this is not necessary as a matter of strength, it does away with the chances of striking a blow-hole in cast iron. The collets, sleeves and nuts, forming the members for holding the dies, are also made from tool steel hardened and ground. The blanking dies *A* are made from a high-carbon steel heated to the recalescent point, cooled in brine, at 62 degrees F., and then placed in an oil bath at 225 degrees F., after which they are ground. Each blanking die is good for approximately 1,000,000 blanks before grinding on the top face, which can be done, as a rule, about ten times, if necessary on account of wear and not due to chipping. It can be seen by referring to Fig. 1, from the way in which the blanking die is held, that if the die is cracked from any cause, after it is ground to size, it still can be used without detriment to the blank. The sleeve holding it is tapered, and in this way as it is drawn up by the nut under the bolster, the die is securely held in place, and if cracked would be closed up.

The cupping dies *B* and *C* are made from "Intra" steel, which is used because of the extremely hard surface obtained when it is heated to the proper temperature and "spouted." It is also extremely tough when heated in this way, and the combination of hardness and toughness is ideal for cupping dies. The small size of these dies makes it necessary to use a steel of great tensile strength, as well as one that will harden well, and "Intra" steel fills these requirements better than any that has thus far been used for this purpose.

The cupping dies are heated to the recalescent point, which is found by using the testing fixture shown in Fig. 2. The die to be tested is placed under the magnet *A* from time to time, as the heating progresses, and when the point is reached where the steel has no attraction for the magnet, the heat is noted on a temperature pyrometer, and all dies made from this grade of steel are heated to that point. If a temperature pyrometer alone is used, without the magnet, readings are taken at stated intervals of approximately one minute apart, and then a chart is laid out by taking the readings as obtained from the pyrometer. This chart, if properly laid out, will show at the recalescent point a horizontal line. When the cupping dies have reached the proper temperature they are "spouted" with brine by holding them under a funnel which hardens the hole and leaves the outside circumference soft. They are then placed in oil, heated to 225 degrees F., and allowed to remain until they reach the temperature of the oil. One noticeable feature of cupping dies made from

* For further information on punch and die work, see "Drawing and Forming an Automobile Clutch Cone," published in the November, 1913, number of MACHINERY, and other articles there referred to.

† Address: 2010 Hearst Ave., Berkeley, Cal.

"Intra" steel is that they have a longer life—more cups per die—when the press is operated at from 125 to 135 R. P. M. than they do on lower speeds of from 90 to 100 R. P. M.; also the cups come square with less trouble.

In making the blanking punches and dies, care should be taken at all times to have the bottoms of the blanking punches and the tops of the cupping dies parallel. If they are not, it will be impossible to get a square cup, as the punch will bear harder on one side than on the other. In reaming out the hole in the cupping die, care should be taken to see that it is perfectly round and square with the top and bottom faces. A good method of determining if such a requirement has been obtained is to wring the plug gage into the die; this leaves a ring around the hole in the die parallel with the top face when the hole has been properly machined. That is to say, after swabbing out the die and cleaning the gage, a slight oil film is left on both parts; then when the gage is wrung into the die the liquid constituents of the oil are squeezed out, leaving a small carbon deposit. This should show heaviest just at the point where the drawing portion of the die commences to round off into the straight or sizing portion. On the lower or stripping die it is necessary to have the line show heaviest on the bottom, as a slight bell-mouth on the bottom will make the cup strip hard. If this line left by wringing the gage into the die is not parallel with the top face, the cup produced will not be perfectly straight, but will have an irregular top edge. This undesirable condition generally results from a chip clinging to the cutting edge of the reamer for a portion of a revolution when reaming out the die. It is also often caused by poor lapping, but more generally by reaming, as previously mentioned. If more attention were paid to this point there would be less trimming with its attendant scrap on re-draw work, as it is practically impossible to get a floating die to draw square unless it has a perfect "ring" bearing.

The blanking punches *D*, one of which is shown to the right in Fig. 1, are held in the punch-block by the split sleeve

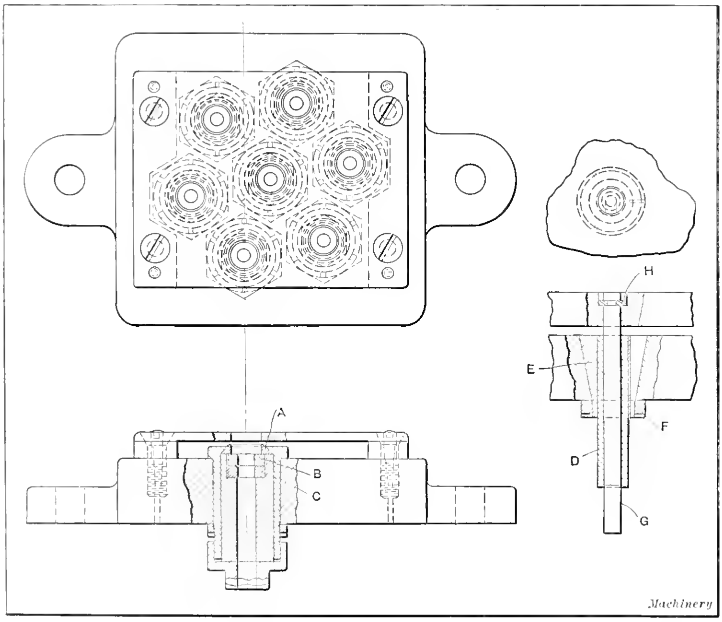


Fig. 1. Cluster Double-action Punches and Dies

E, which, in turn, is drawn down by the nut *F*. This makes it possible for the punch *D* to slip up if more than one blank gets under it, which sometimes happens when a poor piece of metal gets into the press and the drawing punch *G* punches out the bottom of the cup instead of drawing it through the dies. Both the blanking and drawing punches are made from high-carbon steel, heated slowly to the recalescent point in a muffle furnace and rolled around from time to time to get an even heat. They are then plunged in water that has previously been heated to 80 degrees F. This is done slowly with a tank which is so deep that the punch will turn black before being withdrawn. That is to say, the tank should have sufficient depth so that the punch when dipped straight will not touch the bottom before it has been cooled sufficiently to harden; it is also withdrawn straight from the tank. After hardening, the punches are then dipped in oil, heated to 225 degrees F., and allowed to remain in the tank for from ten to fifteen minutes. Afterwards they are ready for grinding.

The drawing punch is made with a taper on the end of from

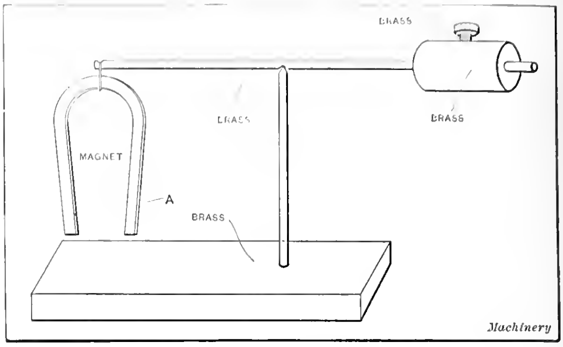

Fig. 2. Magnetic Device for determining Recalescent Point of Dies when heating for hardening

0.004 to 0.005 inch to the inch of length, and is ground to this taper for approximately one inch. When the tapered ends of the punches have worn down below the required size, they are cut off on the end and re-ground, the slide of the press being lowered to compensate for the reduction in length. The upper ends of the drawing punches are held by slotted washers *H* which are fitted into counterbored holes in the punch-block.

The cluster double-action punches and dies shown in Fig. 1 are used in double-action crank and double-action cam presses, but for work using metal thinner than 1/32 inch the cam press is preferable on account of the dwell which it is possible to obtain at the lower end of the stroke while the drawing punches are doing their work. With a strong, well designed and well built press, no trouble should be experienced in cutting with a minimum amount of scrap, when the tools and feeding device have once been properly adjusted.

* * *

Managers, superintendents and foremen sometimes forget in talking with outsiders that their workmen are human beings and have the feelings and instincts common to the race. We have heard superintendents speak in very caustic terms of the characteristics of workmen in general, within hearing of the workmen themselves. This is extremely bad policy. Even if the statements were true, it is not always wise to let the men know how the management feels about them, especially if contemptuous. "Give a dog a bad name and hang him" is an old saying expressing as much truth to-day as when it originated. A better policy is to convey the impression that the management respects workmen as a class and all individuals who merit respect. Thus mutual respect will be engendered, where under the other condition suspicion, hatred and malice are fostered.

* * *

A cement that will resist white heat may be made, according to the *Mechanical World*, from four parts pulverized fire-clay, one part plumbago, two parts iron filings, one part peroxide of manganese, one-half part borax, and one-half part sea salt. These ingredients are mixed together to a thick paste and used immediately after mixing. The mixture is heated gradually after having been first fired.

RELIEF OF TAPS

REVIEW OF DIFFERENT METHODS USED AND DESCRIPTION OF NEW TYPE OF TAP THREAD RELIEF

A great deal has been written upon the subject of the relief of the threads of taps, but notwithstanding this, there is no universally recognized standard as to what constitutes a properly relieved tap, and the product of the different manufacturers of taps varies in this respect. It is possible, however, by analysis and experiment, to determine fairly accurately what constitutes a properly relieved tap, and it is of interest to note that one of the leading tap manufacturers has done this, and has developed methods for producing taps relieved along lines radically different from common practice. These advanced ideas of relief will be explained in the following; but in order to cover the subject comprehensively and give as complete an idea as possible of the results likely to be obtained from taps relieved in various ways, the types that have been used in the past will be reviewed, and an analysis made of the action of taps having different forms of relief.

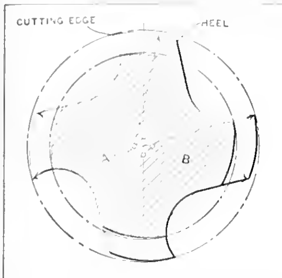

Fig. 1. Cross-section of Tap relieved both on Top and in Angle of Thread

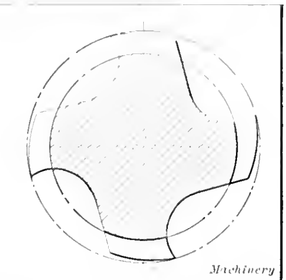

Fig. 2. Cross-section of Tap relieved on Top but not in Angle of Thread

Principles Involved in the Relief of Taps

A tap is said to be relieved when the portions of the land back of the cutting edge are so cut away that the heel of the land (see Fig. 1) is nearer to the axis of the tap than is the cutting edge. In other words, the metal of the land back of the cutting edge has been so cut away that the diameter A of the tap, as measured over two opposite cutting points, is greater than diameter B, measured over the heels of two opposite lands. The effect is simply to give to the land of the tap a relief similar to that given to milling cutters. The object of this relief is to enable the tap to cut more freely, by giving it a keener cutting edge, and by reducing to a minimum the friction between the teeth of the tap and the work being tapped.

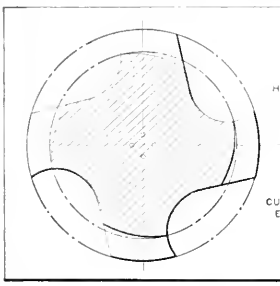

Fig. 3. Cross-section of Tap relieved in the Angle but not on the Top of Thread

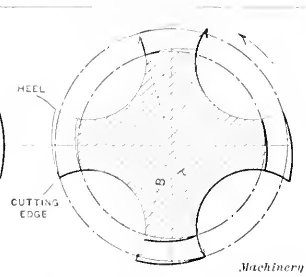

Fig. 4. Tap not relieved, warped in hardening so Diameter over Heel is Larger than over Cutting Edge

It is apparent that taps may be relieved both on the outside diameter and in the angle (and then also at the root) of the thread; as is the case in Fig. 1; or they may be relieved only on the top of the thread, but not in the angle (or at the root) of the thread, as indicated in Fig. 2. It is also possible to relieve only in the angle of the thread, leaving the outside circumference of the tap unrelieved, as shown in Fig. 3. This condition is possible, however, only when the thread is provided with a flat on the top, and permissible only where the maintaining of the width of this flat is of no importance. If the thread is perfectly sharp at the top, it is evident that any relief given to the angle of the thread will of necessity produce a relief on the top of the thread as well.

In order to intelligently analyze the subject, it is necessary to divide taps into three classes, because of the different conditions governing the type of relief required in each of the three divisions. The first class is that of straight-threaded taps; the second, taper-threaded taps; and the third, taps having one portion threaded straight and another portion threaded taper.

Straight-threaded Taps

By a straight-threaded tap, we mean a tap having the same outside, pitch and root diameter of thread at the point of the tap as at the shank end; that is, a tap having the thread parallel to the axis, as shown in Fig. 5. Of course, the extreme end of the tap may be chamfered on the top of the thread as indicated, but that does not alter the fact that the tap is straight-threaded. A number of different methods have been used for relieving taps of this class. In many instances, no relief at all has been given to the full threads, but the tops of the threads of the chamfered portion at the end of the tap have been relieved in a manner similar to that used for milling cutters. In other instances, the thread has been relieved both on the top and in the angle, clear from the cutting edge to the heel, as shown in Fig. 1. Neither of these methods, however, has proved satisfactory; the objection to the first is that the thread being full both in the angle and on the outside, causes the tap to move with excessive friction, and considerable power is required for tapping. The method of relieving the tap both on the top and in the angle of the thread clear from the cutting edge to the heel has the objection that the tap will lose its size as soon as it is ground on the face of the cutting edge,

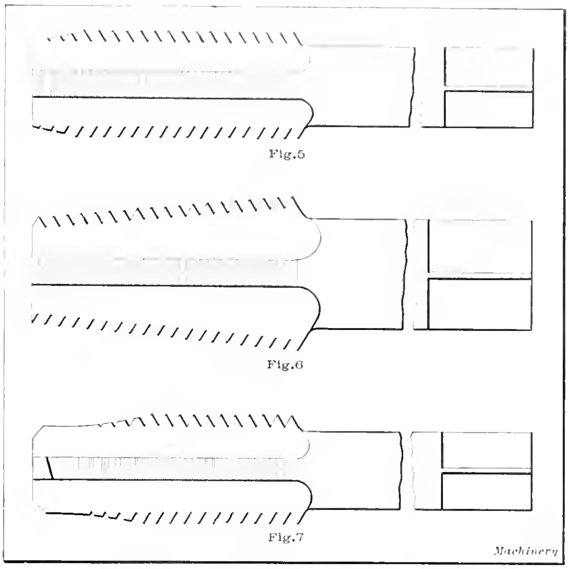

Fig. 5. Straight-threaded Tap. Fig. 6. Taper-threaded Tap. Fig. 7. First Tap in a Set of Three, commonly called "Taper Tap"

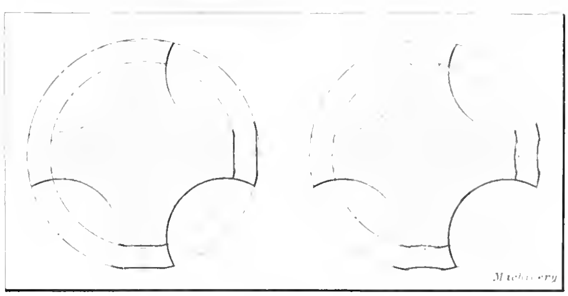

Figs. 8 and 9. Taps relieved in Center of Land both on Top and in Angle of Thread

which is the correct method of sharpening. Furthermore, it is claimed that taps thus relieved cannot cut a perfectly round and smooth hole, because they are not sufficiently supported while cutting, as the surface of contact between the tap and the work is practically limited to four points (in a four-fluted tap.)

To overcome the objection of having only point supports, taps have been manufactured with relief in the angle of the thread only, while the outside was left the full diameter of the thread from the cutting edge to the heel, as shown in Fig. 3. In this manner, the object of producing a free cutting tap has been gained, and the taps are also well supported in the hole to be threaded, but the objection remains that a tap relieved in this way loses its correct size at the pitch diameter as soon as it is ground on the face of the cutting edge. The outside diameter will remain constant, no matter how much the tap is ground on the face, but as the angle or pitch diameter is the most important dimension, it will be conceded that unless the tap is originally made considerably over size it will, after a few grindings, become appreciably smaller than standard. It is also evident that on a U. S. standard thread tap, the flat on the top of the thread becomes narrower toward the heel of the lands, if the tap is relieved in the angle of the thread only. In other words, the form of the thread will not be correct throughout the width of the land. This, however, is a matter of minor importance, as after repeated grindings it will merely provide proportionately more clearance at the top of the thread, which is often a commendable feature.

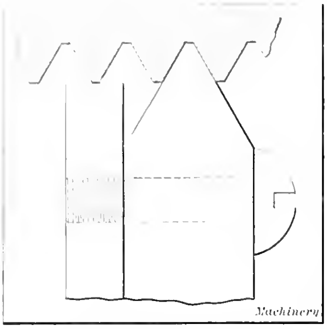

Fig. 10. Tool for relieving Taps in Angle and on Top of Thread simultaneously

A tap with a sharp V-thread, however, cannot be relieved in this manner, because as has been already pointed out, the relief in the angle will of necessity cause a relief of the sharp top of the thread as well. It is true that in practice sharp V-thread taps are provided with a very small flat on the top of the thread, but this flat is not large enough to permit of relief in the angle without relief on the outside. In the case of taps with the Whitworth form of thread, it is impossible to relieve them in the angle without also relieving the top of the thread, if the proper form is to be retained.

To overcome the objections mentioned, another method of relief has been tried, although, so far as we know, this method has not been generally employed on taps manufactured for the market. This method is shown in Figs. 8 and 9, where both the outside and the angle of the thread are relieved in the center of each land of the tap. This kind of relief can be produced in the angle of the thread by hand with a 60-degree, three-cornered file (Fig. 8) or with a regular threading tool, if done in a lathe provided with a relieving attachment (Fig. 9). The outside of the thread can be relieved by filing; but if the relieving is done in a lathe, it can be most economically accomplished with a combination tool, as shown diagrammatically in Fig. 10. In Fig. 11 this tool is shown in use on a lathe provided with a relieving attachment, where both the outside and the angle of the thread are relieved simultaneously. The object of this relief is to obtain a tap which has the same support along its periphery as one that has not been relieved; this object is secured by having a bearing both at the cutting edge and at the heel of the land. At the same time a tap is obtained producing less friction when in action, on account of the fact that the thread does not have as large a contact surface with the work as in the case of the unrelieved tap. The objection to this kind of relief is that in the case of fine pitches or taps with narrow lands, its production becomes an extremely delicate and difficult operation, and is has not proved commercially satisfactory.

Taps with Back Taper

On account of the many objections to these various kinds of relief on straight-threaded taps, some manufacturers began making the parallel portion of their taps with no relief at all, either on the top or in the angle of the thread. Instead, in order to produce a tap cutting more freely, and one that would, as has often been said, "relieve itself," most manufacturers have adopted the practice of providing their taps with "back taper;" that is, the diameter of the thread both in the angle and on the outside is made a very small amount less at the end of the thread joining the shank than at the point. (See MACHINERY, December, 1912, "Notes on the Early History of Tap Making.") This is shown in an exaggerated manner in Fig. 12, where diameter A at the point is shown larger than diameter B next to the shank. When taps are made in this way, the cutting size of the tap will be at the large end of the chamfered portion. At the shank end of the thread, the diameter will be anywhere from 0.0005 to 0.0025 inch smaller than at the point, according to the size of the tap.

This back taper has the effect of producing a tap that cuts well, and such taps are frequently referred to as "taper relieved." However, it is hardly correct to speak of this feature of the tap as a relief, and while back-tapered taps are considerably superior to those that are perfectly straight on the thread, they do not possess the desirable qualities that it is possible to impart to a tap that is properly relieved according to a method yet to be explained. If a tap that has no relief at all in the angle or on the top of the thread should happen to twist in hardening so that the cutting edge diameter A becomes less than the heel diameter B, as shown in Fig. 4, it is evident that such a tap will give trouble. Those well versed in the manufacture of taps are inclined to believe that this twisting of the lands is the cause of a great many of the complaints about improper relief and hard cutting that are received by tap makers from their customers. It is a difficulty that is practically impossible to overcome, except by adopting a method of relief that eliminates the objectionable effects of warping and at the same time overcomes the objections mentioned to the types of relief already shown. No matter how small an amount the land twists in the wrong direction in hardening, it is evident that it will cause any tap to cut hard that is not relieved in the angle of the thread.

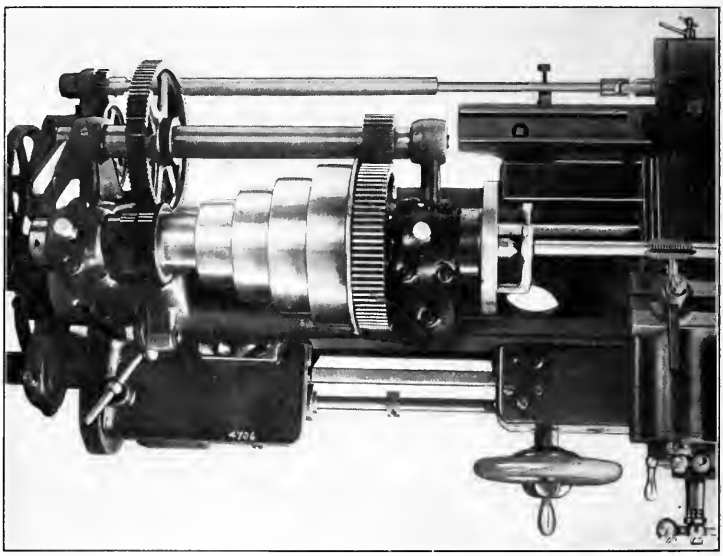

Fig. 11. Combination Tool shown diagrammatically in Fig. 10 in use for Tap relieving in a Pratt & Whitney Co. Lathe with Relieving Attachment

Of course sometimes the land may twist in what we might call the right direction. In fact, this will happen just as often as the twisting in the wrong direction, if the taps are fluted with convex cutters. In that case, the effect is that of a relieved tap. The twisting of the land in hardening can be largely overcome by fluting the tap as indicated in Figs. 1, 2 and 3. It will be clearly seen that this form of flute produces a land that is more strongly supported than is the land of a tap fluted with a convex cutter. (For information relating to tap-fluting cutters see MACHINERY, March, 1913, "Tap Fluting Cutters.")

Form of Relief as made by the Pratt & Whitney Co.

Recognizing the objections to the different types of relief so far discussed, and realizing from their long experience in the tap making business that there was an urgent demand for a tap that was relieved in such a manner that it had not only the proper support in the hole to be tapped, but also a free cutting action and a minimum of friction, the small tool department of the Pratt & Whitney Co., Hartford, Conn., some five or six years ago, originated the form of relief shown in Fig. 13 as the most desirable. As will be seen in the illustration, the top, the angle and the root are concentric for one-third the width of the land, the remaining two-thirds being eccentrically relieved. A tap made in this way can be ground for sharpening on the face of the cutting edge without interfering with the size of the tap or the form of the thread. Hence, there has been secured an eccentrically relieved tap which has enough of a concentric land to permit of sharpening without losing its size and which has more than a mere point support in the hole.

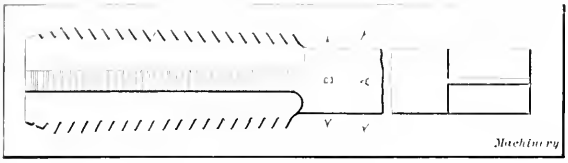

Fig. 12. Ordinary Straight-threaded Hand Tap showing Back Taper Exaggerated

Having determined upon this type of relief, the Pratt & Whitney Co. began to make taps for the market along these lines and for the last five or six years they have manufactured taps with this kind of relief; at the present time all taps suitable to be relieved in this manner are so made. The methods used by the Pratt & Whitney Co. not only secure the above described relief, but also insure the manufacture of a tap having considerably greater accuracy and refinement than it has heretofore been possible to obtain.

It will be seen that the method of relief shown in Fig. 13 is applicable to all forms of thread, the U. S., the V, and the Whitworth, and that it can be adapted with equally satisfactory results to any type of tap. On the chamfered part of the tap, the top of the thread is relieved all the way from the cutting edge, because on this portion it is important to secure a keen cutting edge, and as this part of the tap has nothing to do with the retaining of the size of the tap, there is no objection to relieving it all the way from the edge. The relief on the chamfered part of the tap is also greater than the relief in either the angle or on the top of the thread of the parallel portion, which adds to the cutting qualities of the tool. The regular relief in the angle is also maintained in the chamfered portion.

Taper-threaded Taps

In order to guard against any misunderstanding, the expression "taper taps" should be defined at the outset. While the first tap in a set of three hand taps, as shown in Fig. 7, is frequently referred to as a "taper tap," this is, properly speaking, not a correct usage of the word. A taper tap is a tap that is smaller on the top and in the angle diameter at the point than it is at the end where it joins the shank, and therefore increases gradually in both the angle and outside diameter from the point upward as shown in Fig. 6. The most common type of taper tap is the pipe tap.

It is evident that a taper tap, unless of very slight taper, would refuse to cut altogether if it were not relieved right from the cutting edge and for the whole width of the land; because, as the tap tapers and as the heel of the thread must necessarily be at a point higher up on the taper than the cutting edge (due to the spiral of the thread) the diameter over the heel is greater than the diameter over the cutting points in an unrelieved tap. While taper taps, therefore, must be relieved for the whole width of the land, both on the top and in the angle of the thread, this relief can be made of such an amount that there will be a fair bearing of the tap in the hole to be threaded and so that the tap will not bear merely on the cutting edges. It should also be remembered that when a taper hole is threaded, every tooth which is in contact presents a resting or a steadying point for the tap, while in a straight-threaded tap there are only a few teeth which are actually in the process of cutting and which present any steadying effect.

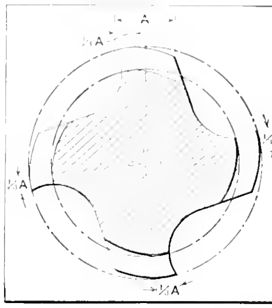

Fig. 13. Type of Relief originated by the Pratt & Whitney Co.

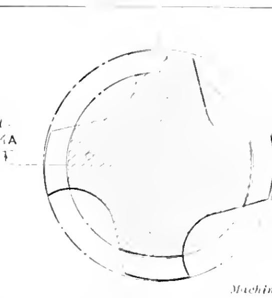

Fig. 14. Method of properly relieving Taper-threaded Taps

Most of the difficulties met with in taper-threaded taps are due to the manner in which the taps are relieved. While a tap as shown in Fig. 1 would seem to have a much greater relief than that shown in Fig. 14, a comparative test between taps relieved by various methods will show that a tap relieved as in Fig. 14 cuts far more freely than the ordinary commercial taper tap. The relief shown in Fig. 1 is, however, the most commonly used, probably because the subject has never been thoroughly investigated. An analysis of the conditions produced by relieving as shown in Figs. 1 and 14 will indicate that the tap in Fig. 14 presents a more even relief throughout, after repeated grindings.

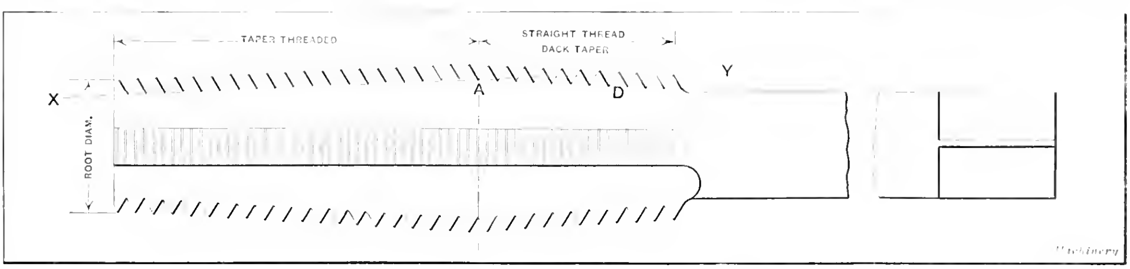

Fig. 15. Tap partly Taper-threaded and partly Straight. The Straight Portion is Back Tapered, the Back Taper being shown Exaggerated

Taps having One Portion of the Thread Tapered and Another Portion Straight

As will be seen from Fig. 15, taps of this kind (machine nut taps, some tapper taps, die taps, etc.) have one portion of the thread tapered both in the angle and on the outside of the thread and the other portion left straight, thus making a

combination of a taper and a straight tap. Taps of this style are used principally for very exacting work, such as the tapping of especially long nuts or nuts made of tough or hard material. They are also used where a nicely threaded hole is required, as each thread in the tapered portion takes what might be called a roughing cut, until the straight portion is reached and a final finishing touch is given to the thread. An ideal tap for this class of work is one in which the tapered portion is relieved right from the cutting edge, as in a taper tap, while the straight portion is relieved like a straight tap, with one third of the land concentric and two-thirds relieved, according to the practice adopted by the Pratt & Whitney Co. as already described. It is obvious that the production of such a tap by ordinary manufacturing methods would involve considerable difficulty.

Taps of this class that have been put on the market in the past are, in some cases, relieved on the tapered part, while the straight portion is not relieved. In other cases, the tapered portion is relieved both in the angle and on the outside of the thread, and the relief is then continued with the same taper into the straight part until the relieving tool runs out because it has nothing more to cut, as shown by the line XY in Fig. 15. The relief thus given to some of the threads in the straight portion is similar to that indicated in Fig. 13, although it is obvious that the proportion between the concentric and relieved parts of the land varies until the relief, which is maximum at point A, gradually decreases to no relief at all at point D. A tap relieved in this manner and threaded with a back taper on the straight portion presents a tool which, so far as relief is concerned, leaves very little to be desired. The back taper in the illustrations is exaggerated, the amount in practice being so small that it would not be visible in an illustration.

PLANING GIB-TAPERS

When planing castings for the tables of the Blanchard vertical surface grinding machines, the Blanchard Machine Co., Cambridge, Mass., employs a labor-saving kink for resetting the work for the gib-tapers. As illustrated in Fig. 1, these table castings are mounted on the planer platen in a string of five. They are set up in the usual way for the straight planing, except that beneath the right-hand projecting side of each casting is mounted a special angle block, the end of one of which may be seen outlined at the right-hand lower corner of the planer table in Fig. 1. A better

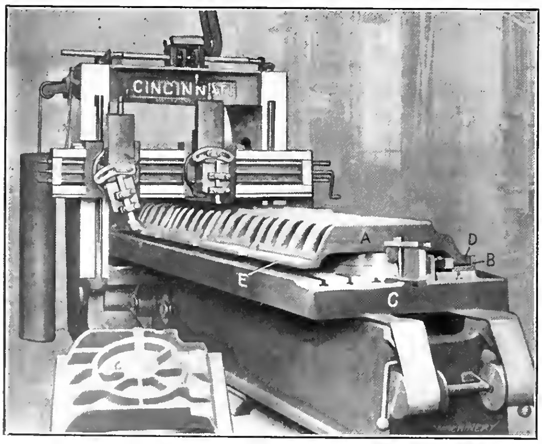

Fig. 1. Planing the Tables for Blanchard Vertical Surface Grinders

idea of this block may be obtained from the line illustration Fig. 2, where one of the castings is shown at A, with its corresponding tapered block B clamped to the planer table C. It should be especially noticed that angle block B does not in any way touch casting A while the straight planing is being done; and the tapered edge of the block is fully an inch away from the outside edge D of the work during this operation, allowing the planer tool plenty of room to work on the edge. Edges E, which are to be tapered, are not planed at this operation, but the other planing on the casting is all done at this setting.

After the straight planing has been completed, the clamping straps, one of which is shown at the end of the string of work in Fig. 1, are loosened slightly, and the castings moved to the right, over the intervening inch to bring their right-hand edges D in conjunction with the tapered sides

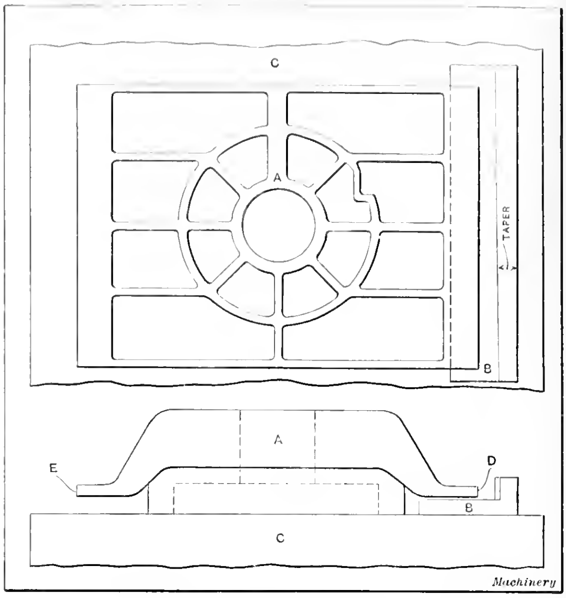

Fig. 2. One of the Grinder Tables on the Planer, showing the Blocks used for the Gib-taper Planing

of angle blocks B. Paper "feelers" are employed in locating the work against the inclined faces of the blocks, and one of these strips shows in Fig. 1. This of course throws the opposite edges of the castings out of line the exact amount of the taper in the angle block. The straps are then re-tightened and the final cut taken along the left-hand edges E of the tables, forming the necessary taper for the gibs that are to work in conjunction with these sides. C. L. L.

GERMAN MACHINE INDUSTRY

In a recent consular report some interesting statistical figures are given relating to the rapid development of the German machine industry. In 1882, the number of persons engaged in the machine and allied trades in Germany was 356,000. In 1895, it was 582,000, and in 1907, 1,120,000. Since 1907, the increase is stated to be at a still more rapid rate than during the twelve years previous. A further evidence of the importance of German machine and electrical industries is given in the fact that in 1912 the exports of all classes of machinery exceeded in value $250,000,000, as compared with $90,900,000 in 1900. German imports of machinery show a relative decrease. In 1900, they amounted to $35,200,000; in 1907, $36,700,000, and in 1912, to $30,700,000. The only classes of machinery which at the present time are imported are American machine tools, shoe machinery, harvesting machinery, computing machines, sewing machines and cash registers, and English textile machinery. A relatively small number of automobiles are imported from France.

Referring specifically to metal-working machinery, the consular report states that the imports in 1907 had a value of $2,262,000 and in 1912 of $145,000, while the exports both years exceeded $15,000,000. The exports of metal-working machinery go chiefly to Russia, Austria-Hungary, France and Italy. With relation to the world's trade in machinery and electrical apparatus, the three principal exporting countries are Germany, the United States and England, their importance, considered on the basis of the value of the exports, being in the order mentioned.

TAPER BORING AND TURNING ATTACHMENTS

DESIGN AND CONSTRUCTION OF LATHE AND BORING MILL EQUIPMENT FOR TAPER WORK

BY ALBERT A. DOWD*

The proposition of accurately machining male and female tapered surfaces is one of almost daily occurrence in every factory, while the tapers required are of every degree of inclination. The materials on which the work is to be done are also varied, both in their general form and in their composition, ranging from steel or brass bar stock of small diameter to cast iron or steel castings of great size. Conditions governing the work are widely different, as the number of pieces needed obviously makes a difference in the method of handling. When only one or two are required, and the size of the work is not prohibitive, the engine lathe is most frequently used, several well-known methods of generating the taper being possible on this machine, *viz.*, setting over the tailstock to the correct angle, when the work is of such a nature that it may be held on centers; using the compound rest with hand feed; and using the taper attachment with which nearly all modern lathes are equipped and which is too well known to need description. There are also occasional instances where the lathe may be used for manufacturing work of this kind in large quantities, by means of special attachments, although this is usually applicable to conditions requiring no other machining operations except the taper. As a general thing when the number of pieces is sufficiently large to warrant it, the work is performed on

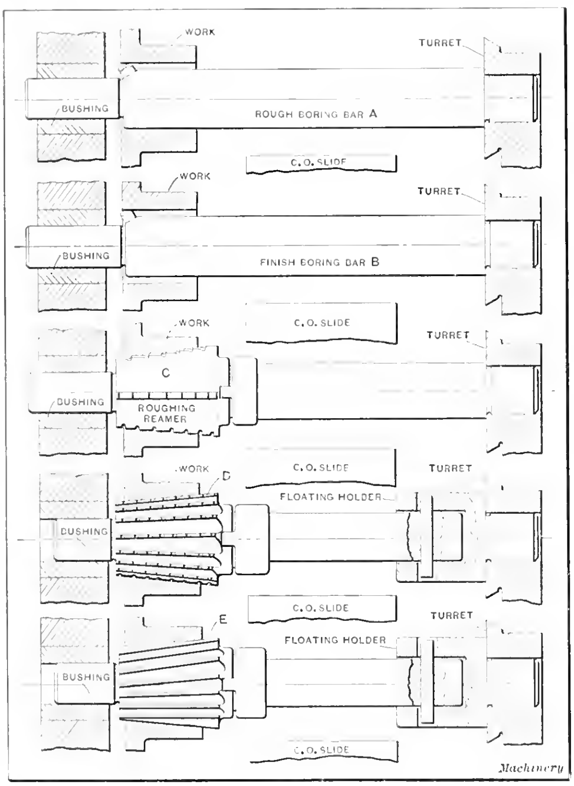

Fig. 1. Typical Boring Tools and Reamers for Taper Holes

the horizontal screw machine or turret lathe, the vertical turret lathe or the vertical boring mill. Many ingenious schemes for generating tapers on these machines have been devised, the construction of a number of which will be described and illustrated in this article.

Taper Turning Devices for Bar Stock

On turret lathes or screw machines equipped for bar work, there are various devices for turning a taper on the bar. These tools are in many instances patented, and may be purchased of the manufacturers. Obviously there are such a number of these that it is out of the question to attempt to describe each one. Detailed information may be easily obtained on request.

Method of Finishing a Taper Hole without Generating the Taper

Before taking up the subject of generating devices for taper work, let us first consider a method much used in tur-

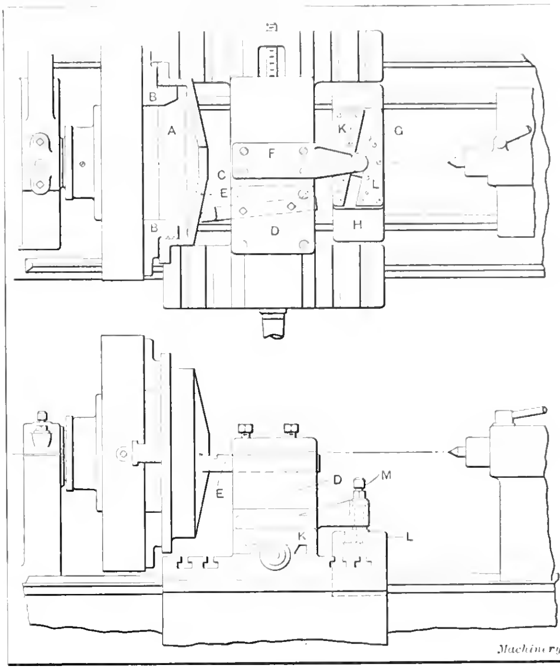

Fig. 2. Engine Lathe Attachment for turning Bevels

ret lathe practice and one which may be depended upon to give very satisfactory results, when absolute accuracy is not essential. When the tools are properly taken care of, good commercial work may be turned out by means of the tooling shown in Fig. 1. It will be noted that all the tools used, are piloted in a bushing located in the chuck. The first tool used, shown at *A*, is a plain boring bar which serves to rough-bore the hole, thereby producing an approximately true generated straight hole. The second tool *B*, is a finish-boring bar which brings the hole to about the required size for the small end of the taper. The next tool *C*, is a roughing taper step reamer which removes the larger part of the stock left in the hole, and leaves the work in the form of a series of grooves or steps with the angle of the correct inclination. A roughing taper reamer *D* is next used in a holder so made that the rear end of the reamer will float. It will be noted that this reamer is straight fluted but that a left-hand spiral groove with about 3/4 inch lead is cut the entire length of the tool. This serves to break the chip and makes for much easier cutting, also having a tendency to prevent pulling in. The hole is sized with another reamer of the floating type *E* which may be either straight-fluted or made with a left-hand spiral of five to seven degrees, depending on the angle of the taper. The method shown here will not give as accurate results as may be obtained by generating the taper, but the sizing of the hole may be kept very nearly correct with little trouble, although slight variations in concentricity are bound to occur. One of the greatest objections to this manner of handling taper work is that the operator does not keep his tools up properly, and by being careless in regard to this

* Address: 84 Washington Terrace, Bridgeport, Conn.

matter, he leaves the reamers to do the most of the work and the results are therefore disastrous on account of the unequal wear on the reamer.

Taper Attachment for Producing a Conical Surface on the Engine Lathe

Fig. 2 shows an attachment fitted to the engine lathe for the purpose of producing the proper angle *C* on the head

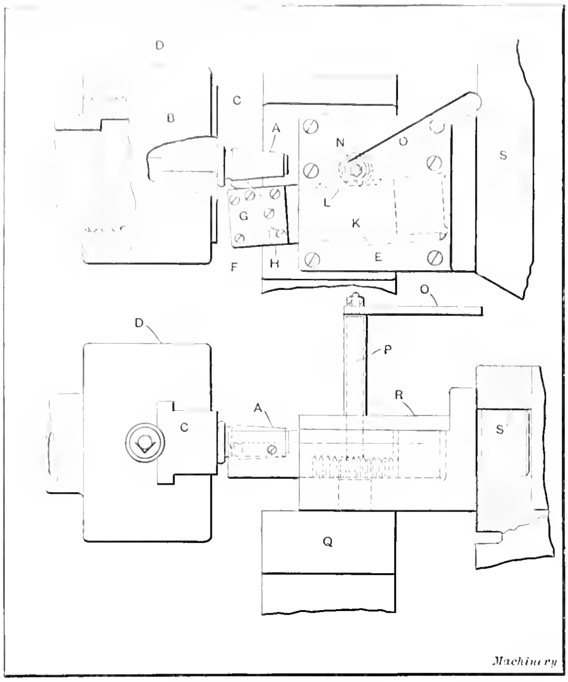

Fig. 3. Taper Attachment for Small Hand Screw Machines

casting *A*. In this case the work is held in special jaws *B* which grip the interior of the casting as shown in the upper

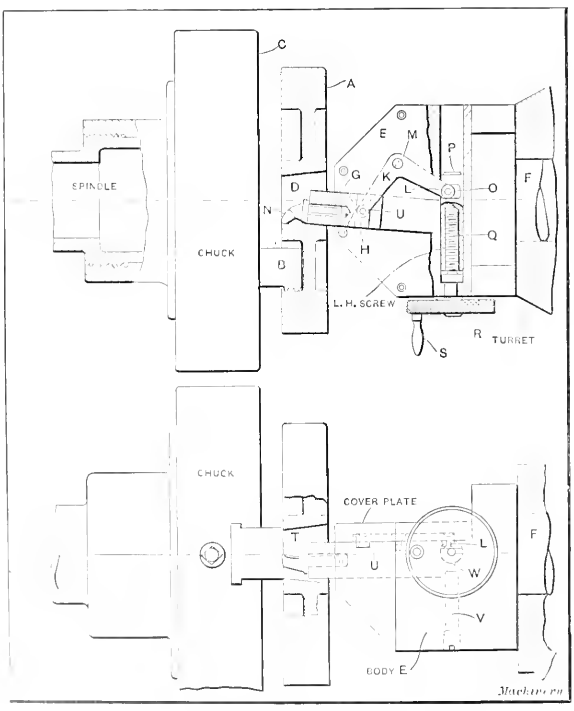

Fig. 4. Attachment for generating Small Taper Hole in a Motorcycle Flywheel

part of the illustration. The cross-slide is equipped with a special tool-block *D* in which the tool *E* is held. The casting *H* was planed on its under side to fit the inner ways of the lathe and was clamped in position by means of straps not shown. Two steel plates *K* and *L* act as guides by which the proper taper is formed. These plates are hardened and the edges of the slot were ground parallel after assembling, to insure accuracy. A bracket *F*, fastened to the cross-slide, carries a pivoted steel block *G* which travels in the slot, thereby controlling the movement of the carriage, and producing the desired taper. An oiler *M* acts as a gentle reminder that surfaces subject to friction are in occasional need of lubrication. The inner surface of casting *A* was machined on the same lathe in another setting, another set of forming plates being applied to the casting *H* to produce the required taper. This method of handling gave very satisfactory results.

Taper Attachment for a Small Hand Screw Machine

A small brass cock, shown at *A* in Fig. 3 is a good example of an outside generated taper. The stem of the cock *B* is held in the special jaws *C* of a two-jawed chuck *D*, this being obviously screwed to the spindle of a small hand screw ma-

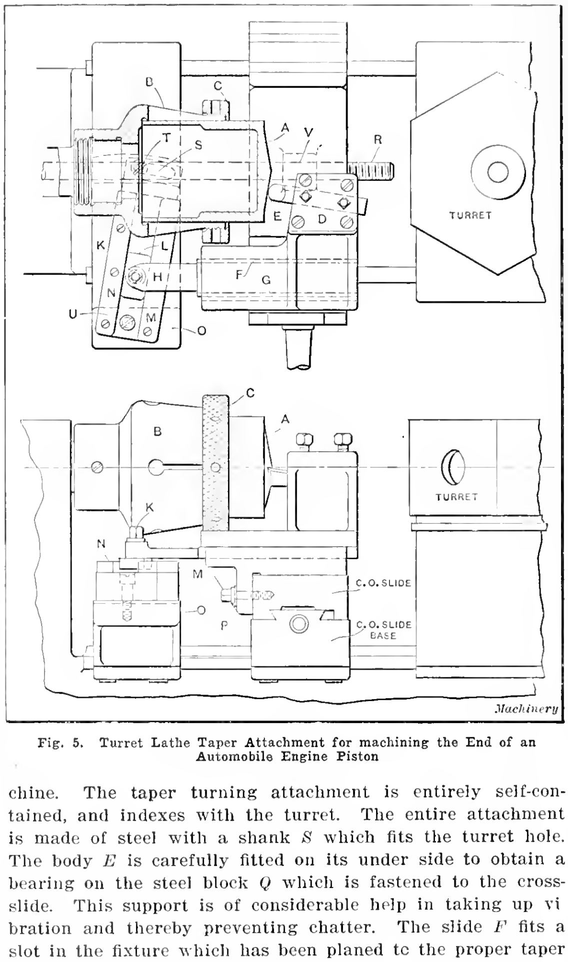

Fig. 5. Turret Lathe Taper Attachment for machining the End of an Automobile Engine Piston

chine. The taper turning attachment is entirely self-contained, and indexes with the turret. The entire attachment is made of steel with a shank *S* which fits the turret hole. The body *E* is carefully fitted on its under side to obtain a bearing on the steel block *Q* which is fastened to the cross-slide. This support is of considerable help in taking up vi bration and thereby preventing chatter. The slide *F* fits a slot in the fixture which has been planed to the proper taper and the gib *K* acts as a take-up for wear. The cutting tool *G* is of rectangular section and accurately fits a slot in the front end of the taper slide. The headless set-screw *H* assists in setting the cut to obtain the proper diameter. A rack *L* is cut along one side of the slide and meshes with the pinion *N*, the shank *P* of which runs up through the body of the fixture and is operated by the lever *O*. A cover plate *R* is carefully fitted and keeps the parts in position. Tools of this type are much used on small brass work and the work accomplished by them is excellent where very little stock is to be removed. They are built to generate a certain specified taper and can be used for no other.

Attachment for Generating Small Taper Hole in a Motorcycle Flywheel

The rather complicated little attachment shown in Fig. 4 was built for a final finishing cut in the taper hole *D* of the motorcycle flywheel *A*. In spite of the fact that the attachment itself is inclined toward multiplicity of moving parts, its action was so satisfactory that a duplicate order was received a few months after the original tool had been built. It will be noted that the jaws *B* of the three-jawed chuck *C* grip the work on the inside of the flange, and hold it far enough away from the chuck to permit back cutting on the hub and flange, thereby permitting the work to be finished in one setting. The body of the attachment *E* is made from a piece of round steel stock beveled on the front end and with the shank *F* turned at its rear end to the proper diameter to fit the turret hole. The taper slide *G* fits an angular slot cut in the body of the attachment and is reamed at its front end to receive the shank of the cutting tool *N*. This tool is forged to the shape shown and is carefully ground to gage. As the amount of metal which this tool removes is very slight, it requires regrinding only at long intervals. A headless set-screw *T* secures it in position. The bell-crank *K* is pivoted at *M* and the hardened steel rollers *L* and *U* are located at the two ends. The roller at the forward end operates the slide by its action in the slot *H*, while the roller at the other end enters another slot *O* in the operating pin *P*. A teat screw *V* enters the spline *W* cut in the under side of the operating pin, thereby preventing it from turning. The

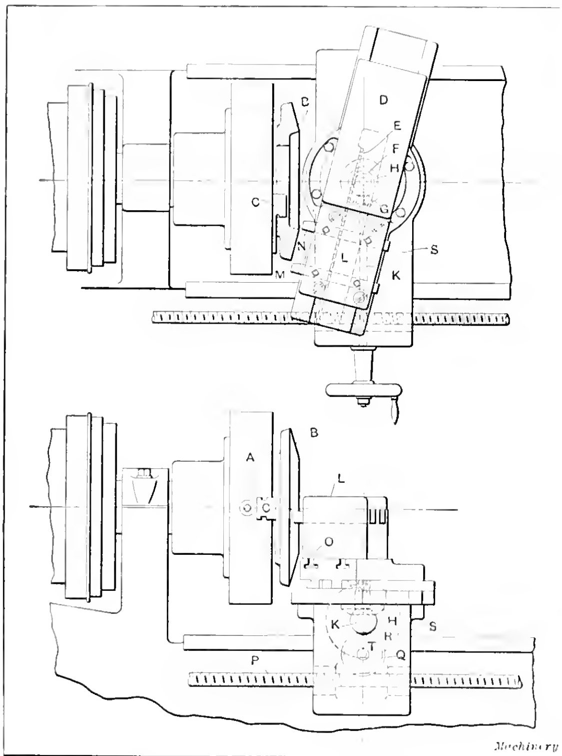

Fig. 6. Adjustable Cut-off Slide Attachment

small knurled handwheel *R* contains a little finger handle *S* which is used to revolve the screw *Q*. The rod *P* is tapped out to receive this screw, and obviously is moved forward or backward by its action, the motion being carried forward through the bell-crank to the operating slide.

Turret Lathe Taper Attachment for the End of an Auto Piston

The automobile piston shown at *A* in Fig. 5 has been finished on the outside but the end has not been formed to the required taper. It is held in a special spring chuck *B* which is closed in on the end by the tapered screw collar *C*. In this instance there were several conical headed pistons to be taken care of, the angle of the cone varying slightly in each case. The turret lathe selected for use in this operation was of a standard make, and the longitudinal movement of the cut-off slide was controlled by the screw *R* engaged with the nut *V* on the under side of the slide. This screw was operated by a handwheel and was not coupled up with the feed mechanism. It was used principally to move the slide back and forth along the ways to any desired location. It will be seen that in this instance any sort of floating action in a longitudinal direction was out of the question and it was therefore necessary to design a special tool block *D* having a dovetail slide *F* and an extension *H*, at the end of which

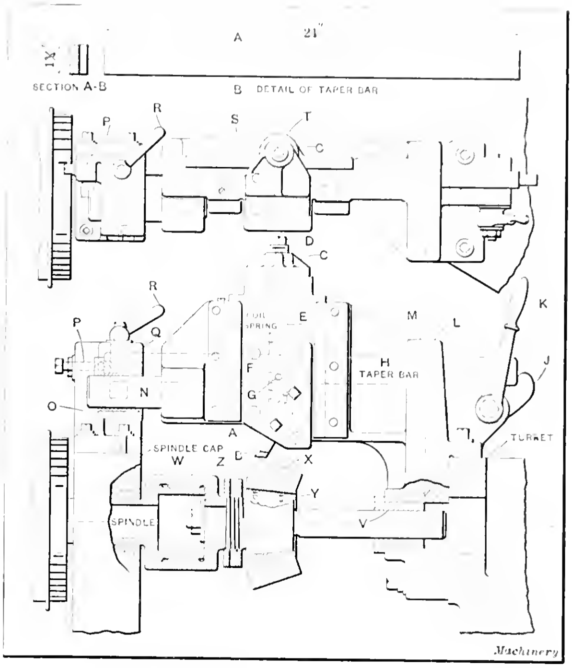

Fig. 7. Taper Attachment for machining a Bevel Pinion

the hardened and ground steel block *L* was located, pivoting on the screw pin *K*. A swivel block containing two parallel plates *N* and *M* may be swung on the shouldered screw *U*, to suit the various angles. The curved slot *S* permits the necessary movement, while the binder *T* secures it firmly. The swivel is mounted on the bracket *O*, which is gibbed to the ways in such a way that it may be moved to any desired location. When the attachment is used the cut-off slide cross feed is thrown into gear and the angularity of the swivel block determines the movement of the tool *E*. As a point in design, attention is called to the way in which the tool block is carried over the edge of the slide at *P*, for the purpose of obtaining rigidity and preventing any chance of side slip. The writer knows of a number of instances where attachments of this kind have been used with very gratifying results.

Swivel Cut-off Slide Attachment

The bevel gear shown at *B* in Fig. 6 is held in the three-jawed chuck at *C*, by means of soft jaws, and the tools *M* and *N* are used for roughing and finishing the face of the gear, the spacing of the tools being such that the finishing tool takes up the work as soon as the roughing tool has completed its cut. This entire mechanism is special.

The carriage *S* is gibbed to the ways in the usual manner and upon this carriage is mounted the swivel slide arrangement *D*. This slide may be swung to any angle within its range and securely fastened. It will be noted that the feed-screw *P* meshes with the wormwheel *Q*, and the movement is transferred through the spur gears *T* and *R* to the shaft *K*. At the inner end of this shaft the pinion *G* meshes with the bevel gear *H* on the upper end of which is the spur gear *F*. This spur gear engages the rack *E* cut along the inner side of the slide, thus giving the necessary feed movement. The

tool block L is held in place by screws which pass down through it into steel shoes in the T-slots O. The operation of this mechanism is so apparent that no comment is necessary.

Taper Attachment for a Bevel Pinion

The bevel pinion X shown in the lower portion of the illustration Fig. 7 has been bored with a taper hole and the back side faced in a previous operation. A keyway Y has also been cut for driving purposes. The equipment shown was designed for a large factory manufacturing bevel gears and pinions and the taper turning device shown is so arranged that it may be used for a variety of angles. A number of taper bars such as that shown in detail in the upper part of the illustration, were made to suit the different conditions.

The spindle nose-piece W contains a tool-steel arbor pilot supported at V in the fixture bushing. The nut Z is simply used to release the work after the machining operation has been performed. A cast-iron adapter L is screwed to the turret face, and on this is mounted the body of the fixture M. The cutting tool B is held in the sliding tool block A, which is scraped to a nice sliding fit, and has a taper gib provided for adjustment. A tool-steel block F is pivoted to the back of the slide on the pin G, allowing it to adapt itself to the angle cut on the taper bar. Referring to the upper view it may be seen that the plate S forms a cover for the open side of the fixture, and that it contains the long boss T which holds the spring E. This spring thrusts against the end of the screw D. The bracket C is fastened to the top of the slide and is tapped out to allow adjustment

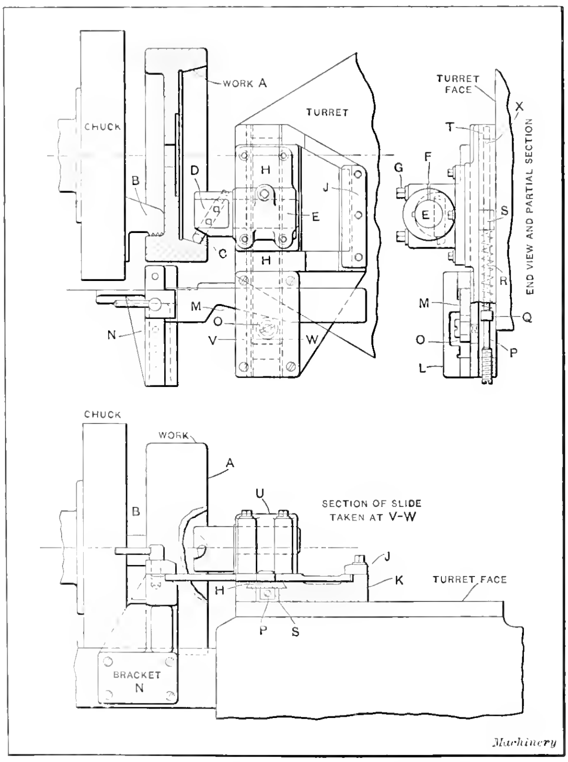

Fig. 8. Exterior and Interior Taper Turning Device

to the spring by means of the screw. A bracket O is fastened to the spindle cap and contains a bronze bushing which acts as a guide for the pilot N. The stop screw P is used for longitudinal adjustment of the taper bar H. The lever K is used to force the taper bar forward by means of the rocker J. The stud Q is slotted to receive the forward end of the taper bar, and when this has been brought forward by the lever until it strikes the end of the screw P the binder lever R prevents any backward movement of the bar. The adaptability of this attachment for various tapers is one of the good points of its design and the results obtained by its use are rapid and thoroughly satisfactory.

Exterior and Interior Taper Turning Device

The device shown in Fig. 8 is adapted for use on a turret lathe having a flat surface instead of the usual box-shaped construction. A taper bar is used in this instance also, which is cut away at M to the desired taper. The attachment may be arranged for either inside or outside tapers, but it is shown in this instance at work on the clutch taper of the

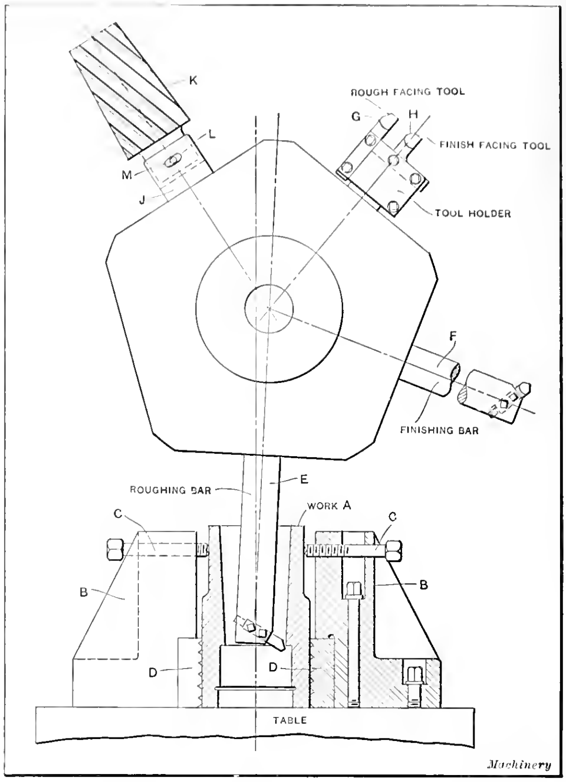

Fig. 9. Attachments for Vertical Turret Lathe and Vertical Boring Mill

piece A, this being held by the inside in the chuck jaws B. The bed or body of the fixture K is fastened to the face of the turret and is dovetailed to receive the slide H. A lug S on the under side of this slide receives the thrust of the spring R (shown in the end view section). A screw P forms an adjustment for the compression of this spring through the collar Q which is made removable and can be transferred to the other end of the rod at X, when it is desired to use the attachment for outside tapers. The roll O is fastened to the slide and in its contact with the taper bar produces the required taper. The tool-holder U is split along the side at F and is bored at E to receive the shank of the tool bar D. The binder screw G is used for clamping. A cast-iron cover plate L is fitted so that the pads shown on its under side allow free movement to the passage of the bar. The bracket N is fastened to a pad on the side of the bed and is cut away at the top to the proper height so that the taper bar M will rest upon it. It is clamped in position by the binder shown, in order to prevent any chance for retrograde action. This attachment has been very successful and is adapted to a wide range of casting work.

Attachments for Vertical Turret Lathe and Vertical Boring Mill

Fig. 9 shows the simplest of conditions which are met with in vertical turret lathe practice, and the method of handling requires no special attachments, the swivel slide of the main head being sufficient to take care of the taper boring, the hole being finally reamed to size by a floating taper reamer.

The work A is a cast-iron hub and it is held in the special jaws B. The work is centered by the steel inserted jaws D and the set-screws C are simply used to prevent vibration. The roughing bar E is first used to generate the taper and it is followed by the finishing bar F. Then the rough- and finish-facing tools G and H face the work, after which the floating taper reamer K is used to size the hole. It will be noted that the upper end of the reamer is flatted and enters a slot in the holder J, the pin M acting as a driver and the slot L allowing lateral movement.

Special Gearing used to produce Tapers

The arrangement shown in Fig. 10 is not adapted to all conditions but may be used when the required angle is not too acute to permit the use of the proper gear ratio. A piece of work such as that shown at A may be handled to advantage by this method.

The strap L is slotted at M to receive the stud S, which acts as a support for the idle spur gear N. The lower spur gear O is keyed to the shaft, while the upper gear P is thrown into use by the clutch mechanism Q, by the action of the knurled screw R. Obviously the gear ratios between P and

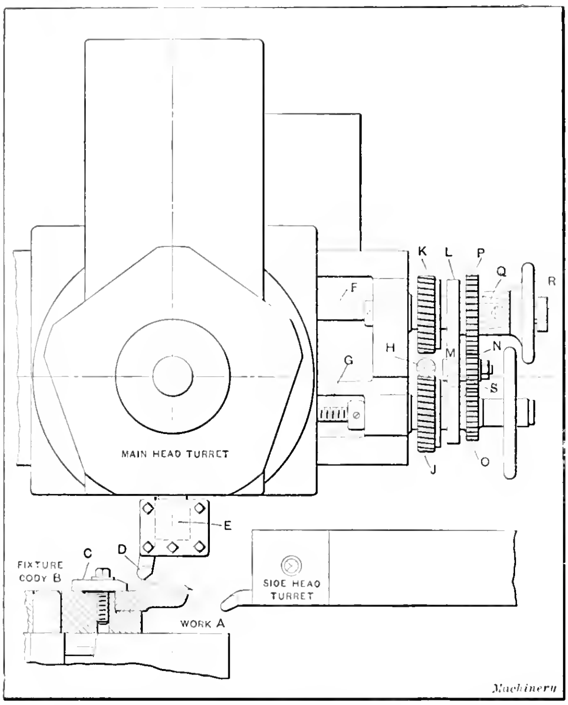

Fig. 10. Illustrating Use of Vertical and Horizontal Feed Combination to produce Tapers

O must be so proportioned that the combination of the horizontal and vertical feed movements will produce the required angle. Attention is called to the fact that the power feed worm H is thrown into mesh with the gear J on the horizontal feed-screw G when the attachment is to be used, but it will be seen that the operation of the feed works is not disturbed by the arrangement shown, the gear P running idle unless the clutch is thrown in.

The work A in the instance shown is held by straps C on the special fixture body B. The tool D is held in the toolholder E and follows the angle generated by the gearing. When it is required to produce an angle such that spur gearing cannot be obtained to give the exact taper, the nearest gears obtainable may be used, and the swivel slide of the main head can be set over to compensate for the variation in the gearing.

Makeshift Taper Arrangement for a Rush Job on the Vertical Turret Lathe

Fig. 11 shows a method of setting up a vertical turret lathe for a rush job, consisting of a few cast-iron male clutch members shown at A. The work is held by the jaws B on the inside of the rim and the tool C is held in the side head turret. A steel plate F cut to the required taper is held in the toolpost G in the main head turret. A roll holder D is fastened in the upper side of the side head turret and the roller E comes in contact with the tapered plate and thereby

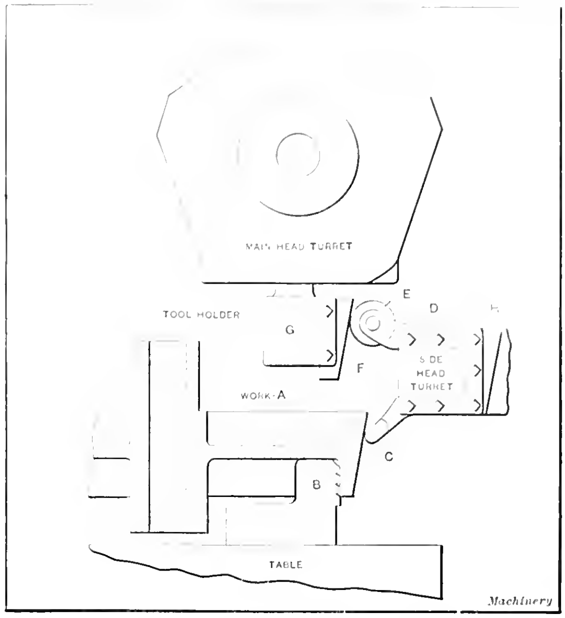

Fig. 11. Makeshift Taper Arrangement for Emergency Vertical Turret Lathe Work

controls the movement of the tool. A flat angular sweep tool H is used for finishing the work. In using this arrangement it is only necessary to lock the main head turret in the proper position and bring the roll E against the forming plate. After this the down feed of the side head is thrown

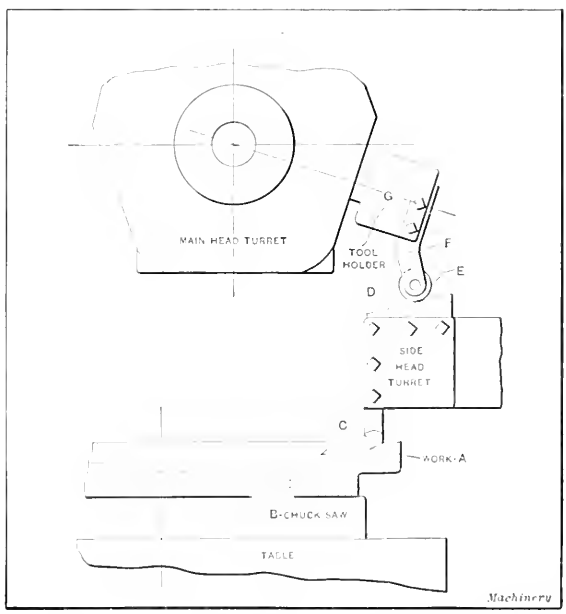

Fig. 12. Emergency Taper Attachment for Vertical Turret Lathe Work

in and the roll crowded against the plate by the transverse feed crank on the apron. This method is very good for a short job and the machine may be quickly set up. Several roll holders of this kind will be found useful adjuncts to the tool equipment of the vertical turret lathe.

Another Makeshift Taper Arrangement

Another instance of a short rush job is shown in Fig. 12, the work A in this instance being held by the inside in the

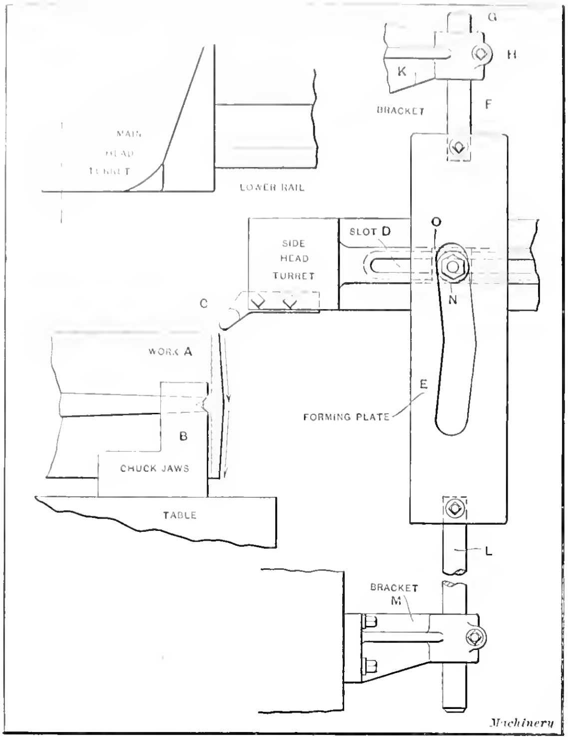

Fig. 13. Taper Attachment for crowning Tools

chuck jaws *B*. The tool *C* is held in the side head turret and is forced down the angle by the contact of the angular plate

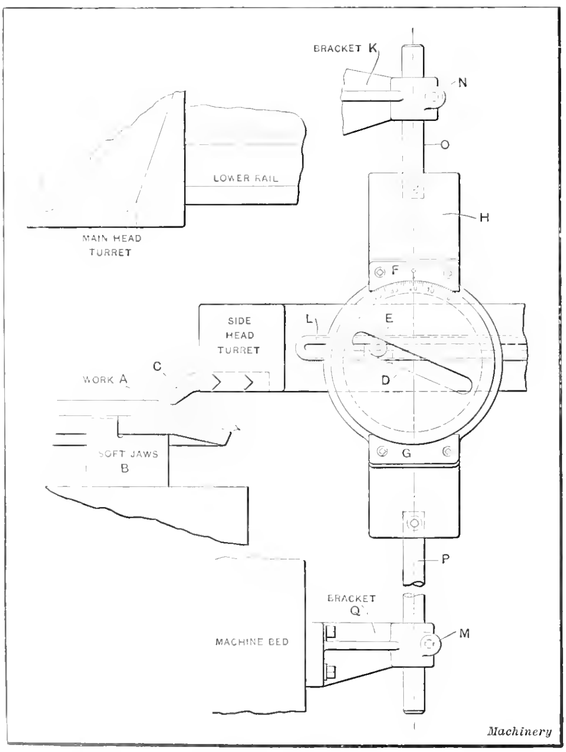

Fig. 14. Vertical Side Head Forming Attachment for the Bullard Vertical Turret Lathe

D with the roll *E*. The shank *F* which holds this roll is secured in the tool-holder *G*, in one of the side holes in the main head turret. When this arrangement is used the transverse feed of the side head is thrown in and the plate *D* crowded against the roll by means of the vertical feed crank on the side head apron. It will be readily understood that this arrangement and that shown in Fig. 11 are not to be considered in the light of attachments for taper turning, but they are given as instances of methods which may be used for short jobs, where no taper attachment is available. It is evident that these methods tie up the main head and prevent its use for cutting purposes while the taper is being formed. As this naturally increases the cutting time necessary to produce the work, the use of such an arrangement is advised only in cases where a few pieces are to be machined.

Angular Taper Attachment for Crowning Pulleys

Fig. 13 is an arrangement which is used where a double angle is required, such as the crowned portion of the pulley *A*. In this case a set of special jaws *B* grip the work on the inside bead in the V-shape part of the jaw. The movement of the tool *C* is controlled by the forming plate *E*, which is cut to produce the angular movement required. This plate is

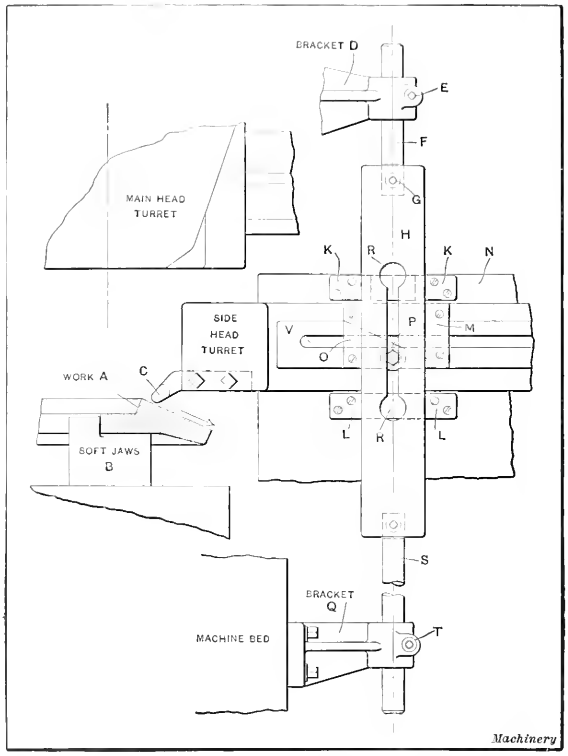

Fig. 15. Taper Turning Attachment for the Bullard Vertical Turret Lathe

fastened at each end to the bars *F* and *L*, and these bars are, in turn, secured in the upper and lower brackets *K* and *M*. The upper boss *G* is split and the binding screw *H* pinches the bar and holds it in the desired position vertically. The arrangement of the lower bracket is on the same principle. Both the upper and lower brackets are fastened to pads on the bed of the machine. When this attachment is used the T-slot *D* is cut along the entire length of the side head slide so that the T-stud *O* which carries the roller *N*, may be adjusted so that various diameters can be machined. This attachment is very satisfactory for work of this nature.

Swivel Side Head Forming Attachment for the Vertical Turret Lathe

Fig. 14 represents an attachment made by the Bullard Machine Tool Co., Bridgeport, Conn., for the Bullard turret lathe. The work shown in this instance at *A* is a large bevel gear which is held by the previously bored interior surface in the soft jaws *B*. The tool *C*, in its angular movement is controlled by the inclination of the slot *D* in the circular swivel plate. This plate is graduated in degrees around its

upper edge so that any angle may be easily obtained. The clamps F and G secure it in position after the setting has been made. The disk containing the slot is mounted on the plate H which is of circular section at the center to allow free access to the roll and block E. As in the previous instance a T-slot L is cut along the entire length of the side head slide, thereby permitting various diameters to be machined. The bars O and P are secured in the brackets K and Q by the binders N and M, these brackets being secured to the bed of the machine. This attachment is adapted and may be used for many varieties of work and the results obtained are uniformly satisfactory.

Another Taper Turning Device for the Vertical Turret Lathe

The device shown in Fig. 15 is also made by the Bullard Machine Tool Co., and is adapted to both angular and formed work, and therefore is more comprehensive in its uses than that shown in Fig. 14. The piece A, held in the soft jaws B, is the same as that previously shown. The principles in the design of this attachment are just opposite to those of the other, for in this case the roller P is located in the slotted plate and may be quickly removed through either of the end holes R, so that the side head may be used for straight work during the same setting of the piece, without much trouble in preparation. The plate H is fastened to the rods F and S and vertical adjustment is obtained by sliding up or down. The binding screws E and T secure it in the desired vertical position. A T-slot V is cut along the entire length of the side head slide and a cast adapting plate O is secured in it by means of T-bolts. The angular plate M is screwed and doweled to the adapter. The brackets K and L are fastened to the side head down slide and are fitted to the edges of the

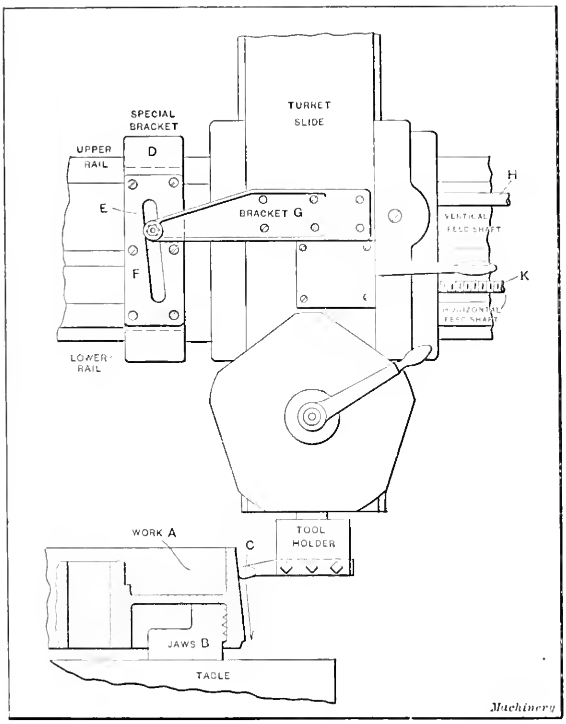

Fig. 16. Taper Attachment for a Vertical Boring Mill

plate H, in order to avoid any bending action which might be produced by the pressure against the roller P. The brackets D and Q are similar to those used in the former case.

Taper Attachment for Vertical Boring Mill

The work A shown in Fig. 16 is a male taper clutch member, and the machine upon which the work is to be done is a vertical boring mill with a turret head. The piece is held by the inside in the jaws B and the tool C forms the taper. In order to permit lateral motion a special nut was required for the horizontal feed shaft K. This nut is not shown in the illustration but was made somewhat on the principle of a lathe feed shaft nut so that it could be coupled and uncoupled rapidly. A special bracket D was fastened to the rail to the left of the turret slide and the forming plate E was fastened to it. A special bracket G was fastened to the turret slide and served as a support for the roller F. In use the vertical feed shaft H is thrown into gear and the turret allowed to float laterally as controlled by the forming plate E. When the other turret tools were to be used, the

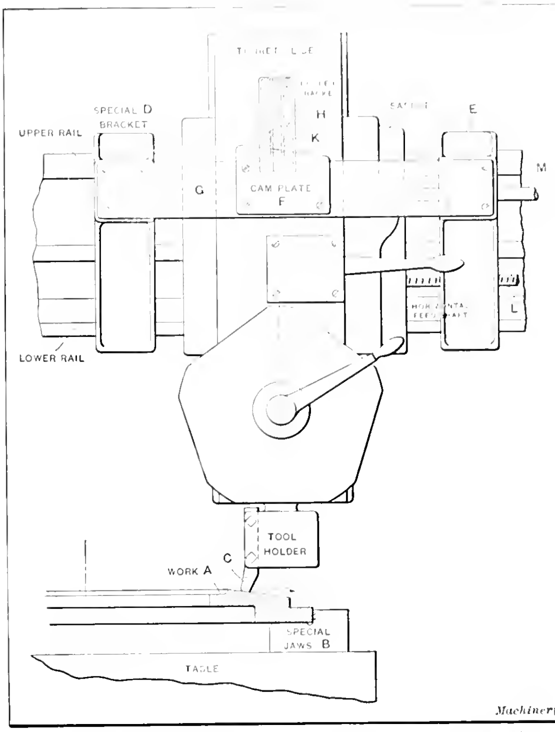

Fig. 17. Angular Forming Attachment for a Vertical Boring Mill

roller F was removed and the horizontal feed shaft nut recoupled. The action of this device was very satisfactory.

Angular Forming Attachment for a Vertical Boring Mill

A very acute angle was to be produced on the work shown at A in Fig. 17 and a vertical boring mill was used to perform the operation shown. The work is held by the outside by the special jaws B; the tool C is used to perform the work. Two brackets D and E are bolted to the rails, one on each side of the turret slide and the cast-iron plate G is used to connect them and form a support for the cam plate F. A portion of the turret slide is machined off to permit the attachment of the roller bracket H. This bracket is slotted with a T-slot and the roller K mounted on a T-stud may be readily adjusted in it. In using this attachment it is only necessary to throw in the horizontal feed shaft gears and keep a downward pressure by hand on the cam plate F, by means of the handwheel on the end of the shaft M.

The various forms of taper attachments and devices which have been mentioned in this article cover nearly every variety of work and may be adapted to nearly any form of taper requirements that may be met with in the course of general manufacturing.

* * *

A "big voice" telephone system is being introduced in factories and warehouses for locating employes and transmitting orders. The system is also being used for the novel purpose of distributing music during working hours or at the noonings. The effect of music in some trades is very beneficial; if the work is of a monotonous repetitive nature it relieves the tedium, makes the workers cheerful and accelerates their movements, thus increasing production.

THE HEAT-TREATMENT OF STEEL

The growth in common knowledge of improved scientific methods of heat-treating steel during the past ten years has been rapid and wide-spread. The development of the automobile, which requires superior materials for durability, has been the prime moving force in the spread of better methods, and the effect on all branches of industry must be beneficial.

The papers on heat-treating methods and appliances read before the October meeting of the National Machine Tool Builders' Association constitute a valuable symposium, notwithstanding some differences of opinion expressed. Ten years ago a large part of the knowledge now freely disseminated was unknown, and that which was known was carefully guarded in a few of the leading plants of the world.

Perhaps one of the greatest benefits to be derived from exact knowledge of steel treatment is the banishing of superstition. When men work in the dark, doing things they don't understand, to bring about results that may or may not be satisfactory, they cannot reason logically on their business in general. In order to progress, a clear understanding of principles must be had, and when that has been acquired, the effect will be noticeable in all branches of the business.

* * *

MECHANICAL SECTION OF THE N. M. T. B. ASSOCIATION

When a mechanical section was proposed for the National Machine Tool Builders' Association, some doubt was expressed as to the expediency of devoting the time of the convention to the reading and discussion of technical papers. It was thought by some prominent members that the profitable work of the association in convention lay rather in the direction of harmonizing differences and bringing about understandings that would result in the betterment of the industry.

The last annual meeting, which was notable because of the presentation of six excellent papers on the selling, accounting and metallurgical sides of the machine tool business, was undoubtedly made more interesting and profitable to those members in attendance by the reading of the papers than if the same time had been devoted to strictly commercial subjects. The keen interest displayed showed that the members were eager to get the benefit of the experience and opinions of those who had specialized in the lines which they represented.

It has been contended that such papers should properly be presented before the meetings of the American Society of Mechanical Engineers, and while this may be theoretically true, practically the machine tool builders would not receive as much benefit. The large and varied membership of the A. S. M. E., the crowded programs and the different atmosphere, would not be conducive to the free discussion of papers peculiarly of interest to machine tool builders.

We believe that the National Machine Tool Builders' Association can profitably develop a mechanical section, and that it should do so with the primary object of discussing principles of design, details of construction on which there can be common agreement, shop construction, metallurgical and foundry practice, and similar subjects. The strengthening of the technical programs will give greater interest to the proceedings, and the publication of the papers in the mechanical journals will advertise the existence of the association to the manufacturing world. The value of the association to its members in some emergencies is its power wielded as a unit; but to have power it must have the prestige and influence that come only from work unselfishly done.

THE APPRAISAL OF MANUFACTURING EQUIPMENT

To estimate the value of a going manufacturing concern is a problem of no little difficulty. Hardly any two experts will agree in their valuations. The market price of the standard machines and tools, that is, those machines and accessories which can be used without change for other lines of manufacture or for repair work, can be estimated closely by those in touch with the demand for second-hand equipment. But to appraise the property of a going concern on the basis of disintegration and sale to the highest bidders is manifestly to grossly underrate its actual value.

Tool equipment that has cost thousands of dollars might be rated at its scrap value only, whereas its actual value to the concern might be eighty or ninety per cent of the cost. But all machines and equipment wear out or become obsolete in time, and a certain charge should be made each year to provide for the overhead cost of manufacture. What these charges shall be depends very much on the nature of the business.

Take, for example, chucks, jigs and fixtures. Chucks for lathes and planers are standard equipment, useful in every machine shop. To estimate their life at twelve to fifteen years under average conditions of use seems conservative, but to extend the same lease of life to jigs and fixtures is not. The conditions existing in the shops inspected by Mr. McKay whose article on appraisal of manufacturing plants appeared in the May number may have given warrant for that assumption; but plants devoted to other important industries surely would not. An expert who devotes his time largely to the appraisal of automobile plants follows the practice of discounting one-third yearly on all tools, jigs, fixtures and similar equipment.

The automobile plant, of course, presents an extreme of rapidly changing conditions. But somewhere between it and the conditions surrounding the manufacturer of standardized machines lies a mean of average life to be reckoned with in making appraisals in general.

* * *

KEEPING MACHINERY IN GOOD REPAIR

One of the dangers of punch press operation is "kicking back." If the clutch pin slips or breaks at the moment of greatest pressure, the ram may fly upward, reversing the crankshaft, and drop down again with disastrous effect. Some of the safety devices provided for guarding the hands of operators fail in this emergency, and serious accidents have occurred with presses that were supposed to be fully protected.

Machinery in general, and presses in particular, must be kept in first-class condition in order to prevent accidents. Safety devices have their place, but human ingenuity can hardly provide against the accidents that may happen when the cycle of mechanical movements is interrupted by the failure of an important part. The repair man of a modern factory may be likened to the outpost of an army. He must be constantly on guard to prevent disaster.

DANGEROUS CHISEL HEADS

The heads of cold chisels, sets, punches and other percussive tools of the class driven by hammers and sledges soon batter and break away under repeated blows. The bits of steel displaced and sent flying by the hammer blows are often causes of painful accidents. The eyes are especially vulnerable, and in foundries, steel works and machine shops especially, many workmen have lost the sight of an eye by being struck with a bit of steel broken from a chisel head.

If goggles with safety glasses were always worn, the danger to the workmen actually engaged in chisel work would be reduced to a minimum, but they are in no greater danger oftentimes than are others near by. If the battered ragged heads were ground off regularly, the danger of steel flying off and causing accidents would be small, but precautions like this are difficult to enforce; there is no one in the imperfect organizations of most plants to keep close watch of such apparently trivial details. The expense of keeping the heads ground off is, too, an item of some importance.

The unsightly appearance and danger of ragged heads can be eliminated by proper heat-treatment of all percussive tools. Tool-dressers should be impressed with the importance of hardening and tempering the heads of chisels, sets and flatters as carefully as the cutting parts. The article by Mr. Cran in this number gives specific directions for treating tool-heads, with illustrations of tools treated and in use.

A QUESTION FOR THE GRINDING EXPERT

As is well known by those who have had experience in cylindrical grinding, it is difficult to lay down rules for determining the proper grade and grain of wheel, work speeds and wheel speeds, because so many variables must be considered. Certain fundamental principles are recognized by all grinding authorities, but at least one important point has not been definitely settled; in fact, the makers of grinding machines hold opposite views regarding it. We refer to the question of work speeds, and more particularly to the changes of speed made for the roughing and finishing cuts. Some advise a reduction of speed for finishing and others an increase in speed. This appears to be a fundamental question and one about which there should be no disagreement at all.

We realize that both sides may be right for the particular conditions under which the grinding is done, but are the conditions right in each case? If one method is more efficient than another, both the grinding machine manufacturer and the grinding machine user would benefit by having the best practice generally adopted. This difference in practice can be accounted for by the fact that wheels of different grades are used for grinding the same kind of material. In some shops soft free-cutting wheels are employed, while in others the wheels are harder and more compact. In the case of soft wheels, the speed for roughing should keep the wheel face sharp, and as a result it leaves a rather rough surface on the work. Hence the work speed is reduced for finishing with the same wheel in order to obtain a finish that cannot be obtained with a higher speed. On the other hand, with a wheel of harder bond, the speed is increased considerably for the light finishing cut. A comparatively soft wheel is generally conceded to be the most efficient grade for roughing, but is it economical to use a wheel that is hard enough to permit increasing the work speed for finishing, and does this increase of finishing speed compensate for the loss of efficiency in roughing? What is the reader's opinion?

* * *

A curiosity in arithmetic has recently been worked out by a British astronomer in answer to the question: What is the largest number that can be expressed with three digits? The answer is 9^{9^9} (nine raised to the ninth power of nine, or $9^{387\,420\,489}$). The number which this represents is so big that it is awesome. If it were printed in full it would fill thirty-three volumes of eight hundred pages each of fine type. The first twenty-eight figures are 428,124,773,175,747,048,036,987,115,9 and the last two are 89. In between these are 369,693,070 figures! —*Saturday Evening Post.*

MEN WHO HAVE WORKED FOR ME

BY A. F. ORMAN

I remember reading an interesting article entitled "Foremen For Whom I Have Worked," and it suggested an article on the converse subject. One man I remember particularly who was a genius in working out methods of overcoming difficulties which befall us in our line. A few instances will suffice to show what I mean. Once when he had a steam hammer cylinder on the planer for the purpose of planing grooves down each side and across each end of the face which is bolted onto the guides, to receive a 3/8-inch copper wire gasket, he set the work up for the endwise grooves and planed them; and then instead of tearing the job down and turning it at right angles, as many others would have done, he turned the tool at right angles and had the helper run the head across on the rail with a long crank which he had on hand. You can imagine how much quicker and easier this operation was when done in this way.

In fitting main-rod brasses he would put them on the pin, pull them together with bolts and clamps, and then insert the "feelers" to ascertain the play. By using the graduations on the shaper head, one-half of this amount was planed off each brass, of course allowing something for fitting. I noticed his method of making some buttons, of which there were about a dozen. He secured six pieces of cold-rolled stock, each long enough for two pieces after allowing for the width of the parting tool. He gripped them in the three-jawed universal chuck and turned the ends to 3/4 inch in diameter, making use of the graduations on the screw; and then inserted the parting tool and cut them all into two pieces. He next gripped them across the 3/4-inch diameter, being sure the shoulder was against the jaws of the chuck, set the facing tool at the proper distance from the shoulder, locked the carriage, and proceeded to face them all off to the same length without moving the carriage longitudinally during the process. These things in themselves may not seem remarkable, but when you have an opportunity to observe the different methods of different men, you will see that the time saved by these simple rules amounts to something in a very short time.

Another man who worked for me for one week was a "home guard." He had worked in all the local shops and started a repair shop of his own soon after I "let him go." I asked one of the apprentice boys—who happened to be a neighbor of his—how he was getting along. He replied: "I stopped in his shop one day. He was drilling a 7/8-inch hole in a piece of brass, had the press running on the slowest speed, and was squirting lard oil on the drill." The superintendent had intimated that I must be mistaken when I said that this fellow was not a good mechanic.

At another time I had two apprentices in the shop. One of these boys could do a splendid job if it happened to be something that he had done before, but if some one else had done the job the last time he did not take sufficient notice of the work to be able to repeat it without being coached. The other boy, though he never neglected his work in so doing, kept his eyes open for ways and means of doing other work than that which he was engaged upon. It is unnecessary for me to say that when I was ready to promote him to the next machine he had, by observation, mastered the principle of its operation and was ready for the promotion. Though he had never performed an operation on the planer, when I gave him a somewhat complicated job to do on this machine I was pleased to see that he was familiar with the principles of clamping the work and the use of the stops, clapper box adjustment, etc., though he was a little awkward with the shifter, which was to be expected.

The next fellow who comes to mind should have had a gold medal for "gall." He had recommended himself very highly as coming from a large locomotive shop and said he could run any kind of a machine. The first job I gave him was a planer job—an oil cellar for a driving box. He put it on the platen, put two clamps on it, and evidently thought it unnecessary to use any stops. He then started the machine. The dogs didn't happen to be in the right places

so that the platen reversed before the job reached the tool. He stopped the machine by putting the belt on the loose pulley, took the clamps off the job, and shifted it further up on the platen so that it would reach the tool before it reversed. He didn't even know what the dogs were there for. I let him go, as I was afraid he might get hurt.

Another man was given a lathe job on a machine which had a back up belt for thread cutting. He happened to pull the shifter the wrong way and started the lathe backward. He looked at the machine as if he thought there was something wrong, but instead of trying to right it he put the tool against the work. Finding that this would not do, he turned the tool upside down and was endeavoring to adjust it this way when my attention was attracted to him. I told him that he was discharged and he got mad and quit. Then there is the fellow who, when given any kind of a job on any kind of a machine, thinks that the first thing to do is to get it in the machine and start a cut before figuring out the best way to proceed. He is not to be compared with the man who figures out the method of procedure first and then puts the piece in the machine.

I have noticed that a considerable number of mechanics who had the reputation of being above the average failed to appreciate the fact that in doing duplicate work it is often quicker and easier to change the piece than to change the tool for the different operations. For instance, consider the case of turning studs on centers when one end is 3/4 inch and the other is 7/8 inch. In turning the end to 3/4 inch, set the tool on the first stud and run the cut up as far as it is to go, run the carriage back for the next cut, and then take the stud out of the lathe and put in the next. Duplicate this operation until all are turned. Then to chase the threads, set the tool for the first one, marking the graduation for each cut and particularly for the last one. You can take a little time to insure a good fit on the first stud; then chase the rest of them without changing the tool and see how much easier it is than to change the tool for each one, not to say anything about trying the gage three or four times on each stud. To those who have mastered these principles the suggestions herein contained may seem superfluous, but I can only say that I have had an opportunity to observe the methods of a number of mechanics, and the ones who make use of all or most of the "kinks" here enumerated are the exception to the rule.

Once in a while you will find an attachment for some machine which does not seem to be of any use, but as a rule they are of benefit if you will only take the trouble to use them. I noticed one of the boys trying to figure out some way to put a piece in the lathe, one end in the chuck and the other in the steadyrest. It was a long piece and there did not happen to be any center in the ends. The piece was a standard size of 1 3/4 inch. I suggested that he put an arbor of this size on the centers, adjust the jaws of the rest, and then put the piece in it. He had no further trouble, but had spent considerable time trying to do it some other way before the suggestion was made. The foreman have their little peculiarities and so have the men.

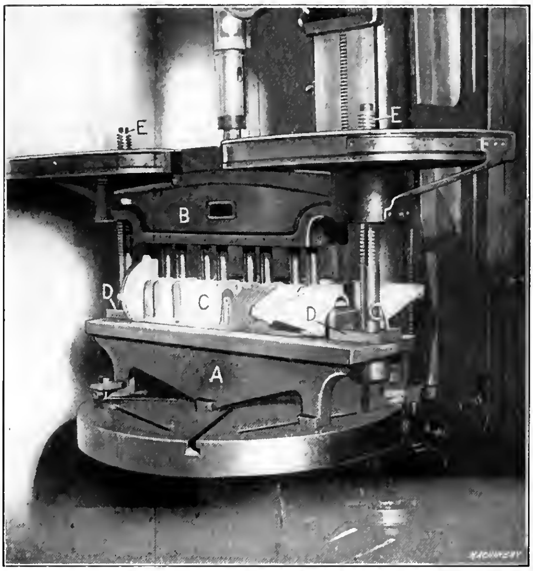
HOT BLAST METAL TREATMENT

A peculiar action has been noted in the operation of the Tolhurst centrifugal dryer for cleaning, drying and brightening small metal articles. This apparatus consists of a centrifugal machine, similar to an oil extractor or clothes dryer, and a fan supplying a blast of hot air. The articles are placed in a basket and whirled at a peripheral speed of 6000 to 8000 feet per minute, depending upon the diameter. The blast of hot air is delivered to the machine in the center of the basket; the impelling force of the fan and the centrifugal force of the whirling mass causes the hot air to pass quickly through the articles. The result is rapid drying and brightening. The temperature of the hot blast when used in government mints varies from 95 to 160 degrees, depending upon the metal, the lower temperature being used for copper and the higher temperature for silver and gold. The peculiarity alluded to is the rise in temperature of the articles in the basket. Frequently the temperature will rise to 212 degrees F. and sometimes higher. The cause is supposed to be the friction of the air passing over the work. A curious feature, however, is that the temperature of the delivered air is cooler than that of the hot blast.

* * *

DRILLING MACHINE FIXTURE FOR BROACHING PUSH-ROD GUIDE HOLES

The accompanying illustration shows a broaching fixture made by the Willys-Overland Co., Toledo, Ohio, for broaching the keyways in the push-rod guide holes of four-cylinder engine aluminum crank-cases. The fixture, which comprises a bed *A* and head *B*, is held on the table of a Cincinnati-Bickford upright drilling machine. The base *A*, on which the crank-case *C* rests, is finished on its top surface, and on it are fixed two locating L-pieces *D*, for aligning the crank-case lengthwise. The eight spindles which carry the broaches are held in the head *B* which is carried on two screws *E* fastened in the base. These screws are provided with square threads and fit in threaded nuts that form bushings inserted



Broaching Eight Push-rod Guide Holes in a Special Fixture attached to a Cincinnati Vertical Drilling Machine

in two large gears, not shown. These two gears are rotated by means of a central gear fastened to a driver held in the spindle of the drilling machine.

In operation, the back-gears of the drilling machine are thrown in and as the spindle descends it rotates the two large gears through the medium of the intermediate gear, thus drawing down the head of the casting and forcing the broaches through the crank-case. When the eight keyways, which are 3/16 inch wide by 3/16 inch deep, have been cut, the rotation of the spindle of the drilling machine is reversed, thus carrying the head of the fixture up again and removing the broaches from the crank-case. The push-rod guide holes are 1 3/16 inch in diameter, and the total broached length is approximately 3 1/2 inches. The eight holes are broached in exactly one minute, not including putting the work on and removing it from the fixture. D. T. H.

* * *

A steel girder, 139 feet long and weighing 180 tons, which is said to be the largest ever built in America, was recently put in place over one of the principal streets in Lynn, Mass. The girder is one of four carrying the B. & M. R. R. tracks but the other three are supported by pillars in the center and are not, therefore, so long or heavy. A pillar could not be placed to support the middle of the girder in question, however, because of the position of the street railway tracks. Hence it had to be built to cover the entire span without support in the center.

CARBONIZATION OF SHAFTING*

MATERIALS FOR CARBONIZING—STEEL TO USE—FURNACE TEMPERATURES—QUENCHING MEDIUMS

The increasing use of anti-friction bearings in various forms, as well as other developments in the construction of machinery, has made necessary the use of harder and better surfaces for shafts than has heretofore been considered good practice. Before entering into any detailed discussion of this subject, we should first have some understanding of what the problem really is, expressed, if possible, in concrete figures. Let use take a piece of soft steel which has been turned and ground to a definite size. We find its hardness, as measured by the Shore scleroscope, to be somewhere between 15 and 25, whereas with a piece of cold-rolled shafting, we obtain 30. Alloy steel of suitable analysis and properly treated will give 60, and if we take still another piece of material, carbonize it and follow this by suitable heat-treatment, we can obtain 80, as shown by the scale of the instrument. Therefore, we can see from these approximate figures, that the method and material to be used is largely a matter of the specific result desired and, obviously, it is impossible to utilize any one method or material for all requirements.

Aside from the condition of the surface, there are other important considerations. Taking the elastic limit of the material as a measure of its load-carrying capacity, we find 40,000 pounds per square inch an average result for soft steel, and 170,000 pounds not excessive for properly heat-treated alloy steels. In the case of carbonized shafts, there is no material increase in the elastic limit, the improvement being entirely a matter of surface condition. Hence, we see the possibility of not only obtaining the required surface, but, at the same time, materially increasing the factor of safety of the shaft, or using a smaller shaft with the same factor, as may be preferable. If the surface requirements are represented by a scleroscope reading greater than approximately 60 to 65, the problem must be approached from the standpoint of carbonization, unless we are willing to use expensive alloy steels which, in this discussion, are considered neither possible from the standpoint of first cost nor a necessity. Carbonization gives ideal results as to surface conditions but no increase in the elastic limit. On the other hand, if a scleroscope reading of 60 to 65, or less, is considered to be a satisfactory standard, it is feasible to use many alloy steels at low cost which, when of the proper analysis and suitably heat-treated, will not only give equally good results as to surface conditions, but a material increase in strength as well. The problem then is naturally divided into two general divisions each requiring a different discussion. First, carbonized shafts having a surface hardness greater than 60 to 65; second, heat treated shafts having less hardness than the figures stated.

Carbonized Shafts

Perhaps no branch of the thermal treatment of steel has been more thoroughly investigated than that of carbonization, but the results show conclusively that there is no standard American practice, either in regard to methods or material. This is doubtless due to variation in local conditions. For instance, one who carbonizes arbors or shafting is not so much concerned about the toughness of the core as one who treats pieces of thin cross-section. Again, one so-called authority will insist that the transition from case to core should be gradual with no sharp line of demarkation, whereas one who is carbonizing very thin sections or shells knows from experience that the case must, necessarily, be distinctly defined and concentrated in order to use to the best advantage the small space allowable to obtain such conflicting properties as toughness and hardness. Where the number of parts requiring carbonization is comparatively small, a high-speed carbonizer whose strength is spent on the first run may prove satisfactory, but if the number of parts runs up into the thousands daily, a more economical material would be adopted. If our problem is that of a few pieces a week, the irritating effect of prussiate of potash is not particularly objectionable, while with a condition involving many thousand pieces daily, in all extremes of weather, its effects are more in evidence. Thus, the authority who endeavors to lay down a hard and fast rule is treading on dangerous ground. Bearing in mind, therefore, the wide divergence of conditions, even when limiting ourselves to shafts, let us first consider the best material for our specific purposes.

Steel for Carbonizing

In considering the steel to be used naturally the carbon content is the point at issue. My experience has indicated that a material varying from 0.15 to 0.20 per cent carbon is the most satisfactory from every viewpoint. Many authorities recommend a carbon content as high as 0.27 per cent, but the writer has not found it possible to obtain uniform and satisfactory results, in a large way, with such material. Irrespective of the particular analysis that may be decided upon, the matter of uniformity is of even greater importance. No matter what the source of supply may be, it is advisable to analyze ten per cent of the material received, in order to avoid irregularities which sooner or later develop.

Carbonizing Mixtures

Most of the carbonizing compounds upon the market contain simple ingredients which can be mixed readily upon the premises, although some are almost beyond the realm of chemical analysis. In fairness it may be stated that a few of them give very good results, but the price is generally set in proportion. For all-around purposes, those which can be mixed easily upon the premises are best. If this method be adopted, the metallurgist in charge can superintend the entire grinding and mixing process and keep the quality of each ingredient up to a standard. The two following mixtures, which for convenience are designated "A" and "B," are easily prepared, reasonable in cost and have given satisfaction in the treatment of several million pieces of the most exacting requirements.

MIXTURE A

	Per Cent
Raw bone	35
Bone black	27
Charred leather	11
Wood charcoal	27
	100

MIXTURE B

	Per Cent
Potassium ferro cyanide	5
Sal soda	14
Coarse salt	9
Powdered wood charcoal	72
	100

The characteristics to be considered in a carbonizing mixture are: Hardness imparted to the work; rate of penetration; cost per pound and renewal cost; ease of manipulation in grinding, mixing, packing, etc. The following table shows mixtures "A" and "B" compared in the first three respects, with one of the best carbonizers on the market, which for convenience is designated as mixture "C."

Material	Scleroscope Reading	Time to Penetrate 5/64 inch	Cost Per Pound, Cents	Per Cent of New Material Required for Renewal
"A"	70	13 hours	2.6	55
"B"	75	12 hours	1.3	30
"C"	75	14 hours	2.5	80

The hardness was determined by using properly carbonized heat-treated and polished specimens and naturally varied somewhat, the values given in the table being averages of several readings. The time to penetrate to a given depth was obtained on specimens of shafting one inch in diameter. The carbonizing process was similar to that recommended later in this article. By referring to the preceding table, it will be seen that mixture "B" shows a gain of about 14 per cent over mixture "C" and about 8 per cent over "A," in respect to speed of penetration. In initial cost, material "B" is the cheapest, while "A" and "C" are about the same. The quantity of fresh material which must be added to that which has already been in the furnace, to restore it to the desired strength, shows a marked advantage in favor of "B." Moreover, material "C" was practically useless after one heat. While cost is an item of minor importance, and quality is cheap at any

* Abstract of a paper by Jay G. Weiss, works manager Hyatt Roller Bearing Co., read before the National Machine Tool Builders' Association, New York City, October 23, 1913.

price, if the other properties are balanced, cost might judiciously be considered in selecting carbonizing mixtures; hence, this data was added for the sake of completeness.

Packing Parts to be Casehardened

If the shafts are not too long, they should preferably be packed in pots standing on their ends, but if the length does not permit of this arrangement, they may be packed in rectangular pots in horizontal layers. Irrespective of the method of packing, each piece should be kept $1\frac{1}{2}$ inch from adjacent pieces and 2 inches from the pot walls. This clearance, which may seem excessive, allows for any settling of the mixture while in the furnace, for if the pieces should come in contact with each other, the penetration would be retarded and the surface would be defective at that point. A layer of mixture 2 inches deep should be placed in the bottom of the pot and be thoroughly tamped down; every successive layer should also be tamped. The pot cover should be thoroughly sealed or luted with fireclay. Large pieces which are too long for pots may be packed in pipe, the latter having a cap on each end, the threads of which have been coated with graphite to facilitate removal. With this arrangement, all moisture must be excluded from the mixture to prevent the formation of steam which might result in an explosion. The pots should be spaced in the furnace so that 2 inches of space is available for the circulation of heat around every part of the pot surface. Even with this precaution, the pot nearest the furnace door will not be heated exactly the same as those farther back, and this should be allowed for. My experience has demonstrated that the best material for the pots is either cast steel or white iron.

The Carbonizing Heat

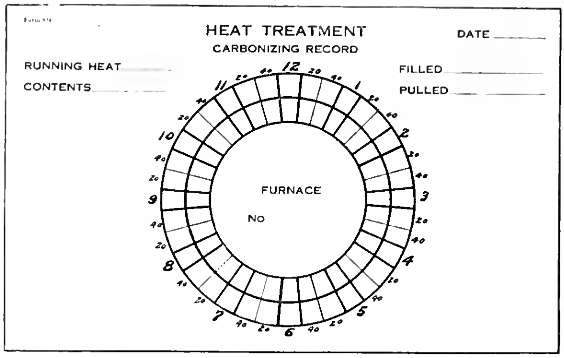
There is a difference of opinion as to the proper temperature for carbonizing. Temperatures ranging from about 1600 degrees F. to 1800 degrees F. are used quite generally. The writer has found that 1725 degrees F. is a safe heat, which does not endanger a good steel. Higher temperatures may be used, but while the duration of the "run" is shortened, the quality of the work is likely to be impaired. For the accurate measurement of this temperature, only the very best make of pyrometer should be employed, those of the high-resistance type being preferable. They have the great advantage of simplicity, as the wiring does not need to be especially calibrated for each location, within reasonable limits, and it is possible to attach recorders to the same circuit without affecting the indicator reading. The pyrometer should penetrate the furnace wall and be placed as near to the work as possible, without liability of actual contact. When located vertically, the life of the porcelain jackets is increased, but the temperature of the cold junction is kept higher owing to the direct radiation from the top of the furnace. By inserting a pyrometer of sufficient length horizontally into the furnace wall, the cold junction may be kept at a lower and more uniform temperature.

At the beginning of the heat the temperature may be kept, say, 50 degrees F. higher than normal, until the heat begins to penetrate the work, when it should be reduced to normal. No fixed rule can be given for the time of complete saturation, as the size, shape and thickness of the pot wall, as well as the size of the work and kind of mixture, are determining factors. The duration of the run can be determined only by actual trial, depending upon such factors as the nature of the steel being treated, the carbonizing material, the degree of temperature and depth of case required. The best practice is to put a trial piece of the material into one of the pots in each furnace and remove this piece about an hour before what experience has shown to be ample time. This trial piece is then heat-treated, as described later, and the depth of the hardened case of a cross fracture is observed. A very accurate estimate can then be made as to the time to remove the rest of the work.

With mixture "B" (see foregoing table) twelve hours will produce a case about 5/64 inch deep on a 1-inch shaft of 0.15 per cent carbon content, with a temperature of 1775 degrees F. for the first two hours and 1725 degrees F. for the remainder of the run. A complete temperature record of each run in each furnace should be kept, the temperature being tabulated at least every twenty minutes. A convenient blank for this tabulation is shown in the accompanying illustration. The temperatures are first recorded in the outer radial spaces, and if the run exceeds twelve hours duration the inner spaces can then be used. Uniformity of temperature is, of course, a very important factor and no matter what type of furnace or fuel is used, more or less regulation is necessary. Perhaps a brief description of the method employed at the Hyatt Roller Bearing Co.'s plant to effect this control would be of interest.

Colored Light System of Controlling Furnace Temperatures

In the Hyatt plant, there are approximately twenty-five large carbonizing furnaces fired with fuel oil and over one hundred semi-automatic gas furnaces for heating alloy steels. The gas furnaces are supplied by a battery of gas producers having a total capacity of 2500 horsepower. The physical laboratory is located on one of the floors of the heat-treating building, and the temperature control room is a part of this laboratory. The furnaces are distributed on the four floors all over the building. Each furnace has a pyrometer which is connected by wires in an iron conduit, with the temperature



Blank for recording Furnace Temperatures

control office. Over each furnace there is a small signal board with three lights; one white, one red, and one green. These lights are also connected with the temperature control office. All these circuits lead to a marble switchboard which has three signal lamps for each furnace, these being in series with corresponding lamps over that particular furnace. There are two operators at the switchboard, each one having control of the furnaces of two floors. By touching a key, the operator can set the pyrometer of any furnace. If the temperature indicated by the pyrometer is normal, or within the allowable tolerance, an observation of the next one is taken, and so on. If the temperature is found to be too high, by touching another key the light over the furnace is changed to red, and if it should be found to be too low, the light is changed to green. At the same time, the corresponding light on the furnace signal board changes. Each attendant has under control six furnaces, and by simply looking at the signal boards he can determine readily whether the temperatures are high, low, or normal, and make the necessary regulations. After signalling a red or green light, the switchboard operator soon returns and takes another reading of the furnace to ascertain if the proper regulation has been made.

Heat-treating after Carbonizing

When the steel emerges from the carbonizing furnace, it is of a dual nature, the case containing say, 0.80 to 1.25 per cent carbon and the core 0.10 to 0.20 per cent carbon. Consequently, the carbonizing temperature is considerably above the critical range of both the case and the core, especially the latter, and as the duration of the run is several hours large crystals form readily in both case and core under these conditions. To restore the steel to the best grain size, two heats are required; a high one for refining the core, and a lower one for refining the case. Of course, it is possible, as well as quite common, to quench the work directly from the pot, using this heat as the first or "core heat" and then following with a second or "case heat," or the second may be omitted

entirety. In the latter instance, the temperature is too high to produce the best refinement of the case, although the core structure may be satisfactory. Again, if the work is allowed to cool so that the temperature is about right for the case, the core will not be perfect. Another disadvantage is due to delays in getting the work from the pot to the quenching medium, the pieces cooling more or less, and thus giving results that are far from uniform. In view of these facts, the writer is a strong advocate of applying two heats after the work has cooled from the carbonizing temperature.

We now come to the important question as to what are the correct heats. There is apparently a great difference of opinion on this subject, owing to such varying factors as the rate of penetration of different quenching mediums, the effect of the mass of the article quenched, and the temperature of the quenching medium. As previously mentioned, the first heat is usually between 1600 and 1800 degrees F. The second heat varies between 1375 and 1475 degrees F. If a single heat is used, the range will vary still more, running high or low, according to whether the quality of the case or core is to be sacrificed.

Quenching

Perhaps nothing connected with the heat-treatment of steel is of more importance than quenching. Slight variations in the angle of immersion often result in distortion of the work, apparently out of all proportion to what might be expected. Shafts should be immersed vertically and moved in the same position up and down until the quenching is complete. No matter how large the work, the results obtained will pay for any special apparatus necessary to carry out this method.

Where the maximum hardness is desired and only one heat is to be taken, water will give the best results, but the danger of distortion is greater than when oil is used; this applies even more to brine and cold water. When two heats are employed, it is advisable to quench first in oil, for as the first temperature is higher, distortion is more likely to occur. After the second heat, the work may be quenched in water. Good results may be obtained by using water in both instances, as far as the structure of the steel is concerned, but there would be greater danger of distortion. When oil is used, care should be taken to maintain its temperature fairly constant.

The advantage of drawing after carbonizing is much disputed. Opponents of this method claim that the core should have the requisite toughness and that any temperature which would toughen the case would soften the core. While this may be true to a certain extent, the writer has found that in some instances good results can be obtained by drawing at about 400 to 450 degrees F., as this temperature relieves the strain in the case somewhat, without materially sacrificing its hardness.

Heat-treating Shafts

The difference between the two methods being discussed is that in one case a material is used to which carbon must be added to obtain the required hardness, whereas with the other method, a material is used in which the carbon forms a constituent part. The amount of carbon depends upon the particular result that is required in each instance. Shafts to meet the general needs in machine tool construction should have a carbon content of 0.40 to 0.50 per cent and, combined with this, the writer suggests alloys of $1\frac{1}{4}$ per cent nickel and $\frac{1}{2}$ to 1 per cent chrome. Steel of this particular analysis has been used very extensively during the past few years and can be readily obtained at a moderate cost. This steel requires only a simple heat-treatment at about 1500 degrees F., the exact temperature depending upon the carbon content. It should preferably be quenched in oil having a temperature not exceeding 80 degrees F. It should also be drawn at 800 degrees F. for approximately an hour, the exact time depending upon the size of the shaft.

With this material, heat-treated as described, a hardness of from 60 to 65 (scleroscope reading) and an elastic limit of at least 150,000 pounds per square inch, can be obtained readily even if the sections are fairly large in diameter. Such a method of solving the problem has the advantage of far greater simplicity, as to apparatus, and is less expensive than the carbonizing process. In fact, it is the opinion of the writer that a simple heat-treatment for an alloy steel of the general analysis suggested is so far superior to the hazard and expense, both direct and indirect, of carbonizing, that there is in reality no comparison between the two methods. This is entirely independent of the fact that in the heat-treatment method, we have a material combining strength, toughness and more lasting quality.

INTERNATIONAL ENGINEERING CONGRESS

An International Engineering Congress in connection with the Panama-Pacific Exposition in San Francisco will be held September 20-25, 1915. The congress will be conducted under the auspices of the American Society of Civil Engineers, the American Institute of Mining Engineers, the American Society of Mechanical Engineers, the American Institute of Electrical Engineers and the Society of Naval Architects and Marine Engineers. The purpose and scope of the congress will be, first, the gathering together of a large and representative body of engineers from all civilized countries for the purpose of forming or renewing personal acquaintances and interchanging views on various phases of professional work; and second, the reading and discussion of papers before the various sections and their publication later in such form as will constitute a valuable addition to engineering libraries. The scope of the congress is to be truly international; it will embrace the various branches of the engineering profession. Eminent engineers throughout the world will be invited to contribute papers on assigned topics, and in the selection and distribution of these topics endeavors will be made to secure papers representative of the world's best engineering practice in the various branches of the profession.

All papers will be presented in English. If papers are written in other languages, they will be translated into English free of cost to the author. The general field of engineering to be covered has been divided into ten groups or branches, which, together with a special field, the Panama Canal, will constitute eleven sections, each of which will be presided over by a chairman. The sections are as follows: (1) The Panama Canal; (2) Waterways and Irrigation; (3) Railways; (4) Municipal Engineering; (5) Materials of Engineering Construction; (6) Mechanical Engineering; (7) Electrical Engineering; (8) Mining Engineering; (9) Naval Architecture and Marine Engineering; (10) Military Engineering; (11) Miscellaneous. The fee for membership in the congress is $5. The fee will entitle the member to receive the index volume and any single volume of the transactions which he may select, and the right of full participation in all the general activities and privileges of the congress.

The officers of the committee are: W. F. Durand, chairman; W. A. Cattell, secretary and treasurer; E. J. Dupuy, executive secretary. The offices are in the Foxcroft Bldg., San Francisco, Cal.

CENSUS OF WORLD'S AUTOMOBILES

A complete census of the number of motor vehicles in the world was compiled for the first time for the International Road Congress recently held in London. According to the data compiled, the United States possesses more than one-half of all motor vehicles, including motorcycles, in the world, the total number for the United States being 628,185. England comes next with 125,728, France with 89,185, and Germany with 70,006. The total number of motor trucks in the world is stated to be 69,556. The automobiles exceed greatly the number of trucks in all countries except in Germany, where it is stated that there are 49,126 trucks and only 15,618 pleasure cars. It is very likely, however, that this statement is due to a misunderstanding of the German expression for commercial car, which is probably meant to include all cars used for commercial purposes and hence the very large number of taxicabs in use in German cities. It is estimated that there are 300,000 motor vehicles manufactured yearly.

METHODS OF HEAT-TREATING STEEL WITH ELECTRICITY*

A DISCUSSION OF THE FEATURES OF THE DIFFERENT TYPES OF FURNACES IN GENERAL USE

BY E. F. LAKE†

The growing demand for a higher quality in heat-treated steels and for a constant improvement of the physical properties of the metal is making the electric furnace a commercial necessity, both in the manufacture of the metal and in its hardening and tempering. Efforts are also being made to use electric furnaces in the fabrication of steels, and such furnaces are now in use for heating steel before it is drop-forged and bent to shape for leaf springs. This is due to the fact that when so heated impurities which are injurious to steel are either removed from or not allowed to penetrate the metal, and thus are present in lower percentages than when the steel is heated in furnaces that use a flame to generate the heat. Another reason is the ease with which the temperature can be controlled and, consequently, the greater accuracy that can be obtained in securing the correct degree of temperature that is required for heat-treating or refining the steel. This has caused many different types of electric furnaces to be developed for heat-treating steels and several different principles are utilized in their design and construction. Of these, the Hoskins types were described in a former article and consequently will not be considered here. Most of the remaining types use either the arc or resistance principle for supplying the necessary heat to the oven or liquid bath furnace. Some, however, heat the steel on an open plate, and others after it has been submerged in the quenching bath.

A recently developed type of electric furnace is shown in Fig. 1. This is the Baily furnace, built by the Electric Furnace Co. of America, Alliance, Ohio. It is shown in use in the manufacture of leaf springs. In this instance the operation consists of inserting leaf No. 1 in the furnace and bringing it up to the fabricating heat, which must be 1800 degrees F. to make it bend properly to shape. The leaf is then removed and throughout its whole length made to fit tight against the bottom plate *A*, by two men who use tongs for this purpose. The bottom plate is held to the proper curve by pins through the eyes and holes in uprights *B* and the central supporter *C*. Leaf No. 1 is then replaced in the furnace, brought up to the hardening temperature and then taken out to be quenched in oil contained in a tank. After that, it is again placed in the furnace where the oil is burned off to get the drawing temperature. The next operation is to fit leaf No. 2 to leaf No. 1 which is held in the frame, and to harden and temper it. Then leaf No. 3 is fitted to leaf No. 2 and so on until the whole spring is built up. Owing to the inequalities in the curves, each spring must be kept separated and each leaf has its individual stamp, as none of the leaves will fit into any other spring. This accounts for the precision with which the spring plates are laid out on the rack at *E*.

Fig. 1. The Baily Furnace in use in the Manufacture of Leaf Springs

It can be seen at a glance that this is a misuse, or abuse, of the electric furnace and destroys its greatest point of excellence, namely the accuracy with which the temperature can be controlled. The correct hardening temperature of carbon spring steels is about 1500 degrees F. To reinsert the leaves in a furnace whose temperature is maintained at 1800 degrees, or more, and get them all within 150 degrees of the correct hardening temperature, during a day's run, is an impossibility. Occasionally one leaf may be taken out at the right temperature, but no means have been devised for telling when the whole length of a leaf has reached a temperature of 1500 degrees F., when it is in a furnace heated to 1800 degrees. Man's eyesight is not sufficiently delicate or accurate. Burning the oil off to obtain the drawing temperature is not to be spoken of seriously. If a separate furnace were used for the hardening operation, the heat in the oven could be maintained at the correct temperature, which would be 1500 degrees in this case. Thus steel could be allowed to remain in the oven of the furnace until it had reached a uniform temperature and then be taken out for quenching. Pyrometers could be used to measure the temperature of

* For further information on the electric heat-treatment of steel see "Electric Furnace Heat Treatment of Steel" in the October, 1913, number of MACHINERY, and other articles there referred to.

† Address: 1153 Waterloo St., Detroit, Mich.

the furnace oven, which would also be the temperature of the steel, and a more uniform product would be obtained. Another furnace operated at the correct drawing temperature would insure uniformity for that operation. The springs would then be much stronger and more resilient. The work could be turned out much faster in this way and with cheaper labor, which would lessen the cost of production.

The furnace is supplied with all the accessories that are necessary for obtaining accurate temperatures and maintaining them during any period of operation. The transformer is located at *F*, the oil switch at *G* and above it at *H*, the regulating controller. With these accessories the voltage can be varied to control the number of kilowatts of power supplied to the furnace, thus regulating its temperature. The switchboard *I* holds an ammeter, or current indicator, to show the amount of current that is flowing at any given time; a wattmeter to show the amount of power that is consumed per hour, day or month; a voltmeter to show the voltage of the current; and a recording pyrometer that shows on the chart the temperature the furnace has attained at any time during the day. These charts can be filed away to keep a permanent record of the temperature of the furnace on any work that is turned out.

A closer view of the furnace is shown in Fig. 2. In this illustration, the cold spring plate *A*, to which the hot leaves are bent, can be more plainly seen and also the rack in which it is held. The rack on which the spring leaves *J* are placed to drain off the oil can be seen in the tank *D*. The front of the oil switch is shown at *G* and the switchboard at *I*. At *K* are shown frames that cover the outer ends of the electrodes and their copper connections, to protect the workmen from the current. No flames, smoke, gases, fumes, or roar comes from this furnace; therefore, no chimneys, piping or blast are needed and an air blast or steam is not required, as in the case of furnaces that use a flame. The temperature of the room is also lowered, as most of the heat is confined inside the furnace. Thus the working conditions are made so much more pleasant that the operators are able to produce more springs for a day's work.

This furnace is called the 100-kilowatt size which means that its maximum consumption of power is 100 kilowatts per hour. The heating chamber is 5 feet wide by 7 feet deep by $1\frac{1}{2}$ foot high and 600 pounds of steel plates can be heated to 1650 degrees F. in one hour. With all openings closed, the furnace can be maintained at this temperature with about 20 kilowatts of power, which replaces the heat lost through the walls, this result being obtained by adjusting the switch so that 200 amperes at 100 volts will be flowing into the furnace. It is based on the theory that each kilowatt liberates 3412 B. T. U.'s in the furnace. If the doors of the furnace are left open, it will require another 8 kilowatts to replace the heat lost through them, and if there are any holes in the sides or roof of the heating chamber for the heat to leak out, it would require considerably more power to keep the furnace up to the desired temperature. Therefore, it is important that no openings should be allowed to remain in the walls, and as the furnace can be completely relined with silicon-carbide, at a cost of some \$2 or \$3, there is no excuse for leakages to occur.

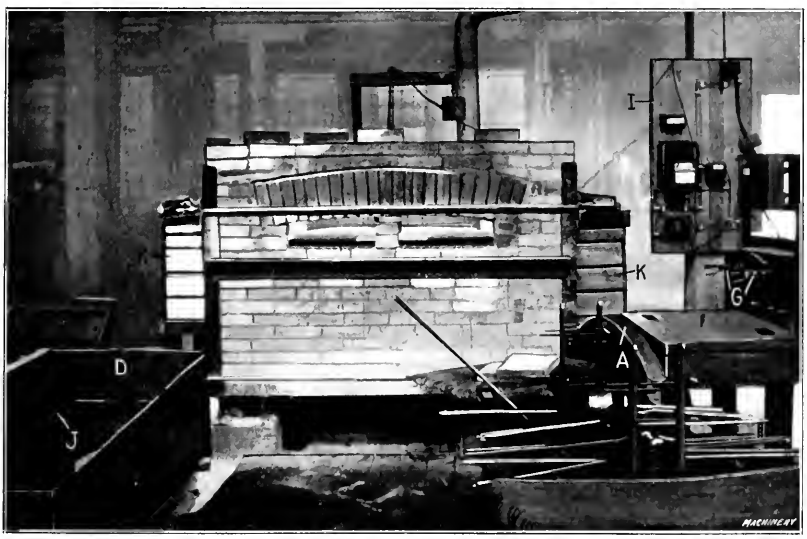

Fig. 2. Closer View of the Furnace illustrated in Fig. 1

With the preceding data, it is a simple matter to calculate the amount of current required to heat a given amount of steel. To heat one pound of steel to 1650 degrees F. requires 300 B. T. U.'s; therefore to heat 600 pounds every hour would require 180,000 B. T. U.'s per hour. This result divided by 3412 gives 53 as the number of kilowatts per hour that the furnace requires to generate this amount of heat. If we add 20 kilowatts for the wall loss and 8 kilowatts for the loss through the door, we have a total of 81 kilowatts per hour as the amount of power that is needed to heat 600 pounds of steel per hour. This can be obtained by adjusting the regulating switch to give 500 amperes at 160 volts. To leave the switch at this adjustment when the furnace was empty would run its temperature up too high, so that if it was required to maintain a temperature of 1650 degrees F while the furnace was standing idle for a short time, a readjustment of the switch would be made to give 200 amperes at 100 volts to make up the wall loss of 20 kilowatts when the doors are closed. If the doors are left open, enough more power would be required to make up the 8 kilowatts loss through that opening.

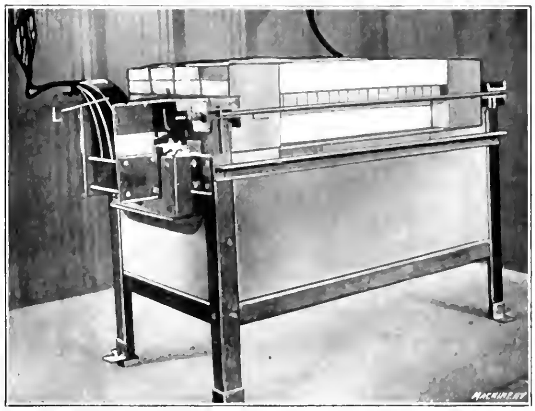

Fig. 3. A 60-kilowatt Baily Furnace for use in a Forge Shop

A 60-kilowatt furnace that was built for a forge shop in Alliance, Ohio, is shown in Fig. 3. This furnace is operated every day to heat chrome-vanadium steel to a forging temperature of over 2000 degrees, and allowed to get cold at night. It has a capacity of 300 pounds of steel per hour and is of the same type as the heat-treating furnaces. In fact, it could be operated just as efficiently at the hardening temperatures of the carbon or alloy steels. At *L* are shown the coppers that carry the current to the electrodes, two copper plates being attached to opposite sides of each of the two electrodes.

The principle on which these furnaces operate is shown by the diagram Fig. 1. Here *T* represents the heating chamber and *S* the opening or door leading into it, while *P* is the floor of the heating chamber on which the work is placed that is to be heat-treated. The leads which conduct the current to and from the furnace are shown at *L* and the copper plates that conduct it to the electrodes *X* are shown at *K*.

A channel O running underneath the floor of the heating chamber is filled with a resistance material, which in this case is coke ground to about the size of peas. The electrodes N extend several inches into the ground coke, and as the electricity passes through the resistance material, from one electrode to the other, the required heat is generated. As many channels may be used as the size of the heating chamber makes necessary.

The salt bath furnace illustrated in Fig. 5 is one in which the steel is immersed in molten salt to bring it up to the proper hardening or drawing temperature. The noteworthy feature of this furnace is that it is electrically heated, and such a furnace can be made to last indefinitely. It is best to construct a sheet-steel shell A that is held together with angle irons, lined with one inch of asbestos and then built up with about 12 inches of common brick B on the bottom and four sides. This brickwork should again be lined with one inch of asbestos C, inside of which about 8 inches of fire-brick D is laid on the bottom and four sides. When completed, the pot so formed should be of the right size for ordinary classes of work. It ought to be enough larger than the steel to be heated to allow space for two electrodes E of boiler plate on opposite sides of the pot, as these are placed inside of the salt bath, and also to allow for keeping the steel at least one inch away from the bottom, sides and electrodes, and immersed two inches below the top of the bath. When such a furnace has cooled down, the hard salt is not a good conductor of electricity. Therefore in starting up, it is necessary to chip a channel across the top of the salt, lay a ½-inch round carbon F in the channel, cover it with the salt chips and start them melting with a hand electrode, as shown in the illustration. When the channel is filled with molten salt, from one boiler plate electrode to the other, it will start the electric current flowing and the balance of the salt in the bath will soon become molten. The temperature is raised and controlled in practically the same manner as with the oven furnace previously described. The electrodes will last something like 3000 hours at temperatures that are high enough for hardening carbon steels.

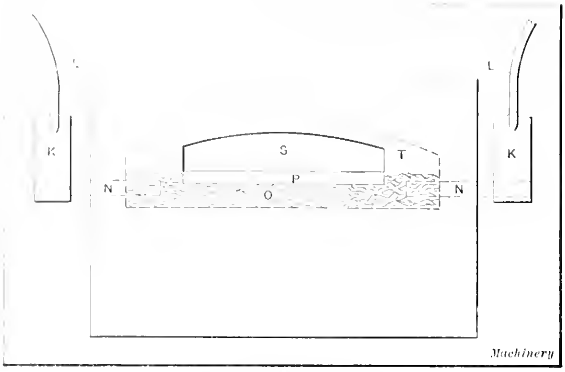

Fig. 4. Diagram showing the Principle on which the Baily Furnace operates

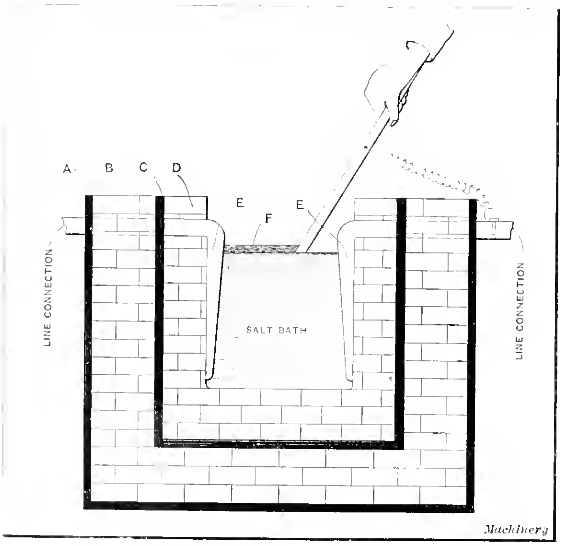

Fig. 5. Electrically Heated Salt-bath Furnace showing Method of starting with a Hand Electrode

When steel is heated to the hardening temperatures in a salt bath and then removed to be quenched, a thin coating of the salt adheres to the steel and prevents oxygen from attacking it and forming an oxide on its surface or raising a scale, while it is passing through the air to the quenching bath. This adhering salt cracks off when it is suddenly chilled in the quenching bath and leaves the steel with a natural color instead of with the black appearance that is produced when hardening it in other ways. At the higher hardening temperatures of high-speed steels, the salt bath furnaces that use graphite crucibles cause the tools heated in them to become pitted. In this electric furnace, however, the pot that holds the salt bath can be built up of other refractory materials, such as silicon-carbide and electrically calcined magnesia, and then no pitting occurs at any of the temperatures used for hardening.

Many different kinds of salts have been experimented with and the best kind to use for the bath depends on the temperature that is required. The melting points of the various salts that have been used are as follows:

MELTING POINTS OF DIFFERENT SALTS USED FOR HEAT-TREATING STEEL

Name of Salt	Melting Temp., Deg. F.	Name of Salt	Melting Temp., Deg. F.
Barium Chloride....	1580	Potassium Carbonate	1526
Sodium Chloride....	1418	Sodium Carbonate...	1317
Potassium Chloride..	1346	Lithium Carbonate..	1283
Calcium Chloride....	1328	Potassium Nitrate...	644
Magnesium Chloride.	1306	Sodium Nitrate.....	572
Lithium Chloride....	1112	Sodium Silicate.....	113
Lead Chloride.......	932	Barium Fluoride....	1832
Cupric Chloride.....	928	Calcium Fluoride....	1832
Silver Chloride......	844	Magnesium Fluoride.	1664
Cuprous Chloride....	813	Sodium Fluoride....	1656
Ferric Chloride.....	572	Lithium Fluoride....	1474
Zinc Chloride.......	504	Potassium Fluoride..	1454
Aluminum Chloride.	356	Strontium Fluoride..	1350

Of these some are too expensive for commercial work, others volatilize too easily and still others cannot be used for various reasons. Several combinations can be made that are better than when one salt is used alone, and some of these combinations have a lower melting point than either of the salts forming the mixture. For temperatures between 1800 and 2400 degrees F., chemically pure barium chloride is without doubt the best salt to use, as it volatilizes less than any of the others and is low in price. For temperatures between 1400 and 1650 degrees F. three parts of barium chloride to two parts of potassium chloride give excellent results. For any of the drawing temperatures below 1075 and above 480 degrees F. equal parts of potassium nitrate and sodium nitrate make a salt bath that is satisfactory in every way. This can be kept molten at 400 degrees F. if it is continually stirred, but if left standing it will solidify at about 475 degrees F.

When the proper salts are used there is very little loss from volatilization and aside from the cost of current, the expense of operating this furnace is very slight. It is particularly adapted for treating small work that can be loaded into metal baskets or racks and then immersed in the molten salt, as large quantities can be handled in this way and the work is clean when finished. In one case, 70 pounds of safety razor blades are heated to the hardening temperature in this way. They are next quenched and then reheated to the drawing temperature in another electrically heated salt bath furnace. Both furnaces are maintained at the correct temperatures for the hardening and tempering operations by a switch with eleven points that correspond to ten steps either

way and thus gives twenty-one adjustments. A pyrometer tells when the bath is at the correct temperature, and then it is only a question of leaving the work in the bath long enough to reach a uniform temperature. The thickness of the work determines the length of time it should be kept immersed, and with a little experience this can be definitely determined.

The electric arc has been successfully used for heating steel to hardening temperatures, and it is especially applicable for localizing the hardening in a certain part of the piece, the point of a cutting tool being a notable example. In Fig. 6 is shown a homemade apparatus that was rigged up for this purpose. The barrels filled with salt water take the place of a more expensive transformer and rheostat. By raising and lowering the steel terminal plates *A* in the barrels, the electric current can be controlled so that the tool is heated to the desired temperature. The carbon holder *B* is a very simple thing to make and any cast-iron plate *C* can be set on a rubber mat *D* to hold the tool *E* to be heated. A welding heat can also be obtained with this apparatus. It is essential that all parts of the body be protected from burns, as the heat from the arc will burn any exposed part in the same way that a sun glass burns on a hot day. Therefore it is necessary to wear gauntlets and a face shield with colored eye-glasses.

The steel is only heated in a spot directly under the carbon, and to heat the desired surface it is necessary to keep the carbon moving in a circle. It should not be brought too near the cutting edge of the tool and the arc should be started at a very low voltage, which is steadily increased to the desired point by adjusting the shunt rheostat. The carbon must also be kept a short distance away from the steel, for if it touches it is very likely to melt the metal at that point. The correct hardening temperature must be judged with the eye, as it would be very difficult to measure it with any kind of an instrument.

As steel becomes non-magnetic when it reaches the correct hardening temperature, or the transformation point, a magnet similar to that shown in Fig. 7 might be used to ascer-

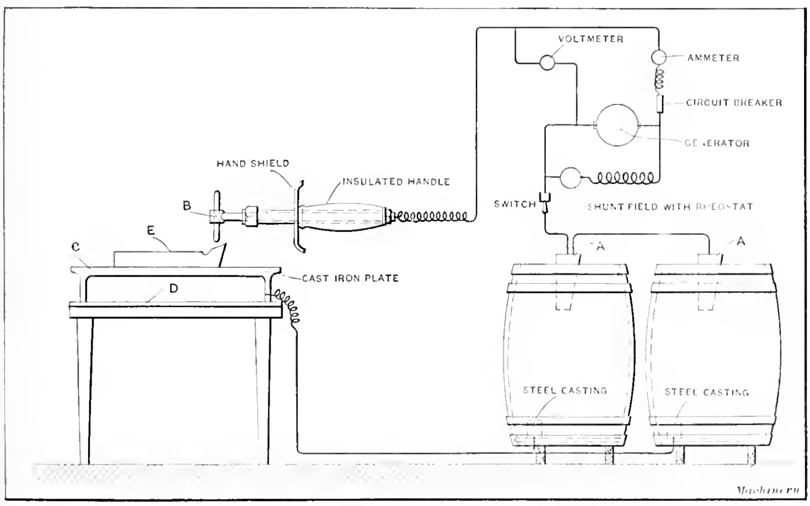

Fig. 6. Electric Arc Arrangement used for Local Hardening

tain when it had reached the non-magnetic stage. This magnet was made especially for use in hardening steel. As steel cannot be instantly cooled from the hardening to atmospheric temperature, it must be heated to from 25 to 40 degrees above the non-magnetic point to allow for the lag when quenching. It is very difficult to judge these 25 to 40 degrees and hence the magnet cannot be used for accurate work in hardening. The rapidity with which a piece of steel can be heated to the hardening temperature is the greatest recommendation of this apparatus, as it takes only two or three minutes to heat quite a large surface on a fairly thick piece. If it were not heated and quenched quickly, the oxygen in the air would have time to raise quite an oxide or scale on the heated steel.

If this principle were used regularly it would be much better to fit it up with a transformer and switchboard control in place of the water barrels, as these require constant attention to keep the water from boiling over, and to raise and lower the terminal plates.

The most rapid method of hardening steel is doubtless that in which the furnace shown in Fig. 8 is used. This consists of a cast-iron tank containing a potassium carbonate solution, a clamp in which to hold the piece to be hardened, and a rheostat, switches, fuses and wiring. After clamping the tool, it is only necessary to turn on the current, lower the tool into the solution and, when it has attained the proper temperature, turn off the current and allow the steel piece

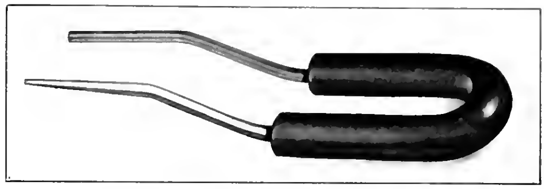

Fig. 7. Magnet used for determining the Critical Temperature of Steel

to be quenched by the solution. When the steel enters the potassium carbonate solution, it completes the circuit and immediately begins to heat up. The correct temperature is reached on a good-sized piece in about a minute and, being quenched before it is removed from the bath, nothing can attack the steel to discolor it. Consequently, when taken from the bath it has a clean steel-colored appearance. Being heated uniformly on all sides, there is no tendency for the work to warp or become distorted, and it can be lowered into the bath only as far as it is desired to have it hardened. With a little experience, the rheostat can be set at the point that will heat the steel to just the required temperature, and then it is only a question of leaving the steel in the bath long enough to attain this temperature before turning off the current. For permanent use, this apparatus can be fitted up to enable the current to be quickly regulated for obtaining any desired temperature in the steel, so that accurate results can be obtained in hardening.

Another principle, or method, that has not yet passed the experimental stage, except for treating tungsten and tantalum for electric lamps, is the vacuum furnace. These metals absorb oxygen and nitrogen very readily, when heated in the air, and become too hard and brittle for practical use. By heating them in a vacuum, however, they expel the oxygen and nitrogen, as well as any hydrogen that may have been absorbed, and are rendered quite ductile. This ductile tungsten has made the tungsten lamp a commercial success. It is comparatively easy to construct and operate an electric furnace inside a vacuum chamber and it is also known that less current is then required to heat metals to a given temperature. This is due to the fact that the loss of heat by radiation is reduced to a minimum and that the furnace retains its heat for a long time. The vacuum thermos bottle is a good example of this kind.

It is a well known fact that all metals absorb gases during melting and this reduces their physical properties. That steels give off these gases when heated in a vacuum has also been proved by many experiments, and some have shown that the higher the carbon content of steel, the larger will be the amount of these gases that is absorbed. Hydrogen, carbon monoxide, nitrogen, carbon dioxide, and methane are the gases expelled, in quantities according to the order in

which they are placed, the percentage of methane being very small and practically nil in many kinds of steel. At the transformation point of steel a new crystalline structure is formed, and the greatest quantity of the gases is given off at that time. As this is also the correct temperature at which to harden steel, it shows the benefit that could be derived by allowing the metal to "soak" for some time, in this degree of heat, when hardened in a vacuum furnace. The evolution of hydrogen begins at temperatures between 300 and 600 degrees F., according to the kind of steel; oxygen,

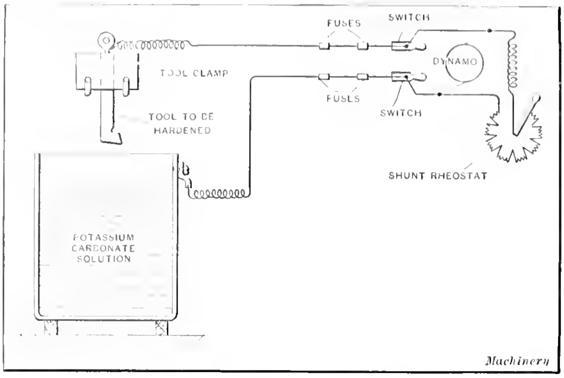

Fig. 8. A Rapid Method of hardening Steel

in the form of CO, at about 750 degrees; and nitrogen at from 1000 to 1200 degrees. Thus if an electric vacuum furnace could be constructed in a way that would make it useful for hardening tools, or commercial work of other kinds, it would doubtless increase the physical properties of the steel so hardened and especially its resistance to fatigue. Electricity is the easiest, quickest, and therefore the cheapest fuel to use in a vacuum furnace and its construction would be much simpler than if any other fuel were used. The results look so promising that it may be developed for shop use in the near future.

SOLDERING FLUXES FOR SOFT SOLDER*

Among the many familiar metallurgical processes with which we have to do, the process of soldering is perhaps the most familiar. As ordinarily defined it is a process whereby two pieces of metal are joined by another metal or alloy, having a lower melting point than the metals joined.

In order that metals soldered together may be securely held, it is necessary that there be more than mere adhesion between the solder and the metal. There must be an alloy formed between the metal and the solder. In order that this alloy may be formed, the surface of the metal must be entirely free from any foreign substances, as oxides, oils, or various solid matter. Since it is not always convenient, or we may not care to take the time to clean the surfaces to be soldered, we resort to the use of various chemicals to clean the surfaces.

The flux selected, in any particular case, is determined by the nature of the work. If ordinary tin-plate, galvanized iron, sheet copper, or brass is to be soldered, the common fluxes, as ammonium chloride, zinc chloride or rosin, may be used. But if the work is something more delicate, as the soldering of 10 by 20 mil zinc wires, in fuse plugs, the effect of the corrosion of zinc chloride on the zinc wires must be considered. It is necessary in many instances to use a non-poisonous flux, as a poisonous flux should not be used in soldering fruit or meat tins. In many operations it is impossible to keep the soldering flux from coming in contact with the operator's fingers, or occasionally spattering in his face.

The rapidity with which a flux acts is an important factor in its usefulness. If the flux be in the form of a dry salt, a comparatively large amount of heat may be necessary to melt it. If an aqueous solution be used, an additional amount of heat must be used to evaporate the water, thus slowing the rate of action by cooling the parts to be soldered. This effect is negligible in most instances, but where it is necessary that the solder attach itself within a fraction of a second it becomes quite important. If the flux does not require melting, but is a liquid, the action is much more rapid, as no time is required for the surface to be covered, and no heat is used in fusing the salt. Further, the excess flux, which should always be present, readily flows out of the way.

Zinc chloride has several properties which make it a valuable soldering flux for most work. It is only with the greatest of difficulty that it can be obtained as a dry salt, and when exposed to the air becomes liquid in a few minutes. When used as a flux it remains a liquid even at the temperature of molten solder, thus being in a condition to act upon the oxides very readily. It possesses other properties which make it undesirable for much work. Zinc chloride is poisonous, and should not be used in soldering fruit or meat tins. It is exceedingly corrosive to the skin, and when left upon it for a few minutes produces severe burns. It also has an action on zinc which makes it useless for soldering small zinc wires in fuse plugs. If low capacity fuse plugs be made, using zinc chloride, as a flux, small zinc wires will be found to be completely eaten through within a few weeks, and sometimes in a few days.

An aqueous solution of ammonium phosphate was tried as a flux and worked quite well on tin, copper, brass or zinc, (but not on iron), where delicacy of operation and speed are not to be considered. But where a quick fluxing is necessary, it is not successful, as too much heat is necessary to evaporate the water and melt the salt. It has the advantage, however, of being non-poisonous and non-corrosive.

Lactic acid and ammonium lactate were tested as to their fluxing qualities, and were found to be splendid fluxes, equal in every particular to zinc chloride, but in a few hours showed a tarnish if used to solder brass or copper. The reason for the ready tarnishing is that lactic acid and ammonium lactate react with copper oxide in the cold. Neither of these fluxes is corrosive or poisonous in any way.

Rosin, either as a powder or an alcoholic solution, is a splendid flux where speed is not required. But it has the undesirable property of leaving a sticky, gummy mass after the evaporation of the alcohol, which is a hindrance in some kinds of work. Quite often a quantity of carbon and half decomposed rosin is left where the solder is to follow. For ordinary work, where a non-poisonous flux is desired, rosin is perhaps the most desirable. An aqueous solution of citric acid is a good flux, having properties very similar to ammonium phosphate. Ammonium chloride is a widely used flux, and is non-poisonous, and does not tarnish copper or brass; but when used on zinc, it forms zinc ammonium chloride and causes more or less corrosion of the zinc.

The Tower Building, 50 Broadway, New York City, which is notable for being the first of the modern skeleton steel frame buildings, is to be torn down. It was erected in 1889 on a narrow lot and is eleven stories high. If it had been built with stone or brick walls, the building laws in force would have made necessary walls so thick that the available space on the lower floors would have been too narrow to be profitable. To meet the situation, the architect, B. L. Gilbert, devised the skeleton steel frame type in which the posts and beams support the entire weight of the floors and side walls and transmit it to the foundations. By resorting to this expedient he was able to erect a building with comparatively thin walls and thus make valuable space available for renting. The building is to be torn down because it is no longer profitable to maintain. A larger building covering the plot and adjacent plots will be erected.

The British Engineering Standards Committee has adopted the following standard for marine boiler stays: The Whitworth form of thread is to be used and the number of threads per inch is to be nine for stays above $1\frac{1}{4}$ inch diameter; for longitudinal stays above 2 inches diameter, six threads per inch will be used.

ALTERNATING-CURRENT MACHINERY TROUBLES—2

BRIEF AND CONCISE ANALYSIS OF THE DIFFICULTIES MET WITH AND THE REMEDIES TO APPLY

BY E. A. LOF*

TRANSFORMERS

Excessive Heating and Burn-outs

Short-circuits—The development of an actual short-circuit in a transformer in service causes a large current to flow in the short-circuited path. When a short-circuit develops in the primary winding, practically destroying it, the secondary coils are likely to remain in fairly good condition. If the trouble starts in the secondary winding it is likely to be localized in that part, and the primary coil may not be injuriously heated.

Short-circuits caused by defective winding of the coils may be due to rough, imperfectly welded joints, to improperly insulated wires, or to extreme pressure or pounding of the insulation. They may also be caused by breakdown of the insulation due to abnormal high-voltage static strains from surges set up by lightning, high tension switching, arcing, grounds, etc., or by moisture entering the transformer.

For drying out of transformers or oil see later paragraph.

There is one class of short-circuits known as "high resistance short-circuits," which are sometimes rather mystifying. They show up as a high iron loss, and it is at times difficult to determine whether the trouble has been due to defective winding or bad iron. Such a short-circuit may clear itself after the transformer is loaded. This is done by the expansion of the coil and consequent separations of the wires which were very nearly in contact. The short-circuit can usually be developed and located by an over-potential or overload run.

When connecting transformers in parallel the polarities must be the same; otherwise there exists a dead short-circuit.

Overheating from Overload.—An excessive heating or burnout from an overload is characterized by a "roasting" of the whole winding uniformly, while a short-circuit started from moisture, for example, produces a local failure. An overload may be either intentional or due to other causes. One transformer of a bank may be accidentally disconnected by, say, a broken lead, putting the load on the remaining units, thus overloading them. It has also been observed in practice that when one transformer of a bank connected delta-delta partially fails, the other two are frequently subjected to heavy currents which are circulated on account of the change of ratio resulting from the failure. The change of ratio that usually attends a failure admits of a difference in voltage which circulates current against the impedance of the three transformers connected in delta. A small difference in voltage may result in the circulation of a heavy current. Thus it may happen that when one transformer of a delta-delta bank fails the other two may be subjected to damaging effects if the bank is not taken out of service soon enough.

In the case of the Y-delta transformation the action is different. The effect here of a change of ratio of one of the transformers, due to partial failure, is an unbalanced secondary voltage. No appreciable current circulates in the secondary delta even where the difference in ratio of the damaged transformer is considerable. Instances are recorded where transformers connected Y-delta have run several months with one of their number in a damaged condition. In this case, therefore, it is not necessary to cut the bank of transformers out of service immediately unless the one damaged should fail entirely. The treatment in this case, however, is based upon the assumption that the neutral of the Y under consideration is not connected to any other neutral. If the neutral is connected to the neutral of another bank and both banks are tied in multiple, the effect in regard to circulating current would be the same as that obtained with the delta-delta transformation.

When two transformers connected in V are operated in parallel with three transformers connected in delta, one of the transformers will take more than its share of the load. The one transformer in the delta which has no corresponding multiple transformer in the V bank will then be carrying full load when each of the other four transformers is carrying only 76.15 per cent of the normal load. It is evident, therefore, that this transformer must be watched carefully to see that it is not too heavily overloaded.

When two transformers are connected in V on a three-phase circuit, the capacity is not two-thirds of a corresponding delta-connected bank consisting of three similar units, but only $1 \div \sqrt{3} = 58$ per cent. This is due to the fact that for the delta connection the current and voltage of each transformer are in phase with each other, while for the V-connection the current and voltage of each transformer are 30 degrees out of phase with each other.

Wrong Connections.—Transformers having series-parallel connections are sometimes so connected as to give double voltage on the windings. For instance, a transformer having a ratio of 2000 or 1000 volts primary to 110 or 55 volts secondary may be installed on a 2200 volt circuit with the primary connected for 1100 volts and the secondary connected for 55 volts. The transformers will give the desired 110 volts secondary, but since the windings are subjected to double the normal insulation strain and a large amount of the magnetizing currents would flow through the primary windings, insulation breakdown will probably occur sooner or later, and unless the connections have been carefully inspected the burnouts will be attributed to defective insulation.

Another wrong connection was a case where the transformer was connected up for 2200 to 220 volts and 1100 volts was impressed on its primary winding, giving 110 volts on the low tension winding. If such a transformer were loaded up at 110 volts to its rated capacity, it would be likely to burn out, as it would take double the current required if properly connected at normal rating. In this case the transformer would be roasted out, whereas, in the above case, its insulation would break down.

Ventilation.—Oil-cooled transformers rely upon the natural circulation of the air for preventing undue temperatures. When it is considered that with a number of large transformers of this type in one station there may be many kilowatts of energy to be dissipated, the necessity for the thorough ventilation of the station in which they are installed is realized. Since the air on becoming hot tends to flow upward, the openings in the station for the inlet of the air should be near the bottom, and those for the outlet should be near the top, all being well distributed. If the ventilation is not sufficient the transformer is bound to have a shorter life than it would have with the proper cooling. The first indications of a dangerous condition are darkening of the oil and a slight deposit on the surfaces inside the transformer. When the deposit once begins to form the tendency is accelerated because of the lessening efficiency of heat dissipation from the transformer. Where the oil has thickened to a considerable extent and a deposit has accumulated, the remedy is to thoroughly clean the transformer by scraping it and washing it out with oil under high pressure, putting in new oil after the treatment.

Cooling Water.—Excessive heating followed by burnouts may be caused with water-cooled transformers by the temperature of the cooling water being too high, or the amount of water not being sufficient. Insufficient cooling water is sometimes caused by a gradual clogging up of the cooling coils. This may be due to chemical actions from impurities of the water, or from a large per cent of organic matter or mud in suspension. Where there is any danger of the water containing lime, etc., iron cooling coils should not be used. In such cases it may be necessary to use copper pipe in order to avoid corrosion.

A very frequent cause of the clogging up of iron cooling coils in water-cooled transformers is the formation of a scaly oxide when the water contains a large amount of air. It is customary in some locations, where the water supply is lim-

* Address: 214 Glenwood Blvd., Schenectady, N. Y.

ited, to cool the water by discharging it into an open basin or tank. Sometimes, to facilitate the cooling, the water is sprayed as it goes into the basin. In either case, and especially in the latter, the water is sure to have an unusual amount of air in it, and consequently will have a very strong oxidizing action. In such cases, therefore, copper coils should be used instead of iron coils.

To clean out a deposit inside the cooling coil the water is first blown or siphoned out, after which the coil is filled with a solution of equal parts of hydrochloric acid and commercially pure water. Let the solution stand about one hour in the coil and then flush out thoroughly with clean water. Usually one treatment of this nature is sufficient, but more may be used. The treatment is effective for removing all sorts of accumulation from coils of the various metals used. In applying the treatment it is not necessary to remove the coil from the tank, but extreme care should, of course, be exercised in order to prevent any acid from coming in contact with any part of the transformer winding.

A deposit of oil is sometimes accumulated on the outside of the cooling coils on account of allowing the oil to reach a high temperature. Such deposits act as excellent heat insulators, and unless they are removed will cause the condition to become worse, resulting in dangerous overheating of the transformer.

With excessive overloads there is sometimes danger in water-cooled transformers that their windings will reach a higher temperature than is indicated by the oil temperature, especially where the amount of cooling water is increased for the overload condition. A thermometer located in the tank near the cooling coil indicates a temperature considerably lower than the actual oil temperature.

Oil Troubles.—Burnouts are sometimes due to neglect to put any or sufficient oil in the transformer case. At other times oil leaks out, owing to a faulty case, or excessive evaporation takes place after a long period of service, resulting in excessive temperature rise and finally in insulation breakdown.

The presence of moisture in the transformer oil, even in the most minute quantities, very seriously affects the dielectric strength of the oil. Moisture may enter from the outside or be formed by condensation on the inside of the transformer. In the former case the transformer should be made air tight by providing the top covers with gaskets, and breathing chambers through which the entering air can be dried should be installed. Condensation takes place when the temperature of the transformer is allowed to fall below that of the surrounding air. It may be prevented by reducing the amount of cooling water at times of cold weather, or by using the cooling water over again several times. The cooling water should also be shut off when the transformer is out of service.

Oil may be dried by blowing heated air through it at a temperature that will vaporize moisture, either at atmospheric or a lower pressure, such as is obtained in the vacuum process. The adaptation of the filter press with blotting paper to the treatment of oil has, however, proved to be most satisfactory. There is no danger of injury from excessive temperature, and both the moisture and sediment are removed. In case it should be found desirable, the oil may also be treated by means of the filter press without taking the transformer out of service.

Oil Testing

It is necessary that extreme care be taken in sampling oil. The sample must be drawn from near the bottom of the barrel or tank containing the oil to be tested, after the oil has been undisturbed for a period of not less than 24 hours.

In drawing samples from barrels, a long glass tube of considerable diameter, thoroughly cleaned and dried, with the lower end drawn to a 1/4-inch diameter may be used. Closing the top end of the tube with the hand, the tube is thrust to the bottom of the barrel and the hand is then removed, thus permitting the tube to fill. Again place the hand over the top end of the tube and quickly withdraw it from the barrel, letting the oil run into the sample bottle. The receptacle of the oil-testing outfit that receives the sample should be dry and clean. Ordinarily, it will be sufficient after each test to wipe the receptacle and the terminals with a clean cloth that leaves no lint. The high potential wires should be connected to the proper terminals of the sample receptacle through fuses of such capacity as will protect the testing transformer under short-circuit. The adjustable terminals should be gaged to exactly 0.2 inch and the sample poured into the receptacle, which should be slightly less than full of oil. Bring the voltage up slowly and continuously until snapping sparks pass at short intervals. This is called the "breakdown at short intervals," or the B.D.S.I. point. The voltage that causes a continual passage of sparks is the puncture voltage and may be considerably higher than the B.D.S.I. If the source of the test voltage is one of considerable power, there may be only a puncture voltage, which ordinarily would represent the B.D.S.I.

Oil for transformers of 40,000 volts and over should be dried before using if it punctures below 35,000 volts. For transformers having voltages less than 40,000 volts, the oil must be dried if it punctures below 25,000 volts. Where oil is dried it may easily be brought to a puncture of 40,000 volts. If a sample contains sediment, it will puncture at a lower voltage than it would without the sediment.

Transformer Drying

When transformers are shipped without oil in the tanks it is necessary to dry them out first. This may be done in several ways, the external and the internal heat methods being mostly used. The first of these methods should always be used for transformers having voltages of 40,000 and above, while for voltages less than 40,000 the second method may be used if facilities for applying the first are not available.

The "external heat" method requires the circulation of heated air through the transformer in its tank. In using this method the caps on the ends of the cooling coil should be removed to prevent the development of dangerous pressure in the coil, which might result from vaporizing the liquid put in it to prevent bursting due to freezing. The transformer having been cleaned, inspected and returned to its tank, the sources of heated air should be connected to the base valve and the manhole cover removed. In order to maintain a sufficiently high temperature inside the transformer, it will be found necessary to partly close the manhole, thus restricting the flow of air. The temperature of the heated air as it enters the transformer should not exceed 90 degrees C. (194 degrees F.). An outfit which is especially adapted for furnishing hot air for this purpose consists of an electric air heater, blower and air strainer. The air heater requires 20 to 25 KVA at 110 or 220 volts to operate it. The blower is designed to run at 3300 to 3500 R. P. M. and requires 2 H. P. to drive it at normal output. The blower may be driven by means of a gasoline engine, motor or any other prime mover which may be available. The air strainer, when in operation, should be wrapped with cheesecloth to prevent the dust from entering the blower and being blown into the transformer. This cloth should be changed from time to time as the dirt accumulates on it.

Drying with the "internal heat" method is preferably done with the transformer out of its tank; but if the transformer is in its tank, the manhole cover should be removed and the valve in the base opened to give as great a circulation of air as possible under the conditions. Short-circuit one winding, and apply such voltage to the other that sufficient current will flow in the windings to raise the temperature to approximately 80 degrees C. (176 degrees F.). The amount of current necessary to effect this temperature ranges between one-fifth and one-third of the full load current, depending upon the room temperature and the design of the transformer. The impedance volt necessary to give the specified range in current varies from 0.4 to 1.5 per cent of the rated voltage of the winding to which the impedance voltage is applied. In every case, however, the current admitted must be so regulated that the temperature of the windings does not exceed the 80 degrees specified.

The duration of the drying run depends upon the voltage

and size of the transformer and also upon its condition as to moisture at the time it is dried. For transformers under 20,000 volts the drying should be continued not less than 24 hours; 20,000 to 30,000 volts, 48 hours; between 30,000 and 40,000 volts, 72 hours. Transformers of higher voltages may require a longer time. It is obvious that some consideration must be given to the capacity of the transformer. Transformers of less than 100 KVA may only require 24 hours. For transformers between 200 KVA and 500 KVA the process may be limited to 36 hours; between 500 KVA and 1000 KVA, to 48 hours; between 1000 KVA and 2000 KVA, to 60 hours; for all larger capacities the process should be carried on for at least 72 hours. In case there is no evidence that the transformer is unduly moist, discretion may be used in slightly decreasing the limits given for the voltage. A transformer of 20,000 to 30,000 volts, for instance, having a capacity of 200 KVA or less may be dried in only 24 hours. The limits given for the capacities, however, should be rigidly adhered to, and in no case should the process be carried on for less than 24 hours.

Parallel Operation

In order that several transformers be able to operate successfully in parallel, that is divide the load properly, it is necessary that they have exactly the same voltage ratio of high-tension to low-tension turns, the same resistance and approximately the same impedance drop. Where the impedances differ, the load on the transformer with the smaller impedance will increase and the one with the larger impedance decrease until the two impedance drops become equal. It is generally a difficult matter, therefore, to secure a perfect parallel operation where the sizes vary greatly, and for this reason transformers intended for parallel operation should preferably be of the same size and with exactly the same characteristics.

SYNCHRONOUS CONVERTERS

Excessive Heating

Overload.—This may be due to incorrect compounding which makes a converter take more than its share of the load. The compounding can be changed by adjusting the series field shunt.

Incorrect Excitation.—Synchronous converters should always be operated at the voltage for which they are designed. However, it appears to be a common weakness among operators to run converters with a 5 to 10 per cent over-voltage on the direct current side. This is done, of course, by increasing the shunt field excitation to such an extent that the shunt field alone draws a leading current at no load, over and above which the series field adds additional leading current as the loads come on. The result of such operation is to practically double the average heating in the armature conductors at full load above that of unity power-factor, on which the converter guarantees are based. More than this, such an operation increases the heating of certain bars near the collector ring taps to three or four times the normal value, this being in addition to the heating resulting from increased core loss in the armature due to over-voltage. The result is to practically cut down the capacity of the converter some 30 to 50 per cent. In other words, a customer purchases a converter at, say, 750 K. W., with the usual guarantees and so operates it as to make it only a 500 or 400 K. W. converter on the same heating basis. In most cases, the average load is so low that no trouble is experienced, but as systems grow and load factors improve the difficulty is likely to appear. The proper cure for this evil is to utilize proper taps in the transformers so as to impress an alternating voltage sufficiently high, and to compel the operators to adjust the direct voltage for sufficiently low value to cause the converter to draw a considerable lagging current at no load, as was previously explained.

Short-circuit in Armature Winding.—This is at once manifest by a burning out of the short-circuited coil, which should be removed and replaced by another one.

Short-circuit in Field Winding.—This renders a portion of the field winding inactive, decreasing the resistance of the same, and causes a greater field current to flow. This in turn may cause a circulating current to flow in the armature and hence a flow of current through the equalizer circuit to balance up the potentials. It may also cause an unbalancing of the current in the alternating current line, resulting in overheating of the armature and the equalizer rings. By means of a voltmeter, readings should be taken across the terminals of each field coil; the one giving the least drop in potential is the defective coil.

Poor Regulation

Compound-wound Converters with Reactances.—If the voltage on the direct current end is too low, a higher voltage is best obtained by changing the connections from the transformer secondary winding to a tap of higher potential. A failure to obtain regulation is usually caused by an open-circuit in the field system, in which case an excessive current is drawn from the alternating current side. It may also be caused by a short-circuit in the regulating rheostat, which would cause the direct current volts to be normally high. Trouble in obtaining a sufficient range of voltage control on a compound-wound converter with reactance coils can be corrected in two ways. The excitation produced by the series field may be increased by increasing the resistance of the shunt across the series field so as to make more current go through the latter. If no shunt is used the amount of reactance in the lines of the converter may be increased, as the amount of raising or lowering of the potential is proportional to the reactance in circuit over a given adjustment of the series field.

Shunt-wound Converters with Induction Regulators.—If satisfactory regulation is not obtained with this combination it may be due to a short-circuit of a portion of the series winding of the regulator or to an open-circuit in the primary winding. A short-circuit in the secondary or series winding would probably result in heating up and burning out of that winding, while an open-circuit in the primary would cause a heavy voltage drop across the regulator, and thus bring down the direct current voltage.

Sparking

Sparking at the commutator may be due to a number of causes similar to those described in the first installment under dynamo and motor troubles. The principal causes are: Distortion of field; reversed field coil; short-circuited coil in armature; open-circuit in armature; reversed armature coil; incorrect brush spacing; high bars in commutator; uneven air gaps.

Starting Troubles

Failure to start.—This may be caused by an open-circuit in one phase of the compensator or line, in which case the machine would be on single phase and thus unable to start. It may also result when too low a voltage is applied, the starting torque being proportional to the square of the applied voltage. To remedy, change connections to a higher voltage tap on the transformer. Excessive bearing friction may sometimes keep large machines from starting, especially if they have been standing still for a long time.

Excessive Starting Current.—It sometimes happens that when six-phase converters are started from the A. C. side an excessive current is drawn from the line in one phase. This may be due to a wrong connection, in that one phase of the machine would be 180 degrees out of phase with one of the line phases and would hence be on short-circuit. This would be indicated on the ammeters and the phase in which the heavy current is flowing should be reversed. If the supply voltage is too high an excessive starting current may result and it may be advisable to try out a lower voltage tap on the transformers.

Parallel Operation

In order that it be possible for two or more synchronous converters to operate satisfactorily in parallel and divide the load properly, it is necessary that they have the same voltage regulation from no-load to full-load. This can be obtained by changing the initial settings of the shunt field rheostat, by adjusting the series field shunt resistance and by inserting resistance in the equalizer connections where necessary. Synchronous converters operated in parallel should

not be connected to the same transformer secondaries. Such a connection would form a closed local circuit in which heavy cross currents would flow, when any difference in the operating conditions of the machine occurs, as, for example, when the brushes of one of the machines are slightly displaced relative to the other.

If for some reason, a short-circuit, for example, the alternating supply voltage should drop considerably, the synchronous converters operating on the system would not drop out of step, as the direct voltage and load would be correspondingly reduced. If other direct current generators or storage batteries were operating in parallel on the same system, however, these would tend to maintain the direct voltage and in such a case the direct current would reverse and flow toward the converters, running them as motors. Care should be taken in such cases, therefore, to provide the synchronous converters with proper speed limiting devices and reverse current circuit breakers.

Hunting

The most common reason for hunting is the variation in the angular velocity of the prime movers of the system. A sudden overload may come on the converter, or the frequency of the supply current may be increased due to a momentary increase in the speed of the prime mover. The current in the converter will increase and the position of the armature with respect to the field may be changed so as to produce a greater torque, which tends to increase the speed of the converter. As the armature has considerable weight, it will take some time for this to occur, and as the synchronizing force may have been more than sufficient to increase the speed corresponding to the frequency which existed at the time of the impulse, the armature will be pushed ahead of the synchronous position. While this is taking place, the angular velocity of the prime mover may drop, thus reducing the frequency and causing a still greater displacement of the armature. In this case the converter is sometimes ahead and sometimes behind the proper phase position and the speed is constantly fluctuating above and below the synchronous value. The remedy is obviously to make the rate of rotation of the prime mover more uniform by providing sufficient flywheel capacity. With the stipulation impressed upon the engine builders this case of hunting is not now so serious and does not exist when the alternators are turbine driven.

Hunting is also produced by a variation of the alternating supply voltage as caused, for example, by the drop due to a relatively high resistance and reactance in the line. This fluctuation in impressed voltage will react in the synchronous converter and, if the magnetic circuit is not very sensitive, causes a state of unstable equilibrium which leads to hunting. It is obvious that if the E. M. F. supplied to the armature varies suddenly the flux must also vary at the same relative position of the armature and field. If the magnetism is lagging, the armature must take a different position from what it would otherwise, thereby setting up a pulsation in speed and causing the converter to hunt.

Hunting will cause a shifting of the magnetic lines of force across the pole faces of the converter. At one instant the alternating current reaction will be too great and the lines will be crowded to one pole corner; then it will be weakened, and the direct current reaction will crowd the lines to the other corner. This causes a shifting of the lines of force across the interpolar space and produces sparking. In order to prevent this the armature teeth and the pole corners are generally worked at a high saturation, and dampening collars of copper are placed at the pole faces so that any incipient shifting of the field produces a powerful reaction. The collars consist of several copper rods placed in ducts in each pole face and short-circuited together at the ends by cross bars. A variable armature reaction can cause but slight distortion of the field and what shifting of the field takes place causes large currents to flow in the copper collars and these will at once prevent the distortion. With the copper rods placed in this manner, all of the currents induced are in a direction to produce useful results and no energy is unnecessarily lost.

HORSEPOWER OF CRANE MOTORS

BY R. H. CREVOISIE*

The following formula gives the horsepower of the motor required to give an electric overhead crane its longitudinal or bridge travel:

$$F = \frac{Lfd}{D}$$

$$\text{Horsepower} = \frac{FV}{33,000}$$

in which V = velocity of crane in feet per minute;
F = force of traction;
L = total load in pounds;
f = coefficient of friction = 0.08 to 0.12;
d = diameter of track wheel axle in inches;
D = diameter of track wheel in inches.

The pressure on the track wheel axle bearings should not exceed 500 pounds.

The use of these formulas will be better understood by showing their application to a practical problem. As an example, consider a 25-ton crane equipped with a 5-ton auxiliary hoist and having a span of 50 feet. Assume the load to be 50,000 pounds; weight of trolley, 24,000 pounds; weight of two girders, 25,000 pounds; weight of lineshaft, brackets and foot walk, 8000 pounds; weight of motor, 2000 pounds; and weight of end carriages, 6000 pounds. This makes the total load L 115,000 pounds.

Applying the formula for F, for a crane with track wheels 24 inches in diameter mounted on axles 5 inches in diameter:

$$F = \frac{115,000 \times 0.10 \times 5}{24} = 2396 \text{ pounds}$$

Substituting this value for F and assuming a speed of 250 feet per minute,

$$\text{Horsepower} = \frac{2396 \times 250}{33,000} = 18$$

A short method of finding the approximate diameter of the bridge shaft that is required to transmit this horsepower, is given by the following:

$$\text{Diameter of bridge shaft} = \frac{\text{H. P.} \times 120}{\text{R. P. M. of motor}}$$

To illustrate the use of this formula, assume the case of a crane in which the motor makes 575 revolutions per minute. The diameter of the shaft would then be found to be:

$$\text{Diameter of bridge shaft} = \frac{18 \times 120}{575} = 3\tfrac{3}{4} \text{ inches}$$

In designing a foot brake for this bridge, nine square inches of brake surface should be allowed for each horsepower required for the motor. The available brake surface is usually taken as three-quarters of the circumference of the brake wheel multiplied by its face width.

RISING PRICE OF PLATINUM

The cost of platinum is, at the present time, $670 a pound, as compared with $290 a pound five years ago. This great increase in price is due to the increased demand for platinum in the industries and for purposes of ornament while the production of platinum has increased but little. The world's total production of platinum during 1912 was, approximately, 21,500 pounds, which was practically the same as the production during 1911 and only 2000 pounds more than the production in 1910. Of the total annual production of platinum all but about 1000 pounds comes from Russia. Columbia produces nearly 1000 pounds per year. The imports of platinum into the United States in 1912 aggregated $4,503,682 in value. The total output of platinum from the United States during 1912 was only 50 pounds.

FORGING AND MACHINING AUTOMOBILE FRONT AXLES

METHODS OF THE WILLYS-OVERLAND CO. IN FORGING AND MACHINING FRONT AXLES MADE FROM SQUARE STOCK

There are several different methods employed in the forging of front axles for automobiles. The Ford front axle, as described in the article "Machine Forging—5" in the September number of MACHINERY, is made in one piece from a $1\frac{3}{8}$-inch round bar of vanadium steel. Another method, used especially for large axles, is to make them in two pieces welded in the center. The front axle to be described in the following is made from a $1\frac{1}{2}$-inch square bar of high-carbon steel. The use of any of these methods, of course, depends largely on the number of axles to be made and the facilities at the disposal of the manufacturer. Judging this proposition from an economical standpoint, it would seem that a one-piece front axle would be the easiest to make and would be superior to that made from two pieces welded together.

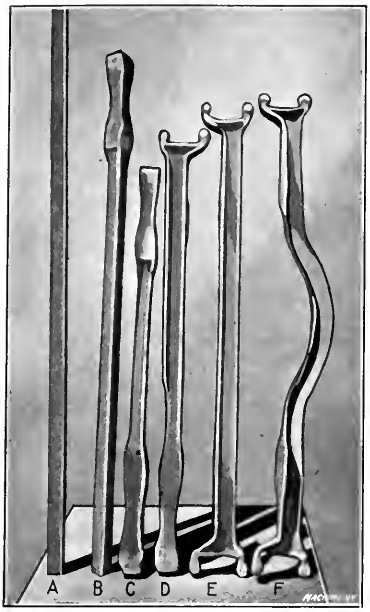

Fig. 1. Sequence of Forging Operations on Willys-Overland Front Axle

Upsetting the "Overland" Front Axle

The first operation on the front axle is to cut off a bar of high-carbon steel $1\frac{1}{2}$ inch square by 59 inches long as shown at *A* in Fig. 1. This is put in the furnace and heated on one end to a "white" heat. The next operation is performed in the four-inch Ajax upsetting and forging machine shown in Fig. 2, which is equipped with sliding dies of a type somewhat similar to those shown in Fig. 62 of the article previously mentioned. In this case, however, the impressions in the dies are made to suit the square stock, whereas in the other case a round bar was used. The method here described also differs in that the upsetting plunger does not rough-form the ends of the bar, but merely upsets two bosses as indicated at *B* in Fig. 1. The end of the bar is upset to form two bulges, which contain sufficient metal to form the axle ends and spring pads. The boss at the end is increased from $1\frac{1}{2}$ inch to $2\frac{1}{4}$ inches square, while the boss for the spring pads is increased from $1\frac{1}{2}$ inch to $2\frac{1}{2}$ inches square.

Forging under the Steam Hammer

After one end of the bar has been upset in the forging machine, it is thrown down in the sand to cool off, and the same operation is repeated on the batch of bars. After this the bars are again placed in the furnace and the other end upset in the same manner. The top impressions in the forging dies are used to rough-form the bosses, while the lower impressions bring them to the required size. Two blows are struck in each position. From the forging machine the upset bars are taken to the steam hammer shown to the left in Fig. 3.

It will be noticed by referring to *C* in Fig. 1 that the bar has not nearly reached the final shape of the axle and requires a considerable amount of drop-forging to bring it to shape. Two sets of dies are used roughing and finishing. The roughing dies are held in the steam hammer shown to

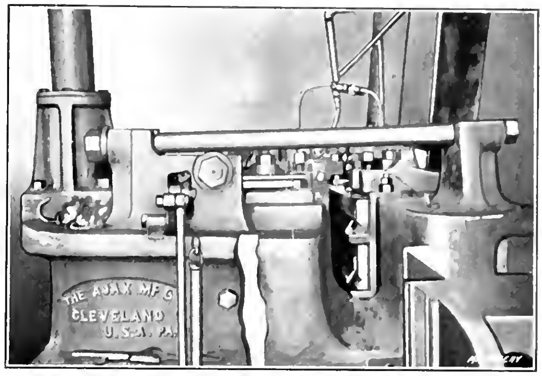

Fig. 2. Ajax Forging Machine used for upsetting the Ends of the Axle

the left in Fig. 3, while the finishing dies are shown set up in the hammer in the center of the engraving, and in the closer view, Fig. 4. The roughing dies only break down and rough-form one end of the front axle, these dies having two impressions. The breaking-down impressions in the dies simply "throw out the stock" into the desired positions, thus enabling the axle to be formed to the rough shape in the roughing die impressions. Two blows are struck with the breaking-down portion of the dies and seven blows in the roughing impressions.

The bar is now taken to the furnace, and upon reaching the proper heat is removed and placed under the finishing

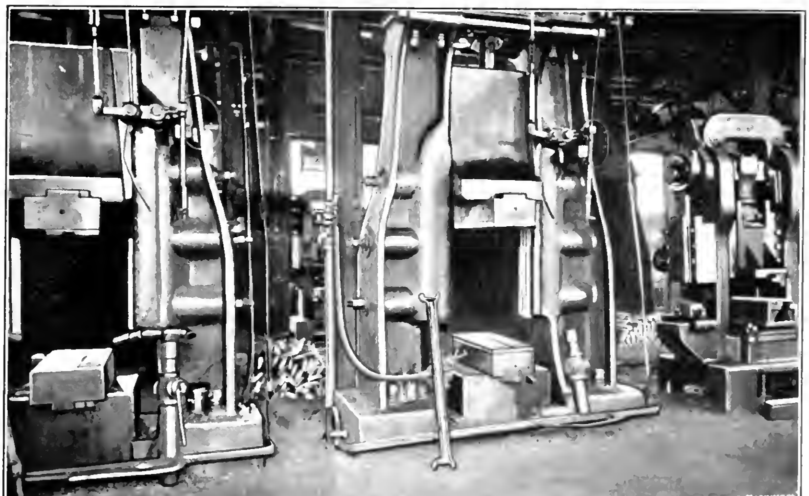

Fig. 3. Steam Hammers and Trimming Press used in performing the Final Forging Operations on the Axle

dies shown in Fig. 4. Here nine blows are struck, and as the axle is brought to its final shape a considerable amount of fin or flash is thrown out around the form. This is removed by the trimming punch and die shown to the extreme right of Fig. 3, which is held in a Toledo No. 57 punch press. After the fin has been removed, the forging is brought back to the same hammer and given a final blow. As shown at *D*

in Fig. 1, only half of the front axle is completed at a time. After one end of the axle has been formed, it is thrown down in the sand to cool off, and upon the completion of the batch the bars are again placed in the furnace and the other end handled in a manner similar to that described.

Stretching and Bending Automobile Front Axles

After both ends of the front axle have been forged, bringing the axle practically to its final shape, it is then placed in a furnace and heated for the final operation—stretching to the proper length and bending to shape. This is accomplished in the Toledo No. 56 punch press shown in Fig. 5, which is equipped with a stretching and bending die of interesting construction. The bending portion of this die consists of a base *A* fastened to the base of the press, in which two slides *B* and *C* are held. Fastened to the top of these slides are two brackets *D*, only one of which is shown, that serve to hold the front axle in position.

In operation, the front axle, after being heated in the center to the proper temperature, is placed between these projecting brackets *D*; then the wedges *E* are placed in the grooves formed in the axle and a square tapered wedge *F* is driven in on top of wedge *E*. This combination of wedges clamps the front axle rigidly in position, and as the ends bear against the outside projecting bosses of the brackets the axle is prevented from shifting when the stretching operation is taking place.

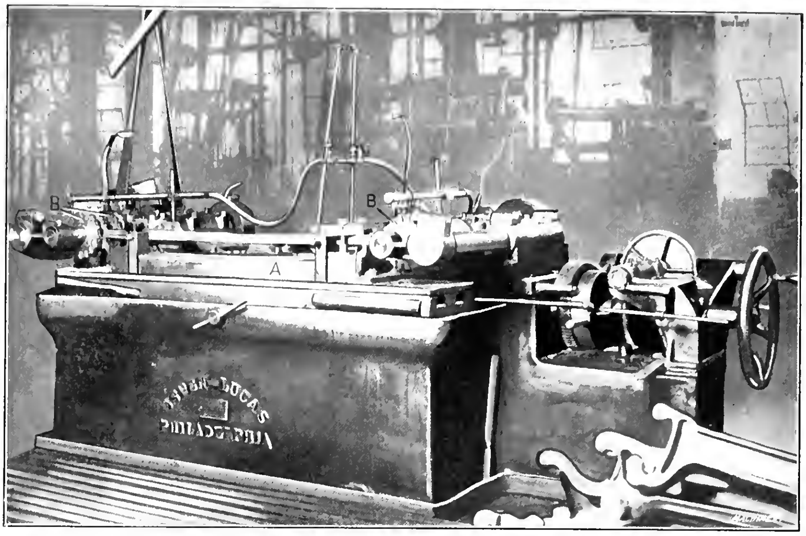

Fig. 6. Milling the Axle Ends in a Special Horizontal Milling Machine

The stretching operation is accomplished by a tapered

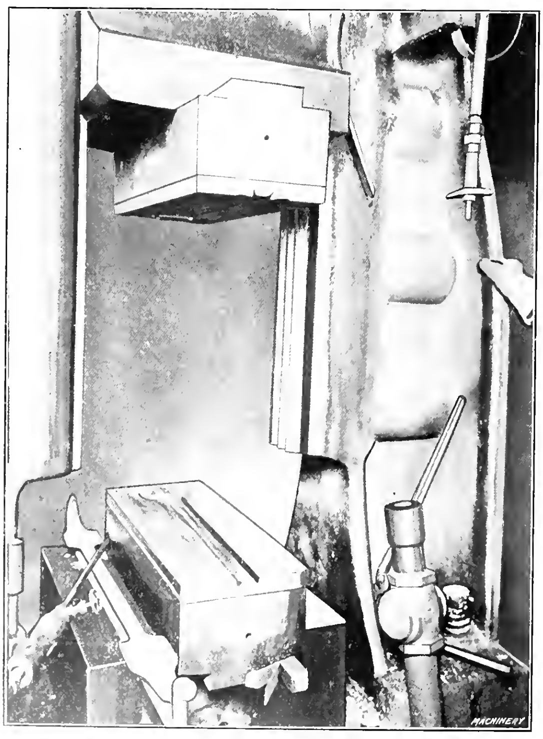

Fig. 4. The Final Drop-forging Dies

plunger *G* held in the ram of the press and operating between two rollers *H* and *I* which are held in projecting bosses formed on the two slides *B* and *C*. As the ram of the press descends, this tapered plunger comes in between the rollers, forcing the slides apart and stretching the axles to the required length. A maximum error of 1/16 inch is allowed in the length of the front axle. After stretching, the tapered wedges are knocked out and the axle removed and placed in the bending die *J* shown to the left. Here the axle is held in grooves formed in this die and is located by the stop *K*. The bending is accomplished by the impressions in the lower die in conjunction with the bending punch *L* held in the ram of the press. The condition of the front axle after this operation is shown at *F* in Fig. 1.

Milling Automobile Front Axles

Two milling operations are required on the front axle after

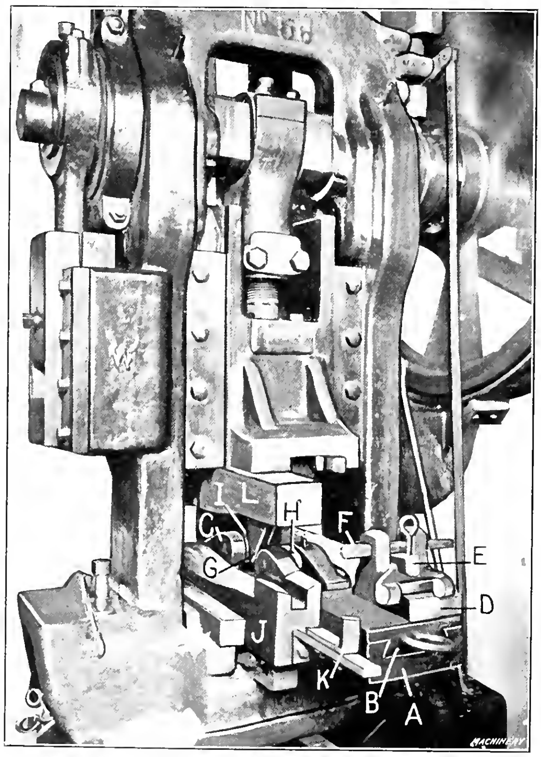

Fig. 5. Stretching and bending the Axle to its Final Length and Shape

it has been forged to the final shape—milling the ends and the spring pads. As the milling of the spring pads is a simple operation it will not be described here. The milling of the axle ends is accomplished in the Espen-Lucas horizontal

milling machine shown in Fig. 6. Two axles are held in the fixture A by set-screws and clamps. The milling of the ends is accomplished with eight inserted-tooth high-speed steel milling cutters B, which finish them in one cut. On an average 5/32 inch is removed from the surface of each axle end and 135 axles are completed in nine hours.

Drilling the Holes in the Spring Pads

After the spring pads have been milled, the ten holes for fastening the springs to the front axle and the two holes

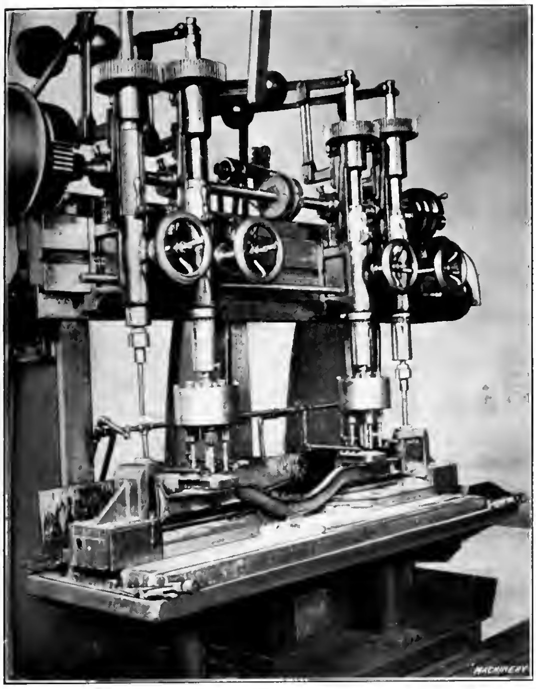

Fig. 7. Drilling and Reaming the Holes in the Axle Ends and Spring Pads

for the universal joints are drilled and reamed. This operation is accomplished in the Foote-Burt multiple-spindle drilling machine shown in Fig. 7, the twelve holes being completed in one setting. The ten holes for holding the springs to the spring pad are produced with the two-center drill heads, each of which carries four 15/32-inch and one 9/16-inch drill. The two end spindles carry 39/64-inch drills which produce the holes in the axle ends. These holes are also reamed with a 5/8-inch reamer after drilling. The axle, when being drilled is located from the ends by lugs and knurled nuts in the fixture shown. Fifty of these front axles are completed in nine hours.

THE SPEED KING

BY DONALD A. HAMPSON*

Conspicuous among a number of men hired during our busy season last fall was one Bud Cook of Philadelphia, who had been employed to run a boring machine in the locomotive works, but the water disagreed wtih him so that he had to leave the city. His tools and outfit had been delayed in transit but he had a four-inch scale in his pocket and thought that he could get along until Saturday, if we could lend him a few things.

Bud stated that he was a good "all-around man," and as the days went by he lived up to this estimate of his ability; he was at home on all classes of work, and what was even better, he was a rapid worker. Very few of the boys could set up a job on the boring mill, for instance, as quickly as he—he invariably had the first cut going. The apprentices dubbed him the "Speed King," and most of the men were secretly jealous of him, for although they tried to equal his production they always fell behind. When talking things over among themselves they were quite frank in making insinuations about the quality of Bud's work.

But Bud continued to make good. "My work speaks for itself," he would say, and after he had been in the shop for a month he looked like a real find—rapid, capable and willing—and he was trusted with many pieces of work of the class that usually goes to the old hands. It was along toward the second month Bud had been with us that a complaint came in about a job he had done. The slide he had fitted up on a punch press had worn loose in remarkably short order, but Bud promptly excused himself on the ground that he had done the work at night and might not have got a full bearing on account of the poor light. As a matter of fact, it looked as if he had scraped the entire bearing low and then fitted up a little 1/4 inch rim around the edge.

About a week later the cement mill 'phoned for a man to come down and look over a job that Bud had done a little while before. The work consisted of putting in a new slide on a pulverizer, and when the man who went to investigate returned he reported that the plate was held on by twelve head screws and the first step he had taken was to tighten up these screws, but an hour later the plate was loose again. An investigation showed that only five screws were holding it down, although twelve bright screw heads showed on the outside of the plate. Seven of these screws, however, were heads only, which Bud had ingeniously cut off and riveted on the reverse side of the plate. Six holes in the frame were filled by old screws which it would have been impossible to get out except by drilling, and the seventh hole contained the end of a new 1/2 inch tap.

Needless to say, Bud was fired for that little job in double-quick time. The cement people were too good customers for us to lose without showing that we meant to do the right thing by them. The climax came, however, the next morning. We had all the work we could handle and were making pretty good headway when the engine knocked out a cylinder head at about ten o'clock. Bud again. The Sunday previous he had been given the job of fitting new cylinder studs to replace the old ones which had become loose. The engineer reported that the job looked first-class, and although Bud had put in a time slip for twenty hours, it was O. K'd because he had done such a good job. Looking at the thing in the light of later experience, it appeared that when Bud took the cylinder head off, he found the studs were still tight in the cylinder, so removing them, he sized them down until they fitted nicely in new nuts, and also took particular pains to face off the nut end of each stud so that it looked like new. Then he replaced them in the cylinder in the reverse position, so that the worn ends went into the holes. By screwing the studs down until they bottomed, they appeared to be quite solid, but as may be readily imagined, it did not take many hours of running with the gage standing at 110, to tear those worn threads from their seats.

The "I-told-you-so" boys in the shop had a day of rejoicing and the stock of the slow men went up several points in the office. It was learned some time afterward that Bud had always been that way. A few weeks of hard conscientious work was all that his nature could stand, and then the spirit of unrest so got the better of him that he seldom stayed in the same place for more than a month or two before taking the short cut routes, to which his undoubted talent lent full aid. His ability had put him in a number of responsible positions, but the result was invariably the same, and Bud is probably even now wondering whether a north or south-bound freight will take him to a place where the water is better.

Sir Robert A. Hadfield, in a paper presented before the September meeting of the British Iron and Steel Institute, reports the results of experiments with a manganese steel whose heating and cooling curves do not show the characteristic points of recalescence and decalescence. Extensive experiments have been performed on this steel but in all cases no points of recalescence or decalescence showed in the heating and cooling curve.

THE USE OF HEAT-TREATED GEARS IN MACHINE TOOLS*

FROM THE STANDPOINT OF THE MACHINE TOOL MANUFACTURER

BY ANDREW C. GLEASON†

It is, of course, impossible to cover thoroughly such a broad subject as the heat treatment of gears, within the limits of this article, so only such points as are probably of interest to the average machine tool builder, will be considered.

At the outset, it should be explained that the methods of heat-treatment described here are those best suited to the requirements at the Gleason Works and it is not claimed that they represent general practice. In fact, it is rather hard to say what is the general practice, as the heat-treatment of steel gears is largely a matter of individual requirements. Methods vary considerably even among manufacturers of a certain class of automobile gears which are of a standard shape and designed for one purpose, so that hardened gears for machine tools may well be considered a distinct proposition. Looking at this subject from the viewpoint of the machine tool builder, the principal points to be considered are:

(1) The advantages to be gained by the use of heat-treated gears.

(2) The selection of steel to suit the purpose for which the gears are intended, and the design to suit hardening conditions.

(3) The methods of hardening and the necessary equipment and materials.

(4) The cost of heat-treated gears.

The advantages in the use of heat-treated gears properly made are greatly increased strength and hard tooth surfaces which resist wear. These points are certainly of vital importance in modern machine tool design, and it seems inevitable that hardened gears will very soon be in general use in this class of machinery. The failure of soft metal gears to stand the wear and tear in machine tools is too frequently the cause of breakdowns, and in spite of the rapid development in design in other ways such gears are still commonly used. They are a serious source of weakness and the logical remedy is heat-treated gears. Heat-treated gears with their increased strength and ability to withstand wear offer almost unlimited opportunity for compact design. For example, the automobile transmission suggests what can be accomplished with such gears in making machine tools more convenient in operation and more durable.

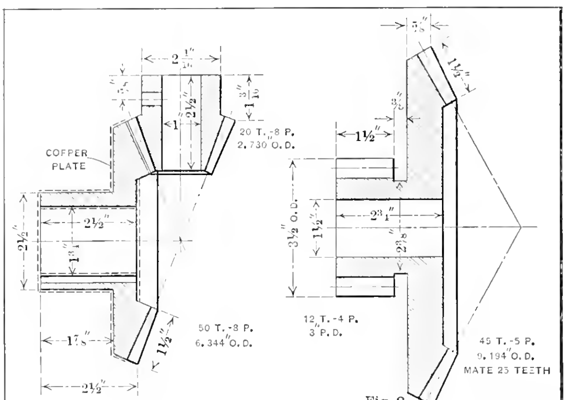

Fig. 1. Gear with Light Hub kept Soft by copper plating

Fig. 2. Gear having Small Pinion Integral with Hub

Steel to be Used

The question of the steel to be used depends not only upon the purpose for which the gears are intended but also upon the design. When the gears are subjected to severe shock or heavy overload at times, a steel which will show the greatest tensile strength possible, without sacrificing toughness, is plainly the most desirable; but steel which will show these qualities has certain limitations for use in machine tool construction, and it will be interesting to note the value of a straight tempering steel as compared with the more commonly used casehardening steels. Straight tempering steels for gears are invariably alloy stock and most of our experience has been with the chrome-nickel alloy. With several different makes of stock of this kind, we have found an increased tensile strength of 150 per cent after heat-treatment. The analysis varies considerably in different makes, requiring a corresponding difference in the heat-treatment, but manufacturers making a specialty of alloy steels now furnish them carefully graded with instructions for hardening which can generally be relied upon.

There are frequent exceptions, however, to the rules for hardening any kind of gear steel, and the only safe method is to experiment with every change in design. It is not sufficient to cut a piece off the bar and harden it, regardless of the shape of the gear being made, as the sample piece should be practically the same as the gear in order to produce the same effect. Take, for example, a pinion solid on a shaft. The teeth will chill much more quickly than the solid section under them, and in order to avoid shrinkage strains special heat-treatment is required to suit this shape and the quality of steel that is used. If a sample pinion of this size were made separate from the shaft, the effect of the same heat-treatment would be radically different owing to the fact that the center would cool almost as rapidly as the teeth.

Our experience leads us to recommend the use of as few grades of steel as possible. If the steel is selected to suit exactly each different shape of gear and the purpose for which it is intended, it would necessitate a large variety for the varied requirements of the machine tool builder. There are some steels which are more adaptable to different conditions in hardening than others, and considering the comparatively small quantities and the variety of sizes and shapes in gears for machine tools, it is well to keep this in mind. "Fool-proof" methods in the heat-treatment of gears, are far from possible, but by the selection of a few grades of steel which show good average results, the work can be greatly simplified.

Tempered vs. Casehardened Gears

On account of the great strength and toughness of chrome-nickel tempering steel and the fact that it hardens clear through, it is well adapted for automobile transmission gears and any similar purpose in the construction of machine tools. Gears of this kind do not chip on the edges of the teeth and will stand almost unlimited hardship in sliding in and out of mesh. Chrome-nickel tempering steels tend to keep their shape in hardening better than the low-carbon casehardening steels, but they do warp somewhat and they cannot be straightened without sacrificing the hardness almost entirely. Gears made of this stock do not show as hard a bearing on the surface of the teeth as those made of casehardened steel. The cost of machining alloy tempering steels will average at least twice as much as that of casehardening steels, and the cost of the steel itself varies from fourteen to sixteen cents per pound, as compared with less than half that price for high-grade alloy casehardening steels.

The chief advantage in the use of casehardened gears is the file-hard tooth surfaces. The easy machining qualities and low cost of the stock are also important advantages, but the superior wearing qualities of casehardened gears make them the best at any price for average conditions in machine tool construction. In designing a machine tool there may often be occasion to make the gears as small as possible and it then becomes a question as to the choice of tempered steel or alloy casehardening steel. The use of 5 per cent nickel low-carbon casehardening steel, will give the best results pos-

* Paper read before the National Machine Tool Builders' Association, New York City, October 23, 1913.

† Address: Gleason Works, Rochester, N. Y.

sible if strength and wearing qualities are considered, although if strength is the main consideration, tempering steels, as previously explained, should be the choice.

Of the alloy casehardening steels, we are more familiar with the three principal grades of nickel than any other. The writer believes that these have become standard to a large degree in the trade at the present time. These are 5 per cent open-hearth nickel alloy; $3\frac{1}{2}$ per cent open-hearth nickel; and 1 to $1\frac{1}{2}$ per cent nickel natural alloy. The principal characteristics of these steels are a higher tensile strength than straight-carbon steel, and a correspondingly higher strength after casehardening. The carbon case has a close bond with the core and is less likely to chip than the ordinary machinery steel. In fact, a number of manufacturers of the higher grade automobiles use the 5 per cent casehardening nickel steel in their change speed transmissions, where tempering steels might be regarded as more favorable.

When it comes to substituting casehardened gears for soft steel or cast-iron gears, in machine tools, it will generally be found that a straight-carbon casehardening steel will answer every requirement, and unless the original gears have been considerably overloaded the more expensive alloy steel gears would be an extravagance. In straight-carbon steels for casehardening, we recommend 0.15 to 0.25 per cent carbon. A lower degree of carbon than this is likely to produce a laminated case which will crack or chip under heavy pressure. Nickel alloy steel for carbonizing should not have over 0.20 per cent carbon; 0.10 to 0.20 per cent carbon suits us the best. The nickel alloy has practically the same effect in hardening as an increase in carbon of about ten points. We have found that 0.25 per cent carbon nickel alloy steel, casehardened, will generally harden clear through very much the same as a straight tempering steel.

The teeth of soft steel gears in machine tools seldom break or strip until they have worn quite thin, and our experience goes to show that durability is generally of more importance than excessive strength in gears of this kind. Casehardened steels show an increased tensile strength ranging from 30 per cent in standard carbon steel, to 75 per cent in high-grade nickel alloy steel. The straight-carbon casehardening steels are not as uniform in analysis as the alloy steels and we cannot always get the same degree of hardness in the case as with the higher grade steels. This is particularly noticeable in gears of heavy section hardened in oil, but it rarely happens that the hardness will drop as low as that of tempering steels.

Selective or Local Hardening of Gears

A strong point in favor of casehardening steels for machine tool gears is that certain parts can be kept soft readily where subsequent fitting is found desirable. Hub projections, web surfaces, etc., can be copper-plated or enamelled with various preparations so as to exclude the carbon in the carbonizing heat, leaving these parts soft for final machining operations. Present-day design of casehardened gears for machine tools often makes it necessary to keep certain parts soft in order to avoid shrinkage strains in the hardening process. In a gear with light hub projections, as shown in Fig. 1, the carbon case would extend almost through the thin section of the hub at the keyseat, making it quite likely to crack on account of the uneven shrinkage in hardening. We advise making gears for hardening of even section throughout, but where it is necessary to use light hub projections like the one shown, they can be made safely by the method of selective hardening.

In selective hardening, we have found that copper-plating the surfaces which are to be kept soft is the most satisfactory method. Generally the parts to be plated can be immersed in the solution, leaving the teeth clear, or the blank can be copper-plated all over, so that when the teeth are cut the bearing surfaces will be free to carbonize. It should be borne in mind that wherever this plated surface is marred, carbon will enter and leave a hard spot after the gears are hardened.

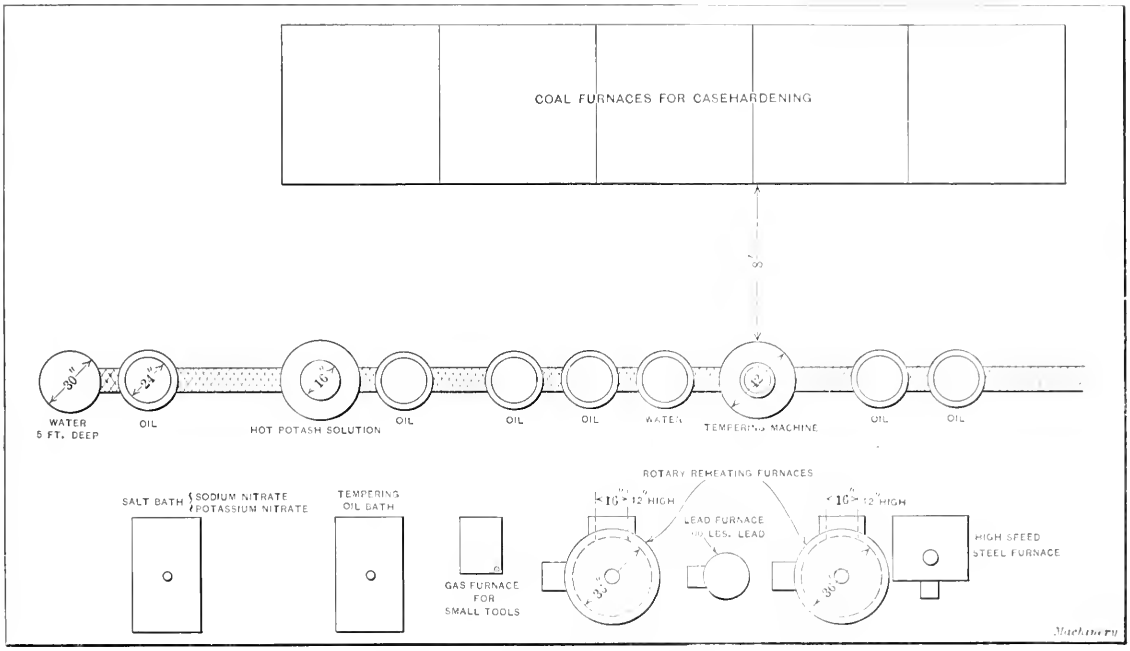

Fig. 3. Plan of Gear Hardening Department—Gleason Works

Some Points in Gear Design

Other points for criticism in the design of the pair of gears shown in Fig. 1 are the extremely long face in proportion to the cone distance and the long backing or overhang of the pinion on its bearing. The chances are all against getting a full bearing of the teeth throughout the length of face, after the gears are hardened and the bores are ground to size. We would advise cutting down the length of face to not more than one-third of the cone distance and using a coarser pitch with a smaller number of teeth for the same diameters.

Another condition which it is necessary to guard against in gears of this kind occurs where a small pinion is made solid with the gear in place of the light hub, as shown in Fig. 2. There would be still greater risk on account of shrinkage strains in hardening this piece. The pinion section would be weak when worked out of the center of bar steel and it would be far better to make it separate from the gear.

All established rules for the horsepower transmitted by gears, as far as I know, are based on the use of soft steel or cast iron. They usually allow a stress for steel of two and one-half times that of cast iron. This may be correct as far as strength is concerned, but it certainly is not right if wear is to be taken into account. We have found that gears of a good mixture of cast iron showing 35 to 40 on the scleroscope test for hardness will withstand wear fully as well as open-hearth cast-steel gears of the same size. Consequently, we have compromised on one-half this difference in stress for steel, making it one and one-quarter instead of two and one-half times that for cast iron.

This brings up the subject again of wearing qualities of casehardened steel gears as compared with soft gears. We have equipped a number of electric motor drives with casehardened gears, making them very much smaller than the soft steel gears formerly used, with most satisfactory results, and judging by these records, we recommend a stress of four times the usual standard allowed for cast iron in standard horsepower rules such as the Lewis formula.

For example, in a 30 horsepower electric drive in connection with a positive pressure blower which we have in use, the original soft steel gears, computed according to our standard rule for horsepower, required a pair of gears having, respectively, 49 and 16 teeth, of 3 diametral pitch, 3¼ inch face, and the casehardened steel gears which have been in use now for several years have 49 and 16 teeth, of 4 diametral pitch and 2¼ inch face. We consider that this rating (four times greater than cast iron) is conservative, as the gears which we have based our calculations on are considerably larger than automobile bevel driving gears transmitting more power. As evidence of the advantage of casehardened gears over alloyed tempered steel gears, we may cite the standard automobile practice in bevel driving gears. I do not know of a single exception to the rule that automobile manufacturers use only casehardened steels for such bevel driving gears at the present time. Their requirements, as is well known, call for the greatest possible combined durability and strength.

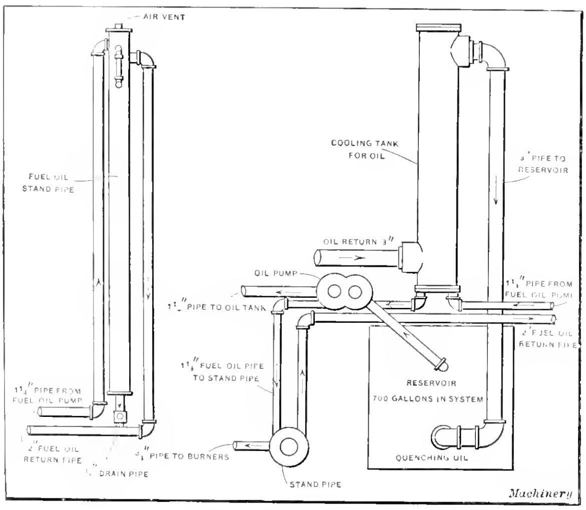

Fig. 4. Diagram showing Quenching Oil Reservoir and Cooling Apparatus

We recommend quenching casehardened gears at the lowest heat possible to produce the required degree of hardness; this in combination with slow carbonizing heats gives excellent results with one quenching heat. In the use of steels suitable for casehardening, we strongly advise against drawing after hardening. We find that casehardening steels allow of a much wider range in the heat-treatment than tempering steels, and we consider casehardened gears the best for general purposes in machine tools, "clash gears" excepted.

Equipment for Heat-treating Gears

We are using coal-burning furnaces for carbonizing in preference to oil or gas (see plan of heat-treating department, Fig. 3). For continuous use with the slow soaking heats which we recommend, we find coal to be the most economical, and with very little attention to the fires, there is no difficulty in maintaining and controlling the heat. The fact that the coal-burning furnaces require practically no attention when run after working hours, and that no power is required for air pressure such as is necessary in the oil or gas burners, is an argument in their favor; the very low cost of fuel is also an important consideration. Furnaces of this kind, however, must be used continuously, day after day, to produce the best results, since it requires about twenty-four hours

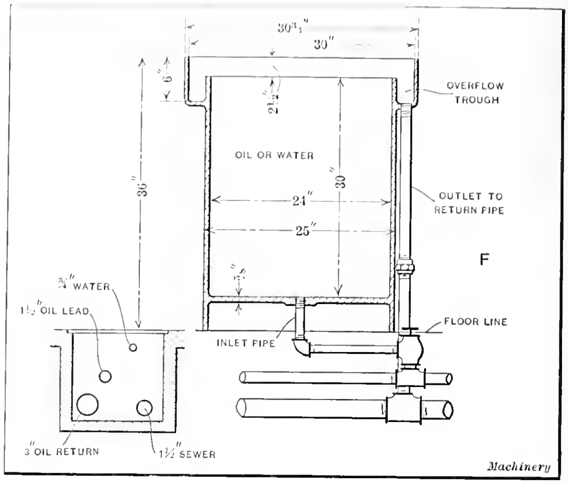

Fig. 5. Oil or Water Quenching Tank

from the start, to bring them up to a carbonizing heat. On the other hand, there is no delay whatever in getting the required heat with oil or gas, and where there is not sufficient work to keep a furnace running continuously, the oil or gas furnace would undoubtedly prove the most satisfactory. An oil or gas furnace is necessary in any case for reheating, so that the same furnace can often be used to advantage on carbonizing as well. Aside from the cost of fuel, the objections we have to the use of oil or gas for carbonizing gears, are that furnaces of this kind require constant attendance when run after working hours and that extra power is needed for air pressure in the burners. There is always the danger of an interrupted flow of the gas or air to be guarded against.

Most of our work requires the use of large carbonizing boxes and these naturally require a longer heat to penetrate than smaller sizes. In regard to the depth of carbon case in gears, we recommend ⅛ the thickness of teeth at the pitch line, and not more than 1/16 inch deep in the coarsest pitches in machine tools. According to this rule, ½ inch pitch should have 1/32 inch carbon case.

At the present time, there are several makes of carbonizing compounds extensively used which have proved much more satisfactory than bone or charred leather. Care must be taken to keep these compounds perfectly dry, not only in the packing of the boxes but also after they are taken out to cool; if any water is allowed to leak in when the material is hot, a chemical action sets up which has the effect of blistering the casehardened surfaces of the gears, the same as if they were overheated. Short pieces of common machinery steel about ½ inch square are generally placed in the top of the boxes for test pieces, and before the work is taken out of the box these pieces should be hardened and broken to make sure that the depth of case is right.

It is a well known fact that nickel alloy steels require a longer carbonizing heat than straight-carbon steel, and in order to determine the proper depth of case, test pieces of the same material should be used with the plain carbon steel test pieces so as to make a proper comparison. We find that it does not pay to use plain cast-iron carbonizing boxes. Semi-steel is better and cast steel is the best.

We use mineral oil for quenching which has a 310-degree

flash test and viscosity of 74 inches at 104 degrees. It is a thin petroleum oil which can be bought for 17 cents per gallon by the barrel. With tempering oils like this we find that a safe rule is to quench one pound of steel to a gallon, every four hours, where no special arrangements are made for cooling the oil. With our cooling system, Fig. 4, we are able to quench 3000 pounds of steel in eight hours with 700 gallons of oil. The tempering oil, as shown, is circulated through the inside of a radiator and we circulate our fuel oil through the outer jacket. The radiator is simply a powerhouse water heater which is adapted for this purpose without change. We use the fuel oil for cooling because of its convenience. Greater efficiency, of course, could be obtained by having a flow of water for the purpose or by increasing the radiating surface. Our radiator has thirty feet of cooling surface. We have never had any difficulty with overheating of the oil with this system, no matter how fast the work is put through; occasionally the temperature is as high as 120 degrees but never any higher. Quenching can be done about twice as fast as without the cooling system.

Cost of Heat-treated Gears

In leading up to the final cost of heat-treated gears, we submit herewith an itemized form—our actual cost of labor and materials in the heat-treatment of chrome-nickel tempering steels as compared with casehardening in general.

Cost data for 1000 pounds of gears made of chrome-nickel tempering steel:

Labor (one working foreman and two assistants, wages)	$ 9.85
Fuel oil (two hardening furnaces, 60 gallons)	3.00
Quenching oil, 1½ gallon	0.25
Tempering oil, 2 gallons	0.50
Pyrometer ends	0.10
Gas for drawing temper, 1500 cu. ft	1.45
	$15.15

$\$15.15 \div 1000 = \$0.0152$ per pound

Cost data for 1000 pounds of casehardened gears:

Labor (one working foreman and two assistants, wages)	$ 9.85
Coal (3 furnaces, 200 pounds each)	2.00
Carbonizing compound	1.00
Fuel oil (two hardening furnaces, 60 gallons)	3.00
Quenching oil, 1½ gallon	0.25
Pyrometer ends	0.25
Carbonizing boxes (average)	2.50
Wear and tear on 3 carbonizing furnaces	0.30
	$19.15

$19.15 \div 1000 = \$0.0192$ per pound

No account was made of the cost of power or other overhead expenses as they are the same in either case.

Following is a tabulated account of the actual cost of labor and materials in making up a small lot of miter gears complete from bar stock using the various grades of steel referred to:

Taking a miter gear having 18 teeth of 4 pitch, 1⅛ inch face, 1½ inch bore and an ordinary hub, the weight of the rough bar stock is 11 pounds and the finished gear, 5½ pounds. Our labor cost for machine work would be practically the same for this gear, in any of the standard steels for carbonizing. The only difference in the complete cost would be in the stock. According to this, and taking the labor cost at $1, the cost of the gear complete would be as follows:

Straight carbon steel at 3 cents	$1.44
1 to 1½ per cent natural alloy steel at 4½ cents	1.61
3½ per cent O. H. nickel steel at 6 cents	1.77
5 per cent O. H. nickel steel at 8 cents	1.99
Our labor cost for machine work of the gear in chrome-nickel crucible tempering steel, would be	2.00
Heat-treatment	0.09
11 pounds at 15 cents	1.65
	$3.74

We have found the cost of machine work practically the same in either casehardening straight-carbon steel or any of the nickel alloy casehardening stock. Heat-treated gears in machine tools are on the side of superior quality and greatest efficiency; therefore, they represent the standard and aim of American manufacturers. It is safe to say that within the next few years, soft steel gears in machine tools will become a thing of the past, just as gears with cast teeth were abandoned twenty years ago.

* * *

GRINDING THE FACES OF POLE-PIECES

In making electrical instruments, the Weston Electrical Instrument Co., of Newark, N. J., has large numbers of small cast-iron pole-pieces to be machined. It is essential that the outside dimensions of these pieces be finished perfectly square and true, and they must all be accurate to size. One of the pole-pieces is shown full size in Fig. 1. The machine used for doing this work is the Blanchard vertical surface grinder. The pole-piece castings are held upon the magnetic table about 150 at a time, as illustrated in Fig. 2, being placed in regular rows with finished parallel strips between them. After one face of each of the blocks has been ground, the blocks are reversed, and the opposite faces finished exactly to the size required. The grinding is facilitated by means of the continuous reading caliper with which the Blanchard machine is equipped—this may be seen directly over the work-table in Fig. 2. After two faces have been finished, the pieces are turned so that the finished surfaces come in contact with the sides of the parallel strips. The strips are then firmly pressed together, and a second set of faces ground. Similarly, the third pair of faces is finished, leaving the pieces perfectly square and finished to size. C. L. L.

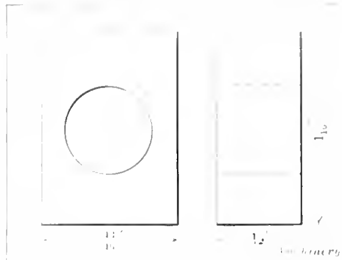

Fig. 1. The Pole-piece (shown Full Size)

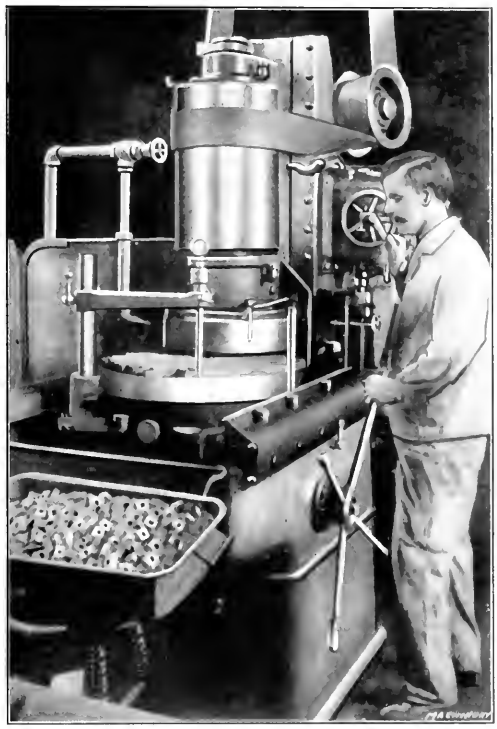

Fig. 2. Grinding the Faces 150 at a Time

Lots of purchasing agents make a good showing by saving a few cents a gallon on oil. The wearing out of the journals of costly machines is not charged on that side of the ledger.

THE USE OF HEAT-TREATED GEARS IN MACHINE TOOLS*

FROM THE STANDPOINT OF THE MATERIAL MANUFACTURER

BY J. HEBER PARKER†

In the earlier days of machine tool construction, when carbon tool steel was used for cutting, and relatively light work was the order of the day, cast-iron gears were used for transmitting power. With the advent of air-hardening tool steel and heavier work, the use of mild steel gears became necessary, while to-day, with tools of modern high-speed steel the use of heat-treated alloy steel gears is well nigh imperative. Gears of this last class may be divided into two general groups—casehardened gears, with a low-carbon soft center or core and a high-carbon hard exterior or case, and tempered gears which are of the same composition and hardness throughout. The characteristics, heat-treatments and merits of these two groups, as viewed in the light of a fairly wide experience with gears used in motor-car construction, will be discussed briefly in the following:

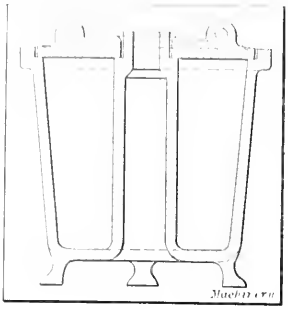

Fig. 1. Cored Pot or Box for casehardening

Casehardened Gears

Case-carbonized gears may be made from four general classes of steel, *viz.*, straight-carbon, nickel, chrome-vanadium and chrome-nickel steel, and of each of these classes several modifications will be found in the market. On the whole, the steels containing chromium are to be preferred, for they are freer from the tendency to lamination shown in nickel-steel (especially 3½ per cent nickel steel) and they also absorb carbon more easily, thereby lessening the length of time and expense of carbonizing. Before carbonizing, the carbon content of each of the steels mentioned, should be about 0.20 per cent, and never more than 0.25 per cent, to avoid brittleness in the teeth. The carbon in the case should be raised to about 0.90 per cent, which can readily be done by the proper selection of carbonizing material and by using the proper temperature for carbonizing.

The temperature for carbonizing, in general, should be about 1600 to 1650 degrees F. for all the classes of steel previously referred to. Lower temperatures do not give sufficient depth of "case," unless the heating operation is much prolonged. On the other hand, higher temperatures result in a case of excessive carbon content and in a core of such large grain-size that it will not respond to the subsequent heat-treatment as readily as if a temperature of 1600 to 1650 degrees had been used.

The heat-treatment after case-carbonizing is the most important part of the process, and upon it depends the physical properties of the finished work. As already stated, after carbonizing we have a piece of steel with a 0.20 per cent carbon core, and a 0.90 per cent carbon case, and the object of the treatment is to put both the core and the case into the best possible physical condition. Both need refining to correct the large-grained structure developed by subjecting the steel for many hours to the carbonizing temperature. Since the refining or hardening temperature of the core is about 200 degrees F. above that of the case, this difference determines the most approved method of heat-treatment.

The old method consisted in quenching the piece in oil or water at the end of the carbonizing operation, right from the box, at the temperature used for carbonizing. This resulted in a large-grained core that was neither strong nor tough, and an overheated granular case which was hard, but which would not stand up in service any better than an overheated piece of tool steel. The first improvement on this old method was to allow the piece to cool in the box after it was removed from the carbonizing furnace, and then to re-heat it to the proper temperature for hardening the case and quench in a suitable fluid. This procedure, however, did not develop a strong tough core.

The proper heat-treatment for casehardening gears is the so-called double treatment by which the pieces are first allowed to cool in the box after carbonizing, next re-heated to 1550 to 1625 degrees F. and quenched in a suitable medium to refine the core, then re-heated to 1350 degrees to 1425 degrees F. and again quenched in a suitable medium to harden the case, and finally drawn in oil at not above 400 degrees F. to further increase the strength and toughness of the casehardened gear. The temperatures given are approximate only; for exact information concerning any particular steel, the user should consult the steel-maker.

There are many case-carbonizing compounds on the market and most of them have some merit. Those of bone are probably the least desirable owing to their lack of uniformity which results in uneven carbonizing. The most desirable are those consisting of definite mixtures of carbon and carbonates; they carbonize uniformly, and most of them can be used repeatedly without losing their power of giving up carbon to the metal.

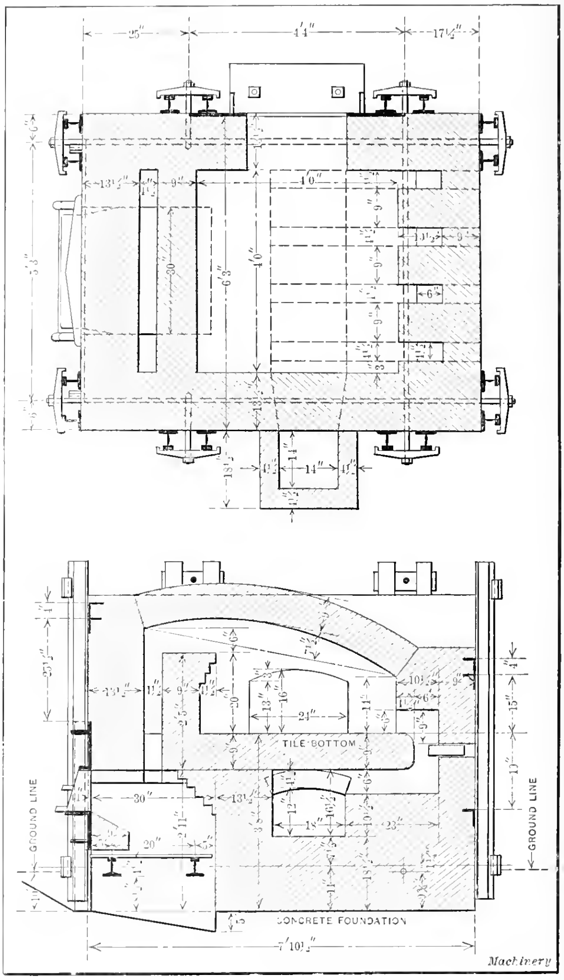

Fig. 2. Coal or Coke Furnace for heat-treating Gears

* Paper read before the National Machine Tool Builders' Association, New York City, October 23, 1913.

† Metallurgist, Carpenter Steel Co., Reading, Pa.

The wear and tear on carbonizing furnaces, the fuel consumed, and the expense of the boxes are three important items in the cost of casehardening. In many cases it is possible to reduce all these items by the use of a cored instead of a solid box, as shown in Fig 1. The proportion, of course, will vary with the work to be done, but if the general idea is worked out for each specific instance, it will be found not only that the cost of carbonizing is diminished, but also that the carbonizing is more uniform.

Tempered Gears

Unlike casehardened gears, tempered gears are of uniform carbon content throughout, and, when hardened, have a uniform hardness throughout the tooth-section. The steels used for tempered gears are of three general classes, *viz.*, silico-manganese, chrome-vanadium and chrome-nickel steel—the last-named, in its several modifications, being by far the most used. The carbon content varies for the different classes from 0.40 per cent to 0.60 per cent. The heat-treatment of all these steels is very simple, consisting merely in heating the gear slowly and uniformly to the hardening temperature, which is usually about 1500 degrees F., quenching in oil, and afterward drawing in an oil bath. The result is strong, tough, dense-grained steel gears; these have been used with marked success in motor-car work, and are fast replacing soft steel and casehardened gears in machine-tool construction.

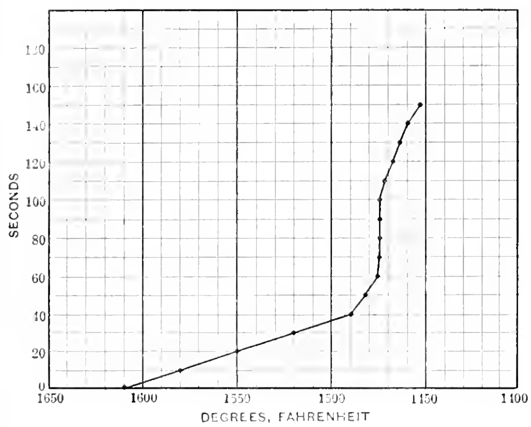

Fig. 3. Diagram showing Calibration of a Pyrometer which is Correct

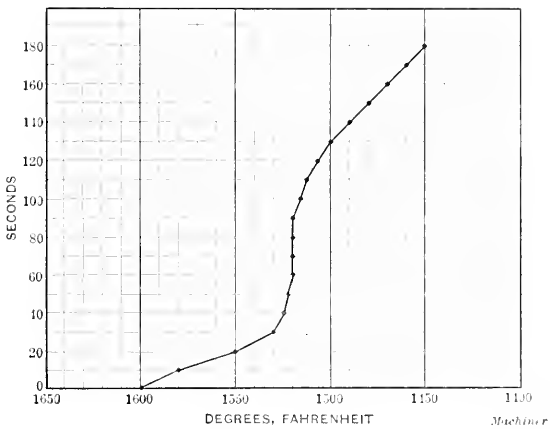

Fig. 4. Diagram showing Calibration which gives Readings too High

Viewed from the standpoint of physical properties in the finished gear, the evolution in gear material from cast iron to tempered steel, may be seen in the following figures:

Material	Elastic Limit pounds per sq. in.	Hardness— Scleroscope	Toughness Guillery Impact Kilogrammeter.
Cast iron	20,000	25	Negligible
Soft steel	40,000	35	2
Casehardened steel; (Average test of alloy steel)	120,000	35	2.5
Tempered steel; (Average test of alloy steel)	225,000	75	5

Tempered vs. Casehardened Gears

For machine tools, tempered alloy-steel gears appear to be preferable to casehardened gears for a number of reasons:

(1) Physically they are stronger and tougher and should therefore be better able to resist sudden impacts and extraordinary loads. Tempered gears do not show by file and scleroscope test the same degree of hardness as casehardened gears, but, nevertheless, with proper design, the dense-grained tempered gear-tooth resists wear most satisfactorily, as was demonstrated recently by the examination of a motor-car transmission that had covered over 100,000 miles. The tempered gears in this car still showed the original tool-marks. Not long ago a designer of machine tools commented on the apparent softness of some tempered gears, but found after several months of hard service that they still showed tool-marks, thus proving hardness ample for wear.

(2) In service, especially for "clash gears," the superiority of tempered gears is most marked. On the clashing faces, casehardened gears are likely to have the hard case chipped off, thereby exposing the soft core to the impact of clashing The hard chips fall into the gearing and may find their way into bearings, thus causing trouble. Tempered gears with a uniform hardness throughout do not chip, nor do they "dub over."

(3) The heat-treatment of tempered gears is much simpler than that required for proper casehardening. It is shorter, less costly and produces a more uniform product, and as the gear is heated but once for hardening, as compared with three times for casehardening, the finished gear is certain to be freer from warpage. The cost of proper casehard-ning is not generally appreciated, but it has been found that a casehardening steel must cost three to four cents per pound less than a tempering steel, if finished gears made from both materials are to cost the same.

With all heat-treated gears, little points in design are important. The gear-teeth should not be undercut, for if the section at the root-line is smaller than at the pitch-line, greater hardness and brittleness is produced where least desired. Great differences in section should be avoided wherever possible, so as to do away with excessive warpage. Sharp edges and angles, even in keyways, are the cause of internal hardening strains which frequently result in failures; hence wherever possible a fillet should be used in place of a sharp angle.

Furnace for Heat-treating Gears

When heat-treated gears are suggested to the machine-tool builder as a remedy for some of his troubles, and as a means of eliminating an excessive item for replacements and repairs, one of his first questions naturally is, of what does a heat-treating equipment consist? Usually the second question is, what will it cost? The first item in equipment is a furnace. There are offered for sale a number of types of gas-and-oil-fired furnaces, but few are located in natural gas districts, and the price of fuel-oil has almost driven the oil-fired furnace from economic use. Coal and coke, however, are available everywhere, and a furnace using fuel of this kind is shown in Fig. 2. Anthracite, bituminous coal, and coke work equally well. When bituminous coal is used, the consumption with ordinary firing should not exceed 500 pounds in a twenty-four hour day. The cost depends somewhat upon the price of labor, but should not exceed $300.

Quenching Baths

The next item is a proper quenching medium. Running water with a suitable tank is always necessary in a hardening room. To take the chill from the water in winter, or to

raise the temperature a little at any time, a jet of live steam in the incoming water pipe will be found very convenient. The heat-treatment of alloy gear steels requires an oil bath, the size of which depends entirely upon the amount of work to be quenched and the facilities for keeping the oil cool. The kind of oil best suited for oil-hardening was the subject of an investigation conducted by the laboratory of the Carpenter Steel Co., with the following results, comparison being made with water as a standard:

Hardening Medium	Hardening Quality
Water	1.000
Mineral No. 1	0.2409
Mineral No. 10	0.2304
Corn	0.1927
Mineral No. 2	0.1607
Cotton-seed	0.1606
Fish	0.1490
Rosin	0.1350

For hardening, several of the mineral oils are more effective than fish and cotton-seed oils, which for a long time were looked upon as the best oils for this purpose. Mineral oil No. 1 has a specific gravity of 0.860, a flash point of 420 degrees F., and a viscosity of 170 seconds at 100 degrees F., as shown by the Saybold viscosimeter. A mineral oil to this specification can be bought very cheaply.

Oil can be cooled by blowing cold air through it, or by pumping the oil through a coil of pipe immersed in cold running water, thus maintaining a circulatory system which admits cool oil at the bottom of the hardening tank and pumps the warm oil from the top through cooling coils back to the bottom. When air is used, care should be taken to avoid an excess during the quenching of a piece, for if air instead of oil were to strike the piece constantly uneven hardening might result.

Drawing or Tempering Bath

The next equipment item is a drawing bath. This may consist of oil, lead, or a combination of salts, contained in a cast-iron or steel vessel. The container is usually of very simple design and may be fired by gas, oil or coal. The oil should be a mineral oil with a flash point of not less than 600 degrees F., this temperature usually being sufficient for all temper-drawing purposes. If higher temperatures are desired, a mixture of two parts potassium nitrate and three parts sodium nitrate may be used. This mixture melts at 450 degrees F. and may be used for temperatures up to 1000 degrees F., or lead, which melts at 630 degrees, may be substituted. To indicate the temperature of the bath, a mercury thermometer should be used rather than a pyrometer, for most pyrometers will show considerable error at drawing temperatures under 800 degrees F.

Application and Calibration of Pyrometers

The last item is a pyrometer. There are a number of good thermo-electric pyrometers on the market, and more depends upon the care of the instrument than upon the selection of any particular make. Following are a few rules for the use of the pyrometer and a simple method of calibration:

(1) Keep the hot end of the thermo-couple as near the work as possible; do not put it through the furnace wall or roof, exposing the end to the direct heat of the flame, but place it so that it will attain, as nearly as possible, the same temperature as the work.

(2) Keep the cold end of the thermo-couple protected from the direct or radiating heat of the furnace; that is, keep it cool.

(3) Protect the volt-meter by a dust-proof case, and place it on a support free from vibration.

(4) All switches should be of the wiping-knife type. Improper contact at the switches is a prolific source of error, and such errors are not readily located.

(5) Carefully check all thermo-couples as soon as they are received from the manufacturer and before putting them into service. Adhere closely to this rule, instead of assuming that new thermo-couples are sure to be correct. New thermo-couples should not be used in blind faith for checking, since they occasionally show a considerable error, and any one making use of them as standards will sooner or later come to grief.

(6) Carefully standardize each pyrometer at definitely stated intervals—at least once a week, and as much oftener as possible. Frequent calibration is a matter not of convenience, but of necessity.

How can the calibration of a pyrometer be accomplished readily and accurately without the use of an extensive laboratory equipment? To this question of immediate interest in every hardening-room, the answer is that the easiest and most convenient method is based upon determining the melting point of common table salt (sodium chloride). Chemically pure salt, which is neither expensive nor difficult to procure, should be used where accuracy is desired. The salt is melted in a *clean* crucible of fire-clay, iron or nickel, either in a furnace or over a forge fire, and is then further heated until a temperature of about 875 degrees to 900 degrees C. (1607 to 1652 degrees F.) is attained. It is essential that this crucible be clean, because a slight admixture of a foreign substance might noticeably lower or raise the melting point. The thermo-couple to be calibrated is then removed from its protecting tube and it s hot end is immersed in the salt bath. When this end has reached the temperature of the bath, the crucible is removed from the source of heat and allowed to cool, and cooling readings are taken every ten seconds on the volt-meter. A curve is then plotted by using time and temperature as coordinates, and the temperature of the melting point of salt, as indicated by this particular thermo-couple, is noted at the point where the temperature of the bath remains temporarily constant while the salt is freezing. The length of time during which the temperature is stationary depends on the size of the bath and the rate of cooling, and is not a factor in the calibration. The true melting point of salt is 801 degrees C. (1474 degrees F.), and the needed correction for the instrument under observation can be readily applied. The accompanying curves (Figs. 3 and 4) illustrate the calibration of a correct and incorrect pyrometer.

Cost of Equipment

The cost of this equipment, including a coal-fired furnace, as shown in Fig. 2, five to seven barrels of hardening oil, one barrel of drawing oil, the tanks for holding these oils and a pyrometer, should be about $500 to $600. The equipment just noted is the one necessary for tempered gears. When case-hardened gears are heat-treated, there is necessary, in addition to this, case-carbonizing boxes and carbonizing compound. A second furnace may also be necessary, depending upon the quantity of casehardened gears to be treated. It is thus seen that for casehardened gears, the heat-treating equipment is more expensive than that required for tempered gears.

Heat-treated gears are bound to appeal to the progressive machine-tool builder. They will make possible the use of gears of smaller section, and while this may not be necessary from the standpoint of weight, as is the case with the motor-car builder, an economy of space is frequently desirable. Their greatest advantage is the elimination of repairs and replacements. In an interview with a machine-tool builder not long ago, the fact was developed that about fifteen per cent of his productive capacity was taken up in the making of repairs and replacing parts. This is a condition which is neither economic nor desirable in view of the commercial alloy steels now on the market, the heat-treatment of which is extremely simple.

* * *

In a paper read before the September meeting of the British Iron & Steel Institute, F. Rogers takes exception to the common assertion that machine members and other parts of iron or steel have broken as the result of becoming "crystallized through fatigue." The writer has made an extensive study of this subject and reached the conclusion that seldom, if ever, does the structure of the metal become more coarsely crystallized as the result of a load applied intermittently. It appears probable that this idea has arisen from the fact that the fracture of test samples subjected to fatigue tests are frequently of a crystalline character, but an examination would generally show that this crystalline structure is no more pronounced at the point of fracture than it would be at other points in the bar which were not subjected to fatigue.

"STELLITE" AS A CUTTING TOOL*

CHARACTERISTICS THAT MAKE IT HIGHLY EFFICIENT AS A CUTTING TOOL FOR HIGH-SPEED WORK

BY DOUGLAS T. HAMILTON†

One of the characteristics of "stellite," the new alloy for metal cutting tools invented by Elwood Haynes of Kokomo, Ind., is that it cannot be forged but must be cast or ground to the required shape. This characteristic, instead of being a disadvantage, is one that causes the alloy to excel the ordinary high-speed steel as a cutting tool. If it could be forged it would become soft when heated to a high temperature in operating on the work, and hence would lose its keen edge. As

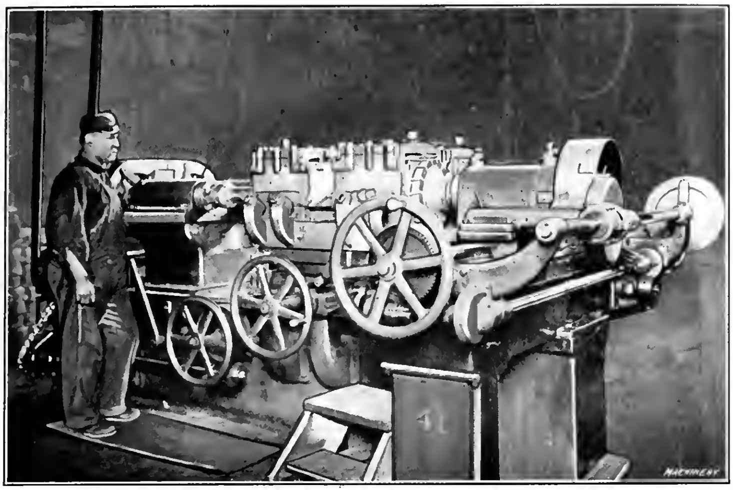

Fig. 1. Increasing the Production of Automobile Cylinders by the Use of Stellite Tools

a matter of fact the high temperature incident to cutting at high speed does not affect the cutting qualities of the stellite tool. Stellite is not a steel, as it contains no iron whatever, but is composed of cobalt, chromium and molybdenum, chromium and cobalt being the chief constituents and molybdenum being added to make the alloy suitable for various requirements. When alloyed with tungsten, the metal becomes distinctly harder, and with a content of ten per cent of tungsten produces an excellent alloy for cold-chisels and wood-working tools. A content of forty per cent tungsten makes the metal suitable for turning cast iron. Not being a steel it is natural to assume that this alloy has some properties unknown in a steel tool, which is true. For example, it can be worked at a much higher peripheral speed. In fact, a stellite tool works

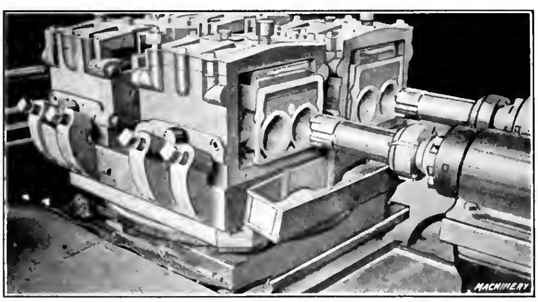

Fig. 2. Close View of Machine in Fig. 1 showing Boring Heads carrying Inserted Teeth made from Stellite

best when operated at high speed and with a comparatively light feed.

It might be mentioned that the original stellite alloy was developed by Mr. Haynes to supply the need for an incorrodible metal to be used in the manufacture of table knives, pocket knives, etc. This alloy, which is distinct from the metal cutting alloy, can be forged. It is unaffected by the ordinary acids and is untarnishable.

Points on the use of Stellite Tools

If a lathe tool, called a "bit," is 3/8 or 7/16 inch square, the best results will be obtained when cutting steel containing up to thirty points carbon by taking a cut from 1/16 to 1/8 inch deep with a feed of from 1/32 to 1/16 inch per revolution of the work. The surface speed of the work should not be less than 150 feet per minute and can be as high as 300 feet per minute. In cutting steel containing from thirty-five to 100 points carbon, the depth of cut can be the same as that just given, but the peripheral speed of the work should be reduced to from 100 to 225 feet per minute. In cutting cast iron the depth of cut, in the majority of cases, should not exceed 1/8 inch, and better results will be obtained by taking a cut about 1/32 inch deep with a higher speed. The feed used can vary from 1/50 to 1/28 inch per revolution of the work, while the speed should not exceed 200 feet per minute.

There are certain points to be borne in mind when using a stellite tool if good results are to be expected. In the first place, if the tool is to be used for turning in the lathe it should be ground to a "round nose" form. If a tool of a different form is required it is poor economy to change the shape; a much better practice is to have another piece of stellite which can be ground to the desired form and kept for that purpose exclusively. A stock of three or four differently shaped stellite bits will usually meet all requirements and will last much longer than if ground first to one shape and then to another, as occasion may arise.

The top face of the tool (when held in the tool-holder) should not, under any circumstances, be ground away to any considerable depth, as by far the best cutting edge is obtained near the surface of the bar. The reason for this is that the outer surface of the bar becomes, in a sense, chilled in casting, this being due to the hot metal coming in contact with the surface of the iron mold. Another important point to be considered is the manner in which the tool is held in the holder. It should fit closely and care should be taken to see that the holder is free from chips and rough places. The set-screw should be tightened lightly, just enough to keep the tool from pushing back in the holder. This requirement shows up an inherent defect in tool-holders as now made, in that there is no provision in the holder for backing up the tool, the only means of clamping being a set-screw which is generally tightened to such an extent that the tool is broken or bent out of

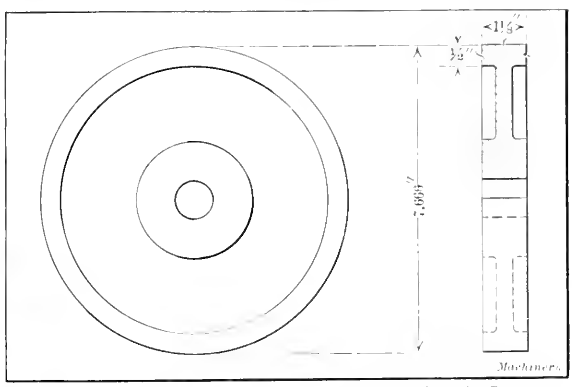

Fig. 3. Cast-iron Gear Blank machined as indicated at the Rate of Sixty-two in Ten hours with a Stellite Tool

* For articles on stellite previously published in MACHINERY, see "Tests made with Stellite Tools," April, 1913, and "New Material for Lathe Tools," February, 1913.

†Associate Editor of MACHINERY.

shape. The pressure sets up strains in the tool that lessen its ability to resist heavy thrusts or shocks. If an adjustable backing-up stop or plug were inserted behind the tool, the set-screw would not need to be tightened so heavily, but just enough to hold the tool in place, and in this way strains in the cutting tool would be avoided and it would be much more effective in removing metal.

In order to meet certain requirements the materials composing stellite and the treatment they receive are changed, so that the manufacturer in all cases should state on what class of work the tool is to be used. For some classes of work, stellite has its disadvantages. For instance, on soft iron or steel where a large amount of metal must be removed in one cut, little, if any, advantage will be gained by using a stellite tool in preference to a good high-speed cutting tool. The reason is that a high-speed cutting tool will resist a much greater pressure than a stellite tool, and while it cannot be worked at as high a speed it will remove a greater amount of metal in a given time, owing to its inherent strength. However, there are many cases in which a stellite tool shows a marked increase in production over any other type of cutting tool, as the following records show.

Increasing the Production of Automobile Cylinders by the use of Stellite Tools

Fig. 1 shows a Beaman & Smith cylinder boring machine which is used in the plant of the Haynes Automobile Co., Kokomo, Ind., for boring automobile cylinders. The cylinders, cast two *en bloc*, are made from close-grained cast iron containing a small percentage of steel, and are very difficult to machine. The bore of these cylinders is 4¼ inches in diameter by 5½ inches long (finished dimensions), and with the best high-speed steel on the market a production of twenty-eight holes (fourteen castings) in ten hours was the greatest that could be obtained under the most favorable conditions. The amount of metal removed was ⅜ inch on the diameter; two cuts were taken—one roughing and one finishing. By removing the high-speed steel blades from the boring head shown in Fig. 2, and replacing them with blades made from stellite, the production was increased from twenty-eight to sixty-two holes in ten hours—an increase of 121 per cent. Four boring cutter holders carrying inserted stellite blades are used—two for taking the roughing cut and two for the finishing cut, these being changed at the end of each cut. Another advantage obtained by using stellite tools was that they only required grinding for every twenty-four cylinders, whereas the high-speed steel tools lasted for one cut only. The large milling cutter shown at the right-hand end of the machine in Fig. 1 is also provided with stellite inserted blades; it finishes the bases of the cylinders which are 11 7/16 by 8¾ inches, taking a cut ⅜ inch deep.

Fig. 4. Doubling Production on Cast-iron Gear Blanks by substituting Stellite for a High-speed Steel Cutting Tool

Doubling the Production on Gear Blanks with Stellite Cutting Tools

Fig. 3 shows a cast-iron gear blank made from a close-grained iron containing a small amount of steel, which is finished from the rough to the dimensions given, ⅛ inch of material being removed all over. With high-speed steel cutting tools the greatest production that could be obtained on this gear blank was thirty in ten hours. By using a stellite tool, the production was increased to sixty-two in the same time without changing anything except the tool. In Fig. 4 is shown two days' work, one being the production obtained with stellite tools and the other with high-speed steel tools. This gives some indication of the enormous increase in production obtained by the use of stellite. These are only two of the many cases observed by the writer in the plant of the Haynes Automobile Co., where stellite has been used to advantage in increasing production.

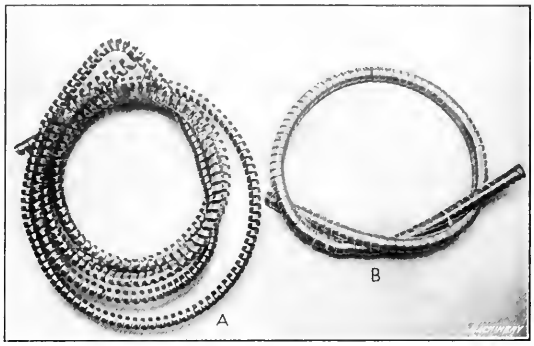

Fig. 5. Character of Chips removed with a Stellite Tool in the Lathe. Note Smooth Finish on Under Surface of Chip

Character of Chips removed by Stellite

One peculiar feature of a stellite tool is that a steel chip removed by it has a glass-like finish, even when the tool becomes red-hot. Fig. 5 shows two chips removed by a stellite tool. The long chip *A* was taken from a steel bar containing 60 points carbon, the cut being taken at a surface speed of 250 feet per minute for a length on the bar of 20½ inches. The depth of cut was 0.050 inch and the feed per revolution was 1/32 inch. The other chip was taken from a bar of chrome-nickel steel, which also shows a very smooth finish. This chip weighs 1.2 pound and was removed from a round bar of chrome-nickel steel with a ⅜-inch square stellite tool in one-half minute.

Another peculiar condition observed when using a stellite tool is that when the chip has once acquired a certain color, it keeps that color as long as the tool is under cut. This is not the case with the chip removed by an ordinary high-speed steel tool, as it changes from a very light color to darker shades and then varies in appearance, which indicates that the cutting tool itself is failing and is attaining a much higher temperature as it becomes duller. The only indication that a stellite tool has become dull is that it absorbs far more power than when sharp. The appearance of the chip does not indicate the condition of the tool, as the surface of the chip still remains smooth even when the tool is dull. A very important point to remember in using a stellite tool is to be careful in clamping it, as it has not the strength to resist shocks that cutting tools working at lower speeds have.

* * *

A method for testing cylinder oils which gives good results is as follows: Heat the oil in a current of air for one hour at a temperature corresponding to that of steam at the pressure at which the oil is to be used. The loss in weight should not exceed 0.5 per cent.

POSITIVE METHOD OF SETTING BEVEL GEAR CUTTER

BY FRANK J. MOULD*

A method of setting the cutter for milling accurate and quiet-running bevel gears is outlined in the following. In using this method, two cuts are required. The set-up for taking the first cut is shown in Figs. 1 and 2, while Figs. 1 and 3 illustrate the set-up for the second cut. As the illustrations show, the cutting angle equals the pitch cone angle of the gear. The gear-cutter is set by a pointer P which is adjusted so that the end coincides with the apex of the pitch cone.

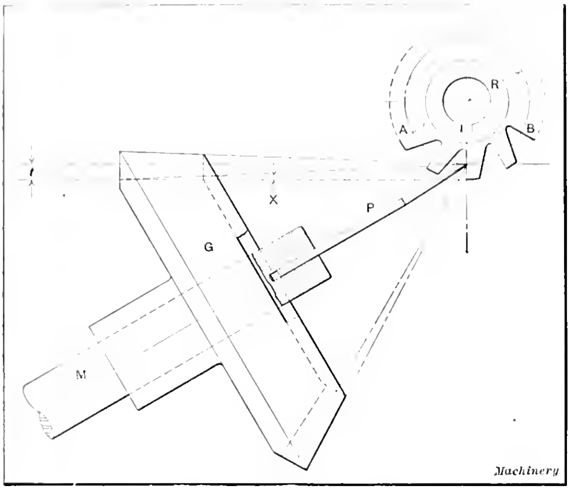

Fig. 1. Method of setting Bevel Gear Cutter

After this pointer is set, the gear-cutter is adjusted until a line on the side of the tooth, representing the pitch circle, coincides with the end of the pointer. The required number of tooth spaces is then milled, after which the lateral position of the cutter is changed as shown in Fig. 3; that is, the pointer is set to coincide with the pitch circle on the opposite side of the cutter. The teeth are then finished by taking a second series of cuts, as explained later.

In order to locate the pitch circle on the cutter, a little blue vitriol is placed on one of the cutter teeth and a pair of dividers is used to mark the arc of the pitch circle AB on this tooth, after a centering plug has been inserted in the bore of the cutter. The radius R of the pitch circle is obtained by subtracting $2t$ from the outside diameter of the cutter and dividing the result by 2. (The distance t or depth of space below the pitch line equals 1.157 divided by the diametral pitch).

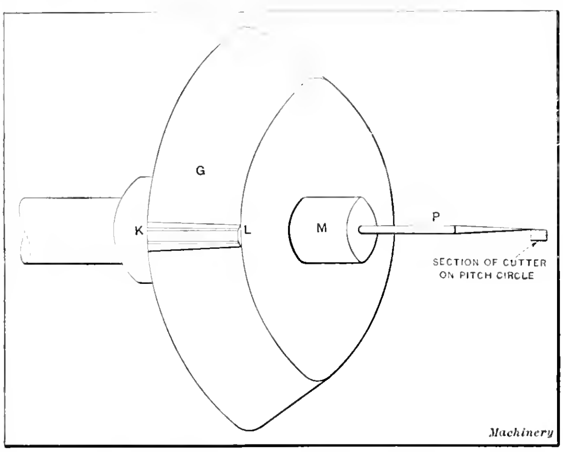

Fig. 2. Gear Cutter set for taking the First Cut

After marking the pitch circle on the cutter, the latter is mounted on the arbor of the milling machine. The gear blank G is next mounted on mandrel M of the dividing head and is inclined to the pitch cone angle. There is a hole 1/8 inch in diameter and about 1 inch deep in the center of the mandrel M and pointer P fits into this hole. The pointer can be moved in and out by hand, but is tight enough to remain in any position. By placing a straightedge against the face of the gear blank, in two or three different positions, and sliding pointer P in or out, as may be found necessary, its sharp end can be made to coincide with the axis of the cone.

The milling machine table is next adjusted vertically, to the right or left, and laterally until the end of the pointer coincides with the pitch line on one side of the milling cutter, as indicated in Figs. 1 and 2. When this has been done, the table is moved to the left and the pointer removed from the mandrel, after which the first cut is taken. When the cutter has been located by this method, the pitch line of the tooth face KL coincides with an element of the cone. After the first tooth has been cut, the succeeding teeth are cut by indexing the gear blank in the usual manner.

The pin is now reinserted in the mandrel and its sharp end again located at the apex of the cone. The table is then moved until the relative position of the pin and cutter are as shown in Figs. 1 and 3, the cutter being set on the opposite side of the center line. In Fig. 3, the dotted trapezoid shows the position occupied by the cutter during the first series of cuts, and the full line its position for the second or finishing cuts.

The table is now moved to the left, the pin removed and the dividing head turned to the left through an angle corresponding to one tooth space or 180 degrees divided by the number of teeth. The machine is now ready for taking the second cut, which is usually very light, seldom exceeding 0.012 to 0.015 inch. With the work located in this way, the pitch line of tooth face ON also coincides with the surface of the pitch cone. Fig. 1 shows the amount X by which the cut taken by this method exceeds the correct depth at the inner ends of the teeth.

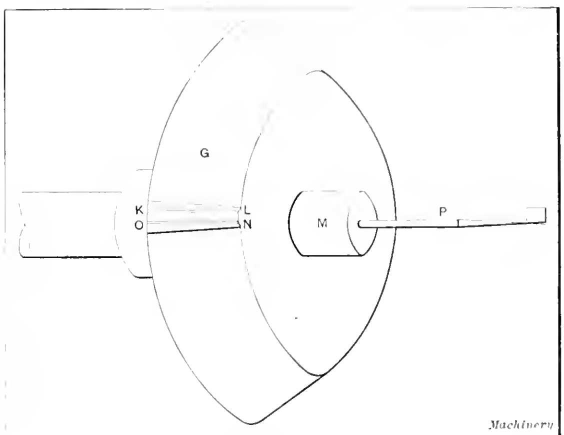

Fig. 3. Gear Cutter set for taking the Second Cut

* * *

For some time a commission has been at work in Germany preparing a new patent law. The commission has concentrated its work upon three points, namely, the regulation of the right of employes to inventions made by themselves; a reduction of the patent fee; and a simplification of the patent procedure. As regards the right of an employe to an invention made by himself, the commission seems to have taken but little account of the rights of the individual and his comparatively unfavorable position as compared with that of his employer with respect to patents. It appears that about all that the commission recommends to safeguard the inventor's rights is that he shall have a right to have his name appear on the patent specifications. With relation to the change in the patent fees, it is proposed to increase the initial fee, partly with the idea of preventing applications for worthless patents; but the annual fees charged to keep a patent in force will not be as high as in the past

CLAMPING WORK IN JIGS

A COLLECTION OF METHODS APPLICABLE FOR USE IN JIG AND FIXTURE DESIGN

BY SERVER

The methods of clamping work in jigs and fixtures presented in this article may be regarded as supplementary to those shown in MACHINERY'S Data Sheet No. 134, contributed by Mr. H. E. Wood, and Data Sheet No. 124, contributed by Mr. Lucien L. Haas. Most of the devices described in this article may be quickly operated, the purpose being to show a collection of efficient designs that will hold the work securely. They possess the further advantage of being relatively simple, so that the jigs can be made at a moderate cost in all cases where there are a sufficient number of pieces to be machined to warrant making a good tool.

A method of holding a piece of work with an oval shaped flange is shown in Fig. 1. It will be seen that this piece is held between V-blocks, one of which is stationary while the other is moved by a screw. Referring to this illustration, it will be seen that a pilot on the end of the adjusting screw enters a hole in the V-block, the two members being held together by a pin which fits in a groove in the pilot. The movable V-block is held to the body of the jig by two steel straps. Fig. 2 illustrates another method of attaching a screw to a sliding clamp member. In this case, the sliding piece is used for forcing the work down into place. It will be seen that this screw runs in a tapped hole in a stationary part of the fixture, while the collar at the end of the screw fits into the movable wedge to push it forward or draw it back. Fig. 2-A shows a movable clamp member that has a tapped hole to receive the adjusting screw. Here it will be seen that two collars on the screw are located at each side of a boss on the fixture and the adjustment is obtained by the screw turning in the tapped hole.

The use of hinged covers that can be swung out of the way when removing work from a jig or fixture is found convenient in numerous cases. Such covers are frequently used for clamping the work in place or for carrying bushings which guide a drill or other tool. Two examples of this kind are shown in Figs. 3 and 4. The cover shown in Fig. 3 is held in place by a locking screw, while the work is secured by a set-screw carried by the cover. The hinged cover illustrated in Fig. 4 is provided with a floating stud that secures the work, the cover which carries the stud being held in place by an eccentric binder with a hook which slides under the pin *A*. This provides a very quick-acting jig. The lug *B* at the opposite end of the cover prevents it from swinging back too far and breaking the hinge.

Fig. 5 shows the application of a bell-mouthed bushing, which is screwed down onto the hub of a lever, thereby locating the work and at the same time providing a guide for the drill which is to operate upon it. A rather unusual method of clamping is illustrated in Fig. 6, where it will be seen that the hand-knob has the thread milled out to the edge to give a "slip over and twist" motion for clamping the work. Practically the same idea is illustrated in Fig. 7, except that a wrench handle is provided in this case to facilitate tightening. Both of these arrangements enable work to be tightened in the fixture with great rapidity. Fig. 8 shows a special nut for a box wrench, the purpose of which is to permit lifting the wrench off the "hex," and moving it back for a new grip. The round part of the nut serves to keep the wrench in place to be slipped back onto the "hex," while the pin at the top of the nut makes the wrench an integral part of the fixture so that it cannot get lost.

Two unusual examples of jig and fixture design are illustrated in Figs. 9 and 10. The distance that the clamp has to be raised in removing the work from between the vees of these fixtures made it desirable to provide some method of releasing the clamp more quickly than by turning the screw back through the necessary distance. The way in which this was accomplished is clearly shown in the illustrations, and will be seen to consist of loosening the screw and then swinging the block which carries the screw on the pivot *A*, the direction being indicated by the arrow. This moves the screw off its bearing on the casting in the case of the jig shown in Fig. 9, while in Fig. 10 the binding screw is removed from the clamp. It will be noticed that the clamp shown in Fig. 10 has been cut away at *B* to permit the point of the screw to clear it; a spring pin holds the clamp against the screw at all times.

Fig. 11 shows a hinged cover with the clamp attached to it. This is a convenient arrangement to remember when considering the design of jigs and fixtures. It will be seen that the clamp and cover are held by the same pin and that both parts are swung out of the way at the same time by means of the corner of the clamp, which catches on the hinged cover at *B*. The design is such that the fixture has sufficient clamping range when the cover is held in place by the screw *C*. The clamping is effected by means of the screw in the cover which forces the clamp down on the work. A little "stunt" is illustrated in Fig. 12 which is often used when it is desirable to keep the clamp out of the way of the cutter. This is simply a clamp beveled at the end to pull the work down flush and push it into the vee at the same time. It will be seen that the clamp is tightened by a screw and a spring forces it open when the screw is loosened.

Two examples of the use that can be made of cams are shown in Figs. 13 and 14. The device shown in Fig. 13 is simply an eccentric stud operated by a handle; this device pushes the clamp against the work, and it will be seen that a hole is drilled in the clamp to slide over the guide pin mounted in the frame of the jig. Fig. 14 shows a cam for operating a sliding vee, the method being evident from the illustration. Another form of quick-acting clamp is shown in Fig. 15. This device consists of a bar that is hinged on a stud at one end and has a slot cut in the opposite end to slip under a second stud. The screw that clamps the work also serves to secure the clamp in place.

A simple form of gang milling fixture is shown in Fig. 16, where it will be seen that the different pieces are clamped by separate screws held in a bar that can be swung out of the way to enable the work to be removed from the jig. This also makes it possible to brush the chips out at the side of the jig.

Although these examples of clamping devices may be used in a great variety of cases, it is well to remember that the tools for any particular job must be built up to suit the work that is to be machined in them. In all cases, the designer uses the method of clamping which experience has shown to be the most suitable. As an example of jig and fixture design, consider the tool shown in Fig. 17. This illustration shows a fixture for holding the two bracket shoes that are to be milled. After studying the requirements of this case, the designer decided to machine these pieces in pairs and the following gives a description of the device which was finally developed. One of the brackets is laid in the fixture, as shown in the plan view, the work resting on the three supporting points *A*. The reason why three points of support were used is that the designer would not be sure of having four or more points of support in contact with the work, owing to slight irregularities in the castings. After being laid in the fixture, the work is pushed back against the locating points *B* and *C* which locate it in the desired position. The second bracket is laid in the opposite side of the fixture in the same way. The work is then held against the stops with one hand and the wedge shaped clamps are tightened with the other hand to hold the work securely in place. There is still one corner of the work left unsupported and the next step is to release the screws *D*, which allows the springs *E* to force the pins *F* up against the unsupported corners of the work. The screws *D* are now re-tightened, thus holding the pins *F* securely in place so that the required support is obtained.

A similar construction was followed out in the design

of the fixture shown in Fig. 18. In this case, the work is laid in the fixture on the three supporting points *A* which are placed under parts of the work that afford ample strength.

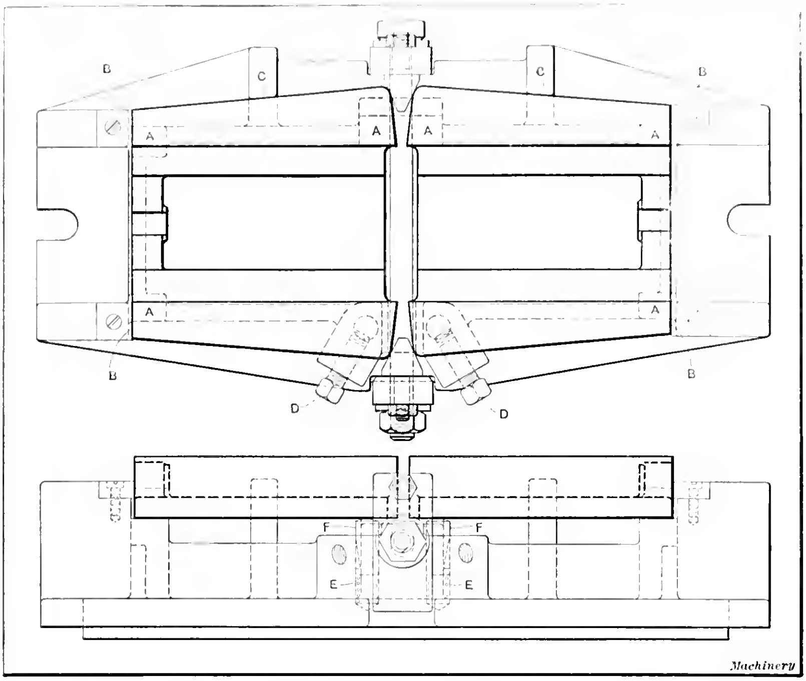

Fig. 17. Method of supporting Work in a Jig that insures a Uniform Bearing

The work is located in the following manner: Two screws *B* come into contact with a boss on the work, which is pushed against these screws by a third screw *C*. The screw *E* also pushes the work back against the locating stop *D*, thus bringing the piece into the desired position. In this case, there are two additional points of support provided by the pins *F* which are raised by coil springs and tightened by screws in a manner very similar to that which was described in connection with the fixture shown in Fig. 17. The work is held down in the fixture by means of two clamps *G* and a hinged cover which carries a binding screw for holding the work while the surfaces marked *f* are being milled. All subsequent operations on this piece are located from these finished surfaces. The accuracy obtained in this operation depends largely upon the judgment of the designer in selecting the proper locating positions and using the most satisfactory combination of clamps and supporting members for the work in hand.

COOLING GAS ENGINES

In a paper read before the British Institution of Mechanical Engineers, Prof. Bertram Hopkinson presents the results of experiments in cooling gas engines by means of water sprayed into the cylinder, instead of by using the customary form of water jackets. It is claimed that several important advantages are obtained through this method. In the first place, the design and production of the castings is simplified, as it is unnecessary to provide water jackets and cored out pistons for the cooling water. It is also believed that the water-jacket method is responsible for many cases where gas engine cylinders break, due to the strains produced by having a great difference of temperature between the inside and outside.

The idea of introducing water into the cylinder of an internal combustion engine is not new. It is a common practice to introduce water along with the oil used in oil engines in order to enable the compression to be raised. Water has also been sprayed into gas engines for the purpose of preventing preignition. The idea of cooling engine cylinders by spraying water into them has been considered, but none of the devices tried for this purpose have met with any degree of success, apparently due to the fact that their originators did not appreciate the conditions which must be fulfilled if the water is to be effective as a cooling agent. The results of the present investigation appear to show that the water must be injected in comparatively coarse drops and directed against the surface to be cooled, so that it reaches the metal in a liquid form. The water must also be distributed properly so that each portion of the surface receives an amount of water which is proportional to the amount of heat it receives. If the water is turned into steam before reaching the metal, it will not exert any cooling effect except by indirectly lowering the temperature of the flame and this means a loss of efficiency.

The method of injection consisted of spraying water through a hollow casting projecting into the combustion chamber and provided with a number of small nozzles about 1/32 inch in

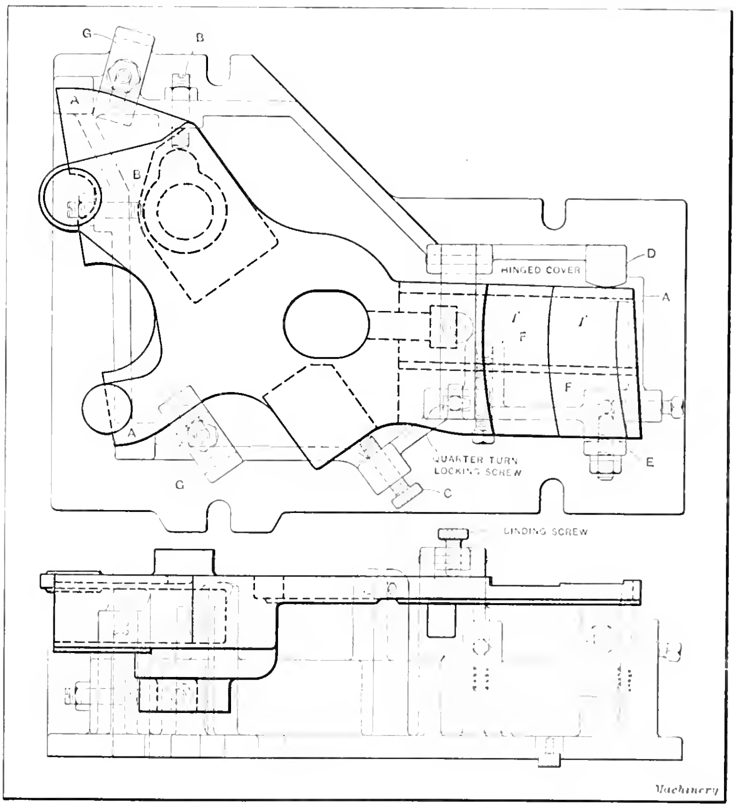

Fig. 18. Method of Support shown in Fig. 17 adapted for milling Seat *f*

diameter. The jets so formed are comparatively coarse so that even when projected into the flame, the water reaches the wall with relatively little evaporation.

HARDENING THE HEADS OF FORGE TOOLS

BY JAMES CRAN*

In the interests of safety and economy, it is advisable to harden the heads of all forge tools, such as sets, chisels, fullers, swages or any other tools made of high carbon steel, that are used by being struck upon their heads with a hammer. Upon the face of it, this may not appeal very strongly to a great many users of such tools, as it is common practice to leave the heads just as soft as possible. Some have even recommended annealing the heads from time to time to keep them soft, the idea being to prevent burrs breaking off and flying around when the heads get battered down from use. The writer considers this a mistake, for when soft steel is subjected to hammering for any length of time, it not only begins to batter down and burr over on the edges but also becomes crystallized. This makes the metal very brittle—although it is quite soft—with the result that the burrs begin to break off and fly around when the tool is in use. This shortens the life of the tool.

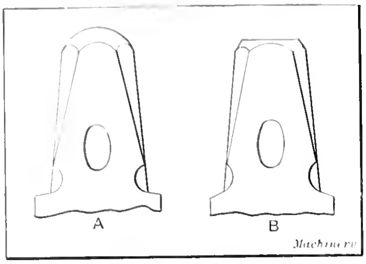

Fig. 1. Approved and Objectionable Types of Heads for Forge Tools

Experience has proved that high carbon steel can be hardened and tempered to make it suitable for any purpose from cutting tool steel in an annealed condition to withstanding the impact of blows. Therefore, theory, as well as the results of practical experience which will be given later, favors hardening the heads of tools. The best and safest type of head to use, either in a soft or hardened condition, is dome-shaped without a single sharp corner. By referring to Fig. 1, a head of this kind will be seen at *A*, and if used soft it will be in service for some time before the center becomes flattened, and burring does not commence until the head of a tool is more or less battered. Such a tool is much safer to use than the flat headed type shown at *B* which will commence to burr almost as soon as it is put in service. When hardened, the dome shaped head will last for years without showing wear, while the flat headed one is likely to chip off in splinters.

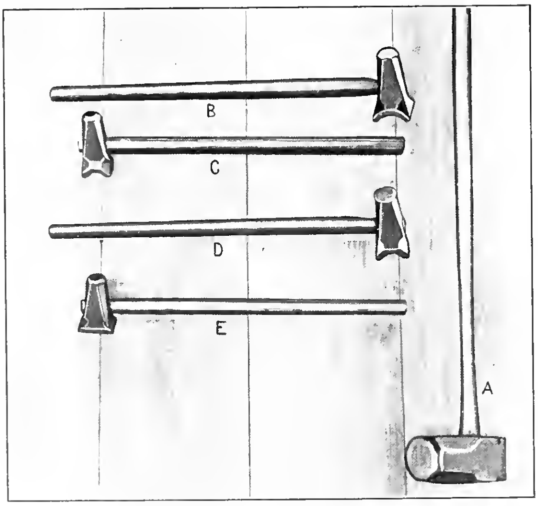

Fig. 2. Tools with Hardened Heads which show Little Wear after being used Several Years

For a number of years, the writer has made a practice of hardening forge tools on both ends with very good success. An idea of how these hardened tools will wear may be obtained by referring to Fig. 2, which shows a few tools that have been in constant use for upwards of eight years. The sledge *A* was made and hardened by the writer nearly nine years ago; it has been in use practically every working day since it was made and is still in perfect condition, not having even been reground on the face. The 1⅞-inch swage *B*, which is about eight years old, has been in constant use the whole time and is still without perceptible signs of wear. The 1¾-inch swage *D* is about the same age and belongs to the same set of tools; it has begun to burr slightly and needs grinding. A 1½-inch swage *C* from the same set has been ground once, as will be seen by the light colored band around the head. The rectangular set *E*, which is one of the tools that a blacksmith uses the most, is about five years old, and like the sledge it is still in perfect condition.

The writer's method of hardening a sledge or hammer of any kind is to first heat the peen to as near the point of recalescence as possible and then quench it in water in an ordinary slake tub, until the heat has been so far withdrawn that it will "carry water." The tool is then polished with a piece of wood covered with emery cloth and the temper drawn with the back heat until it shows a light copperish color, after which it is cooled off. The face is next heated in the same manner as the peen but it is cooled in a stream of water rising straight from the bottom of the quenching tub and striking the center of the face, as shown in Fig. 3. This insures the center being equally as hard as the edges, if not harder, as steam cannot generate and form a cushion as it may do where the tool is immersed in the water. When the face is fairly cooled to a depth of about 1 inch, it is polished and laid in a hot fire, which in a very short time draws the temper on the outer edges to a blue color, leaving the center just as hard as possible. When a hammer has been properly hardened in the manner described, there is practically no danger of its cracking or burring, as the hard center is supported on all sides by the softer and tougher metal around the edges.

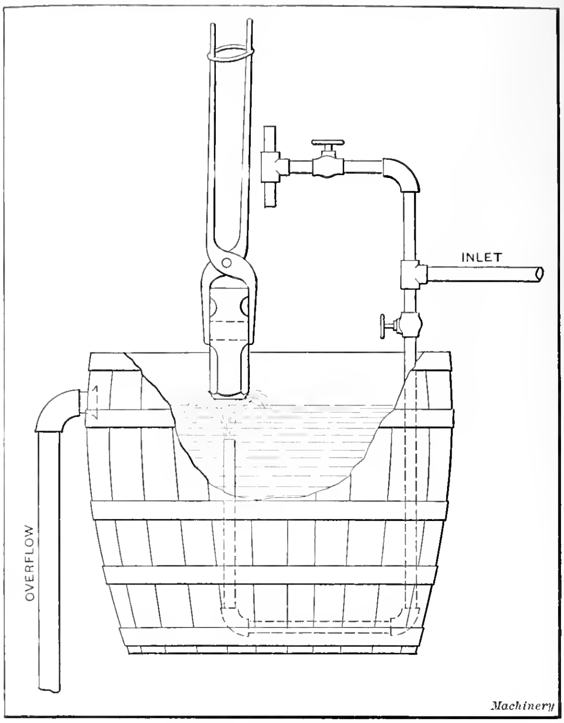

Fig. 3. Arrangement of Piping in Quenching Tank used for hardening Forge Tools

The faces of fullers, swages, sets, etc., are hardened in exactly the same manner as the face of a hammer, but the heads are heated slightly under the critical point and are quenched to a depth of about ½ inch. They are then polished and the temper drawn by the back heat until the color has all but disappeared. What color is left may be described as light seagreen. Another gage for drawing the temper of the heads of tools is to let the temper run until the piece is hot enough to freely ignite thin scrapings of hickory wood; it is then dipped in water, just enough to prevent the temper running any further and allowed to cool in the air.

LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY.

BROACHING KEYWAYS IN GEAR BLANKS

An interesting fixture for holding a gear blank while broaching two keyways in it, applied to the J. N. Lapointe broaching machine, is shown in the accompanying illustration. This gear blank is made from a vanadium steel drop-forging, and the broaching length is 1⅜ inch, two keyways which are 5/16 by 5/32 inch being cut in one pass of the broaches. In cutting these keyways it is not necessary to remove the broaches, which are held in the head, as the operator simply allows the head of the machine to advance toward the fixture, then grips the two broaches, closing them together, and slips the work over.

Fig. 1. J. N. Lapointe Broaching Machine which turns out 800 Broached Gear Blanks in Ten Hours

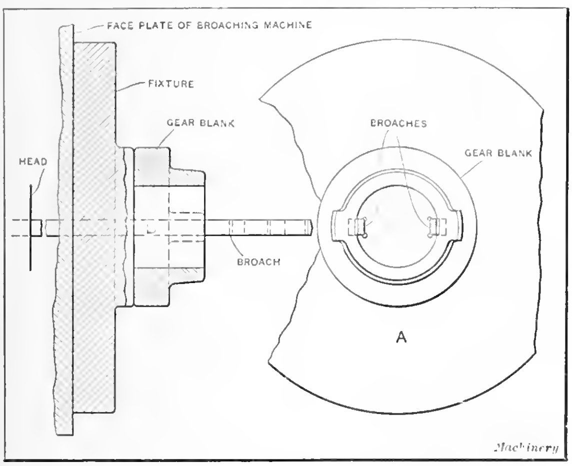

Fig. 2. Fixture used for holding Gear Blanks while broaching Two Keyways in One Stroke

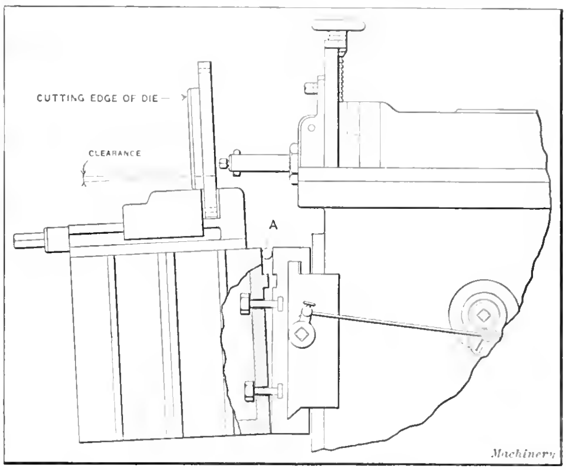
The broaches *B*, as shown clearly in Fig. 2, have no teeth for a distance of about 2½ inches from the face of the fixture, so that when these are held together it is a simple matter to slip the work over them and locate it on the fixture *A*. It is evident that when the head of the machine travels away from the fixture, the broaches are drawn in, and as they are made thicker toward the outer ends, they cut the keyways to the correct depth. Fig. 2 also shows how these broaches are guided when in operation on the work. Holding the broaches in the manner illustrated, enables a large production to be obtained, the time generally taken in removing and replacing the broach being saved. On an average, 800 gear blanks are broached in ten hours, which means that 1600 keyways are cut in this time. The possibilities of broaching when suitable fixtures are provided are almost unlimited, and the job described in the preceding illustrates the adaptability of the broaching method to the cutting of keyways in gears. D. T. H.

MACHINING CLEARANCE IN DIES

When it is required to machine dies in a shaper, I have noticed that the usual method employed to get the proper clearance is to place a thin strip of metal between the vise jaw and the die. However, this is not a very satisfactory plan because it is almost impossible to get a uniform clearance. By referring to the accompanying illustration, the method I employ will be readily understood. The angle of the shaper apron shown in the illustration is somewhat exaggerated in order to illustrate the principle more clearly. In practice, it will be found that a cold-rolled rod *A* of ¼ or 5/16 inch diameter will be about right for producing a clearance of one degree. The angle which is obtained by any size rod can be readily determined by means of a bevel protractor. The gap caused by the rod should be carefully filled with waste in order to keep out chips, thus avoiding trouble when it is desired to draw the apron back into the original alignment. This method has the advantage of enabling a standard clearance to be obtained on a number of dies without causing trouble in setting up successive pieces.



Method of setting Shaper Apron for machining Clearance in Dies

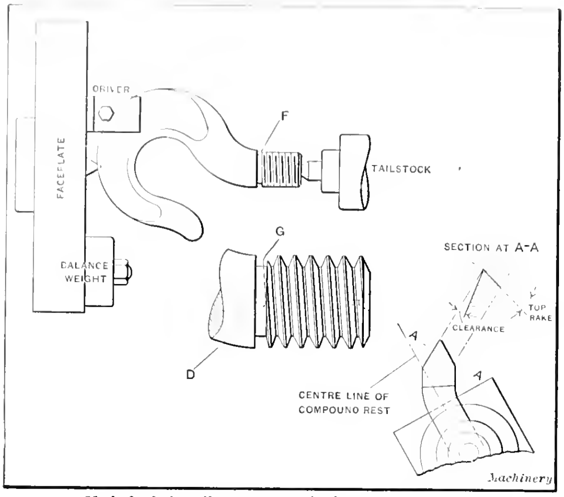
Delphos, Ohio. A. J. BRICKNER

THREADING CRANE HOOKS IN THE ENGINE LATHE

Large crane hooks are generally fitted with ball or roller thrust bearings which are held in place by collar nuts. The usual practice of crane shops in machining such hooks is to first bore and thread the nut, and then turn and thread the hook so that it has an accurate fit in the nut. There are two points in connection with the latter operation which require careful attention, as they affect the quality of the work produced and also the time occupied by the machining operation.

In order to explain the method of procedure, let us assume that the crane hook has been properly centered, balanced,

turned and grooved on the shank as shown at *F*, so that it is ready for the threading operation. In order to save time in threading and produce a good finish, the tool used should have top rake on only one side, such a tool being shown in the illustration. The compound rest is set over and the tool fixed in the toolpost in the usual way. For the roughing cut, the tool is fed into the work in a direction parallel to the center line of the compound rest. When used in this way, it cuts freely because the cutting edge has a suitable top rake. After the bulk of the metal has been removed, the



Method of threading Crane Hooks in the Engine Lathe

thread is finished by feeding the tool in at right angles to the axis of the work. By so doing, both edges of the tool work on the finishing cut and produce a thread which will fit accurately in the nut. When performing this part of the operation, care must be taken to cut away the thin fin *D*, which will form at the point where the tool runs into the groove at the inner end of the thread. If this precaution is not taken, the fin will spring away from the tool, as indicated by the dotted line at *G*, and after the tool has passed, the fin will still be left and result in a badly fitting screw which will bind at the end of the thread.

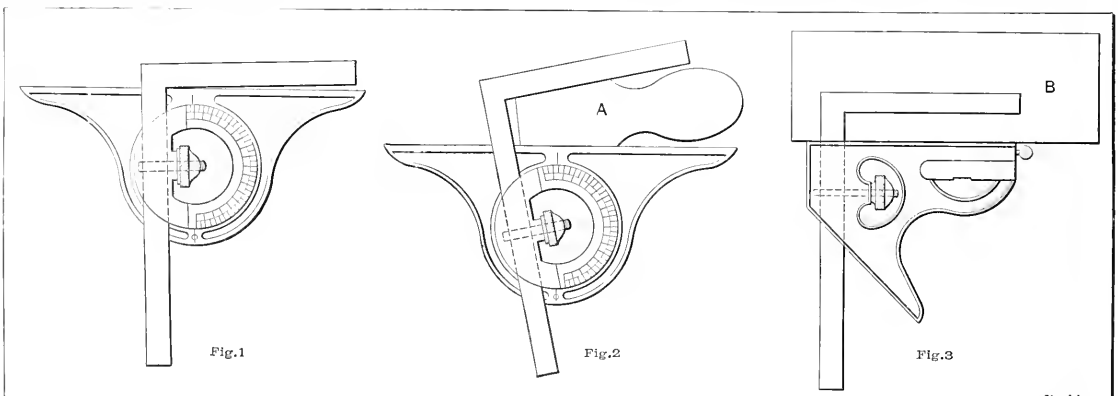
Wilkinsburg, Pa. T. PILKINGTON

ATTACHMENT FOR COMBINATION SET

There is hardly a machinist who does not feel disappointed, after buying his first combination set, when he tries to use the protractor head for laying out a small angle on work such as shown at *A* in Fig. 2. The smaller the angle he is trying to get, the less satisfactory the protractor becomes, until it is practically useless at angles of 20 degrees and under. This is due to the fact that when the head is set for such angles, there is practically none of the straight edge of the head above the blade.

To overcome this difficulty, I made a skeleton square for use in the combination set, the design and method of using this attachment being clearly shown in the illustrations. With this tool, it is possible to handle angles from zero to 180 degrees with equal facility, and also to use the combination set for a number of purposes for which it is not available without this attachment. Fig. 1 shows the protractor set for laying out a 1 degree angle. Fig. 2 shows the use of the protractor for obtaining the required angle on a sheet-steel gage *A*. In Fig. 3, the skeleton square is set for scribing lines on the block *B* parallel with its edges.

Dallas, Texas. GEORGE AKSBAN



Figs. 1 to 3. Attachment for the Combination Set, and Three Purposes for which it can be used

CONCERNING RING OILING BEARINGS

Mr. A. De Signer's inquiries concerning the design and operation of ring oiling bearings which appear in the October number of MACHINERY, seem to cover most of the interesting points in connection with this branch of machine design. In reply to his question as to why the two ends of the oil reservoir had to be connected in order to get the bearing to operate properly, the writer would suggest that "windage" may have been the cause. Windage is the name given to the movement of air which results from the operation of some classes of high-speed machinery, and under certain circumstances it may be necessary to provide some sort of wind checking device in order to obtain proper lubrication of a ring oiling bearing.

The great variety of rings that are in successful use would appear to indicate that the section of the ring that is adopted, has little to do with its efficiency. It can be seen that a ring of relatively heavy section will be less likely to be stopped by the oil than one of small section and correspondingly light weight. Rings and oil that do acceptable work after being started often fail to start satisfactorily because the oil is stiff enough to overcome the very slight friction that exists between the shaft and the ring. This is at least a partial answer to Mr. De Signer's question concerning the size of the oil reservoir and the kind of oil that gives most satisfactory results. If the reservoir is made large enough to provide sufficient oil storage to reduce the necessity of frequently renewing the oil, and the ring hangs deep in it, there will be a tendency to retard the ring when the reservoir is filled to its capacity. Large rings have a smaller area in contact with the shaft, and have a tendency to assume a position oblique to the shaft and to swing laterally; consequently the diameter of the rings should not be too large.

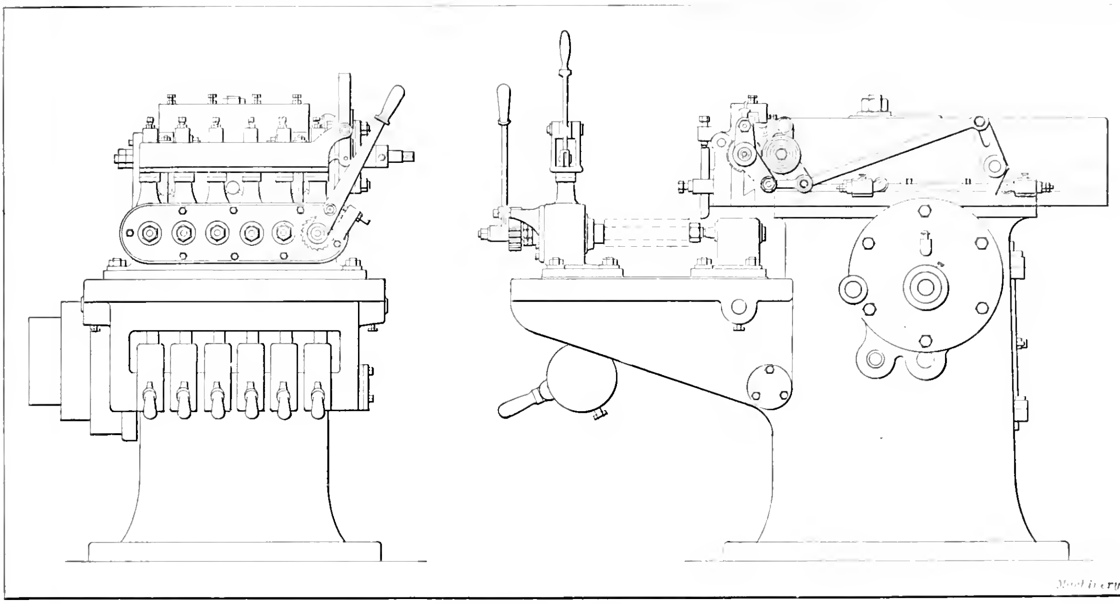
Chain oiling seems to offer many advantages over ring oiling, but the cheapness of rings and the fact that they give satisfactory service in millions of bearings, appears to be sufficient commendation to insure keeping them in use. Some large producers of ring oiling bearings make all their rings below 5 inches in diameter out of seamless brass tubing. The only objection to this material is that a tube is occasionally found that is eccentric enough to prevent satisfactory action. If the ring is very slightly out of balance, it will not move properly and fails to carry oil to the bearing in a satisfactory manner. By way of conclusion, the writer desires to join

Mr. De Signer in his request for more and dependable information on the design of ring oiling bearings.

Hamilton, Ohio. WILLIAM S. ROWELL

SEXTUPLE NUT PLANING MACHINE

The machine shown in the accompanying illustration is used for planing the six sides of hexagon nuts. The method of operation is similar to that of a shaper, except that six tools are employed instead of one. In order to provide for mounting six tools, the machine is designed with a wide guide upon which the ram slides; this ram has cross-feed and a clapper with grips for all six tools. The rough nuts are held on six horizontal mandrels mounted between two chairs which are carried by an extension of the bed. These mandrels are held by bushings in the front chair and are supported at the rear by tail-centers. The arrangement is such that all six mandrels are held exactly horizontal and parallel to each other and to the ram guides, thus providing for the production of accurate work. It will be seen that six weighted levers are located under the extension of the bed which carries the mandrels. By lifting each of these levers, the tail-center which it controls is moved back so that the mandrel may be removed to take off the finished work and put on fresh blanks. When the mandrel is put back into position, it is merely necessary to drop the lever in order to allow the weight to move the tail-center forward against the end of the mandrel. This method of operation adds materially to the rapidity with which the machine can be operated.



Sextuple Nut Planing Machine for the Rapid Production of Nuts

All six mandrels are indexed by means of a single lever mounted on the front chair. This lever turns all of the mandrels simultaneously through an angle of 60 degrees. The transverse feed of the ram and tools takes place automatically in both directions, but this feed can be controlled by hand if so desired. When the ram returns, the tools are automatically raised out of contact with the work in order to preserve their cutting edge as long as possible. A small chain-driven pump delivers cutting compound to the tools, the supply being contained in a reservoir within the column of the machine. The cutting compound is returned to the reservoir through a system of channels and pipe.

The stroke of the ram is about 9.75 inches so that six nuts 1½ inch in height may be mounted on each mandrel. The drive is through a three-step cone pulley and gearing, and a slotted crank disk. The ram is actuated by a wrist-pin carried in a centrally located fork. The speed of the return stroke is several times that of the cutting stroke. The cross-feed and the lift of the tools are effected by means of a ratchet and pawl which are driven from the ram through a system of levers and dogs.

Dresden, Germany. ROBERT GRIMSHAW

MUSICAL ORGANIZATIONS IN MANUFACTURING PLANTS

Some time has elapsed since the entrance of the "general welfare man" into many of our leading and successful business institutions, and the general welfare movement has been pronounced a success by many. A musical organization, of course, would come under this head, or department, and I am of the opinion that too few concerns realize the value of such an organization in connection with their business. *Esprit de corps* is one of the keynotes to success in business organizations.

An atmosphere of goodfellowship, harmony and concord can probably be created quicker and better and be more lasting among employes, and between employe and employer, by a musical organization, be it a band, glee club or orchestra, than by any other medium. Get a group of strangers together, get them to sing, and behold the fellowship that reigns in a very short space of time.

In suggesting an organization of this kind I would place a band of from twenty-five to forty pieces at the head of the list. A band could appear at shop-outings, base-ball games, etc. Then from a strictly business point of view, can you imagine a better "ad" for a going concern than to have its employes march in a body to the opening base-ball game in a major league city, headed by the company band? Or an automobile concern entering an industrial parade with its section headed by the factory band?

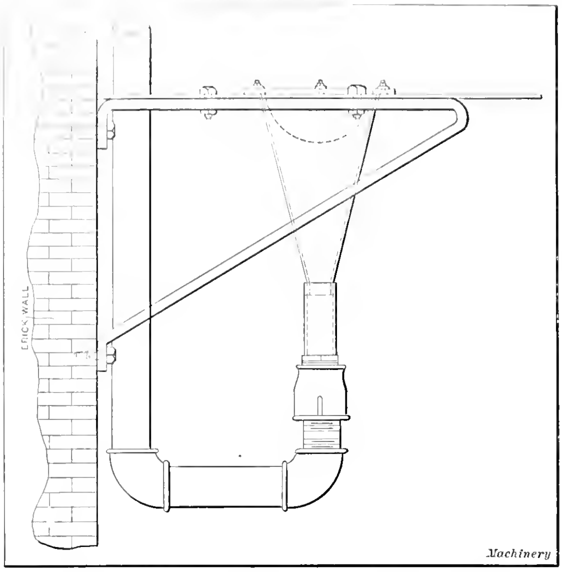
Next, in order, I would suggest a glee club. In many instances it would be possible to organize a glee club where a band would be out of the question. There is plenty of good material for glee clubs throughout the factories and offices of this country. Some surprisingly good material is to be found wherever Welshmen abound.

Picture a convention program being opened by an address of welcome by the mayor of a city, followed by a good stirring male chorus number by a Live Co.'s glee club, or a musical program at the foremen and superintendents' club some winter night, by the same club. It is a well known fact that a musical organization in a school creates "school spirit." Why will not a factory or office musical organization create—what shall I call it—well, the right spirit?

Cleveland, Ohio. JOHN W. VICKERMAN

AIR HARDENING FIXTURE FOR TOOL DRESSERS

The tool dressers in the shop where the writer is employed often asked for some arrangement that would provide for air-hardening tools and other parts. After the subject had been given a little study it was found that there was an overhead air exhaust which could be used by the hardening department. For this purpose a pipe was connected with this exhaust and carried down the wall to connect with the fixture illustrated herewith. It will be seen that this fixture is funnel shaped, the top of the funnel being covered with a wire mesh and provided with a steel shelf around its edge.



Fixture connected with Exhaust Pipe for Aid in hardening Tools

The steel shelf can be conveniently used for holding a variety of tools of all sizes, and the wire mesh not only prevents tools from falling off the shelf into the funnel, but is also used to support the smaller sizes of tools. Such tools can be laid directly upon the wire mesh, where they are exposed to the air blast until cool. The larger tools are either held in the blast or arranged on the shelf in such a way that the ends that are to be hardened are exposed to the action of the blast. M. W. W.

CASEHARDENING AND TOUGHENING PROCESS FOR GEARS, STUDS, ETC.

In order to obtain the best results by the casehardening and toughening process referred to in this article, it is necessary to give careful attention to the small details. A few degrees difference in temperature, or careless packing of the parts to be hardened, may cause the loss of the finished product. The equipment and materials used should also be selected with care. The furnace we use for heating the parts is a No. 8 Franklin gas furnace (capacity 24 inches by 27 inches) and a Franklin oil or drawing furnace to impart toughness. A good pyrometer should be used for the temperature readings and a good thermometer for the oil bath.

The carbonizing materials used are selected with reference to the results desired. We use a No. 1 rawbone, supplied by Rogers & Hubbard, of Middletown, Conn., and a charred leather which we prepare ourselves. This is obtained, if possible, by buying the scraps from shoe factories, using sole leather. To char the leather, it is placed in a box which is sealed with fire-clay. After the fires are turned out at night, the box is placed into the furnace and allow to remain there over night; the leather is then in good condition for use.

The boxes in which the work is packed are of cast iron. The walls are about ½ inch thick, and a flat iron plate forms a lid. Most of the boxes are round to conform to the general shape of the parts to be treated. This shape permits more uniform packing and heating than the square box.

The gears are cut and machined before hardening, sufficient allowance being left for grinding the holes to size after hardening. These allowances are determined by experiment. When heat-treating gears, a layer of the rawbone and charred leather, about two inches deep, is placed on the bottom of the box in the proportion of three parts bone to one part leather. A gear is then placed in the box and the mixture is securely packed around it with a layer of about one-half inch above. Another gear is then packed in the same way, and this is continued until the box is filled, allowance being made for two inches of bone over the top gear and a space of one-half inch below the top of the box. A mortar is next made by mixing together fire-clay, fine iron borings and salt, and a layer of this mortar is put over the top of the bone, flush with the top of the box; the lid is then put in place.

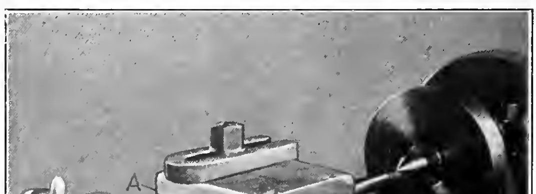
The heat-treatment is as follows: The temperature of the furnace is slowly raised to 1100 degrees F.; then the box is placed in it and the temperature is increased to 1650 degrees F. This increase should also be gradual about two hours being required to heat the box and its contents thoroughly. The temperature should remain at 1650 degrees for four hours. The box is then removed from the furnace and set in a dry place to cool. After cooling, the work is removed and again placed in the furnace, the temperature of which is gradually raised to 1550 degrees. The parts are then removed from the furnace and quenched in a good fish oil at the normal temperature. They are then placed in the oil bath of the drawing furnace and the temperature is raised to 475 degrees, after which the parts are removed and allowed to cool in the air. This process will produce a "case" about 1/64 inch deep, and the rest of the gear will be very tough so as to resist shocks.

To harden studs, pack them the same as described for gears and seal the box. Then place the latter in a furnace heated to 1100 degrees F., and slowly raise the temperature to 1600 degrees F. After the temperature has remained at this point for about eight hours, remove the box and let it cool until the next day. Then take out the studs and place them in the furnace loose or unpacked and heat to 1550 degrees F., then remove and quench in clean water. Finally, replace the work in the furnace, reheat to 1450 degrees and quench in water. This will produce a case of 1/16 inch depth and give the studs a tough center.

CASEHARDENER

MAKING A BRASS TUBE

Some time ago I required a brass tube about 6 inches long and 1.25 inch outside diameter, the bore to be true and straight and the shell about 1/32 inch thick. No tube answering the requirements could be obtained, so I made one as follows: Stock was selected about 1/16 inch thick, from which a blank of suitable width was filed up, bent round a mandrel so that the joint butted, and silver-soldered, no spelter of a low enough melting point being at hand. To bore it I used the device shown in the illustration. The fixture *A* was made from a piece of soft pine plank about 2 inches



Method used in making a Special Brass Tube

thick. This was gripped in the toolpost of the lathe and a hole rather smaller than the outside diameter of the tube drilled through it. This hole was then enlarged by using a boring-bar between centers and a single-point cutter, till the tube could be twisted through. The clamp was then split with a saw, as shown, and two small bolts put through to close it.

The tube was gripped sufficiently tight in this way to hold it while boring. As it had been rounded pretty well with a mallet on a smooth bit of shaft before clamping, it was not likely to become distorted by this mode of holding. The same boring-bar that was used for finishing the hole in the clamp was used to clean up the bore, the cutter being adjusted to the required diameter. To finish the outside to size, the tube was put on a parallel mandrel by hand pressure, stuck at one point with a drop of solder and then turned in the usual way.

Christchurch, New Zealand. JOHN PEDDIE

ATTACHMENT FOR DRAFTSMAN'S PEN

Fig. 1 illustrates an attachment for a draftsman's ruling pen or bow-pen which enables him to make either dotted or full lines with equal rapidity. In addition to the increase in speed, dotted lines can be ruled with the dots of exactly the same length. Making dotted lines that look well is one of the slowest tasks a tracer has to do. This is particularly the case when a bow-pen or compass-pen is used, as great care must be exercised in order to make the dots of uniform length. If such care is not taken, the general appearance of the tracing is ruined. Fig. 2 shows examples of dotted lines made with pens fitted with this attachment. As such lines can be produced when working at a high speed, the advantage is evident.

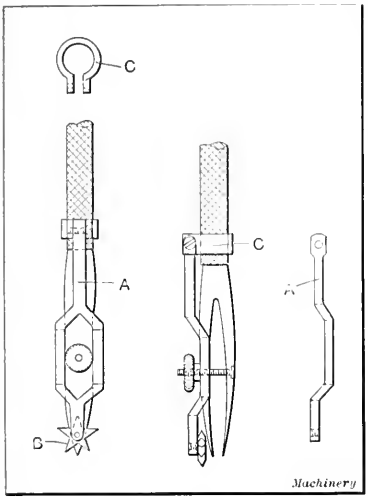


Fig. 1. Attachment for Draftsman's Ruling Pen

Referring to Fig. 1, it will be seen that the attachment consists of a bracket *A* which has a small star-wheel *B* mounted at one end of it. The bracket *A* is secured to the

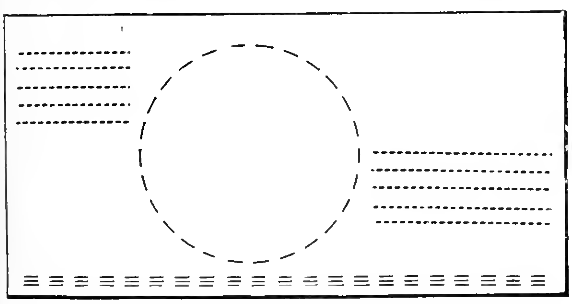

Fig. 2. Examples of Work done with Pen fitted with Ruling Attachment

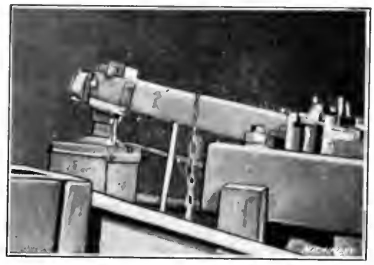
pen by a collar *C* and can be swung back out of the way when the pen is ruling full lines. When dotted lines are being drawn, this star-wheel raises the pen from the paper as each point on the wheel passes the the center, thus producing a dotted line. Several star-wheels can be made and arranged to screw on and off the same bracket. By having different numbers of teeth on these wheels, dots and spaces of different lengths can be obtained. The same idea could be applied for producing dot and dash lines and other combinations. In this case, a larger sized wheel would be used and its periphery would be cut to control the movement of the pen point to give the desired ruling.

Chicago, Ill. C. W. HINMAN

OLD TILT HAMMER

The illustration shows a primitive tilt hammer built almost entirely of wood about fifty years ago. The hammer has been in more or less active use until the last two years. The ram is about nine feet long. On the rear end, which is tapered, is banded a small iron projecting about one inch beyond the wood. This iron is about one inch thick and three inches wide. In the center of an arbor which is about $4\frac{1}{2}$ inches diameter is a cam wheel carrying four cams twelve inches diameter and eight inches in the center where the cams are located. On one end of the arbor is a heavy balance wheel about three feet diameter and on the other end is the driving pulley. The construction of the anvil and hammer head is shown in the illustration.



Old Tilt Hammer

New York City. P. R. GOODWIN

SPINNING TOOLS

The tool used for spinning tinned iron, sheet-iron, steel or aluminum, should not be glass hard where it presses the sheet, as is the rule in spinning brass, for this tends to produce cracks and rough places. Especially in spinning tinned iron it may be noticed that the tin layer is injured. To avoid this difficulty when using excessively hard tools, the speed can be reduced, but, of course, this reduces the output. Another way is to use tools which are softer, and hence do not tend to scratch or tear the surface of the work. Ordinary brass would be a good material for working the metals named, but presents the objection that it is difficult to give such tools the desired form. Attempts made with the so-called malleable brasses, such as Delta and Durana metal, etc., have not been wholly successful.

A German foreman has made numerous experiments in this line, and has come to the conclusion that for tinned iron and steel, iron, aluminum or zinc sheet tools of certain aluminum bronzes give the best results. The best alloy in question consists of 90 per cent copper, 8 per cent aluminum and 2 per cent iron. This material permits forging the most complicated tools at a red heat. The advantages gained by its use are as follows: In working tinned iron, no tin is torn loose from the iron or steel underlay; in spinning sheet iron or steel, the material does not get rough; zinc and aluminum may be very easily spun when using tools made of this alloy; the work can be done with a much higher speed than with steel tools. Perhaps the reason these tools give good results is that the friction of working makes them hot, instead of the part being spun.

Dresden, Germany. ROBERT GRIMSHAW

ETCHING ON BRASS AND STEEL

In the August number of MACHINERY, a request was made for formulas for resisting grounds and etching fluids for use on brass and steel. For use on brass castings, I would advise the following method: after cleaning the work with gasoline place it in clean boiling water. A pot of beeswax is melted and kept at a temperature of from 200 to 250 degrees F. by standing it on a gas plate or some other heater which will retain the desired temperature. After the work has been washed, the surface to be etched is painted with wax and the work is then hung up to cool. The surplus wax will drain

off and some sort of pan should be provided to catch the drippings. This process leaves a very thin coat of ground which adheres firmly to the metal. I believe that asphaltum would be as satisfactory as beeswax if the castings were heated before the ground was applied. This preheating tends to bind the ground firmly to the metal.

The following is a very satisfactory formula for an etching solution: nitric acid, 16 parts; muriatic acid, 4 parts; water, 100 parts. Dissolve 6 parts of potassium chlorate in 80 parts of water. The two solutions produced in this way are then thoroughly mixed and allowed to stand for a few minutes until the gases have escaped. The solution is then stirred, after which it is ready for use.

For etching steel, the etching solution is composed of the following ingredients: nitric acid, 60 parts; copper nitrate, 8 parts; muriatic acid, 20 parts; water, 100 parts; alcohol, 120 parts. Either paraffine or beeswax may be used for a ground. Where there is a quantity of work to be etched, both the work and wax should be heated according to the preceding instructions, but where there are only a few pieces, the work is heated slightly and the ground applied with a piece of sheet metal that has been heated sufficiently to melt the wax.

New Britain, Conn. W. C. Betz

BORING AND FACING SPRING SHACKLES

Having read with interest the article in the October number on a "Jig for Drilling Automobile Spring Shackle Links" by C. T. Schaefer, the writer thought that many readers of your valuable paper would be interested in the boring and facing fixture illustrated herewith. Of course, this is for a different design of shackle, and is used in a turret lathe. The shackles are bored and faced, thus completing the operation in one fixture.

The construction of the fixture is as follows: The back plate *A* is of cast iron and contains a boss *B* for locating the fixture centrally on the lathe faceplate. The plate *A* is machined to accommodate the slide *C* which is held in place by the steel V-strip *D* and the screws shown. The shackle is held between two jaws *E* having machined vees which locate it centrally. The jaws are operated by a right- and left-hand

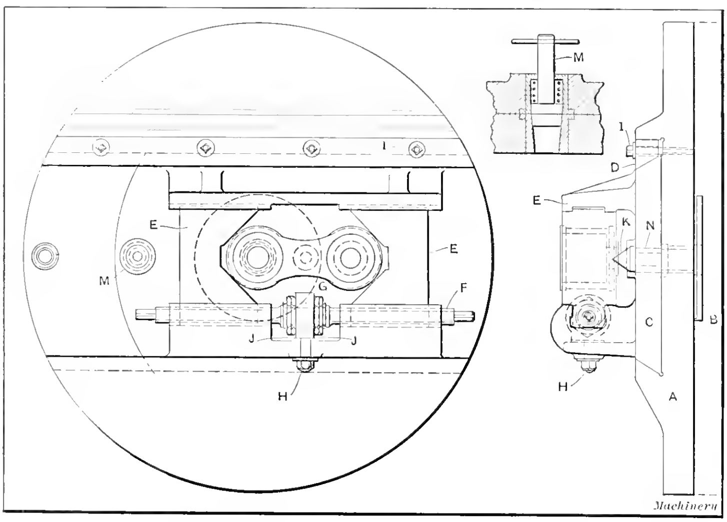


Fig. 1. Fixture used when boring and facing Spring Shackles

square-thread screw *F* which has a square on each end. These jaws, as will be seen, slide in machined grooves so as to prevent any possibility of springing. Note should be taken of the arrangement for centering the jaws. By this method the jaws can be set without any trouble by the simple adjustment of the nuts. It consists of two complete halves of a steel bushing, threaded at each end with a very fine thread. These are slipped between the two collars of the screw *F*. The bracket *G* is then put over the bushings, swung into position, and locked by the nut and washer *H*. The jaws can be adjusted to any desired position by the nuts *J* and also locked by the two end nuts. This construction saves considerable time and trouble in fitting.

When operating the jig, a shackle is placed between the jaws *E* and is pushed back to the stop. The screw *F* is then turned to tighten the jaws. One hole is then bored, after which the slide *C* is moved to the other position for boring the other hole. The slide is located in these two positions by the taper spring-plug *M* (see detail view) which engages holes in plate *A*. After the slide is in place, it is securely held by turning the screws *I*.

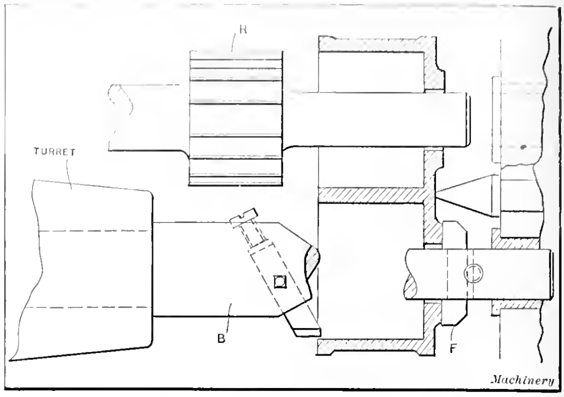

Fig. 2. Tools used for machining Spring Shackles

The shackles are steel castings and the fixture is held in a chuck or bolted to the faceplate. The first operation is to drill a hole in the bosses to allow the boring-bar to pass right through for piloting in the bushing *N* back of the fixture slide. The second operation is to swing around the turret with the boring-bar *B* (Fig. 2) set in position, and bore out the inside of the shackle to $1\frac{1}{2}$ inch diameter. The facing cutter *F* is next put in position and the boss faced. The third operation is to bring in position another facing cutter of sufficient diameter to true the large diameter at the front of the shackle. The final operation is to ream out the bored hole with the reamer *R* which also pilots in the bushing back of the slide. The slide is then moved across to the other position and the same operations are repeated on the opposite end. This fixture has been such a success that six were made for six different machines, and many thousands of these shackles are machined yearly.

Cleveland, Ohio. C. F. George

HIGH-SPEED SHAFTING

In connection with the subject of high-speed shafting which was discussed by J. E. Linabury in the September number of Machinery, it should be pointed out that while there may be a distinct economic gain by increasing the rotative speeds of lineshafts from about 200 to 600 revolutions per minute, such a course is only possible where the use of ball bearing hangers is adopted. There is at least one practical consideration which is opposed to such a rate of speed; *i. e.*, the comparatively low countershaft speeds for which machine tools are designed and the correspondingly small countershaft pulleys that are in common use. If the lineshaft speed were multiplied by three, as suggested in the article previously referred to, the lineshaft pulley, to drive a countershaft at the speed at which it should run, must be one-third of the diameter of the pulley used on the lineshaft running at the original speed. In a great many instances this would be an altogether impracticable proceeding, especially where the existing pulleys are of such commonly used sizes as 10 or 12 inches in diameter.

Looking at the subject from another point of view, it will

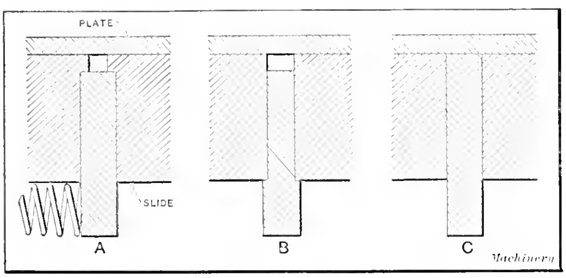
be seen that as a rotative speed of 600 revolutions per minute is far greater than the countershaft speed suitable for existing designs of machine tools, it would be necessary to make the lineshaft pulley much smaller than the countershaft pulley. As a specific case, consider a lathe driven by a countershaft running at 200 revolutions per minute. With a countershaft pulley 10 inches in diameter, the lineshaft pulley would have to be 3.33 inches in diameter for a lineshaft speed of 600 revolutions per minute. This would be a practically impossible dimension for such a case, and plainly shows that the problem is not capable of such easy solution as it might appear at first sight. This is largely due to the fact that the design of machine tools has been based on comparatively low lineshaft and countershaft speeds. This difficulty could, and doubtless will, be surmounted in the future by adapting the design of machine tools for increased speeds. In certain instances, however, such a change would require a great deal of careful study to enable it to be made with satisfactory results.

Sheffield, England. GEORGE W. BURLEY

SMALL SPRING TROUBLES—THEIR CAUSE AND CURE

The use of small spiral springs in connection with certain classes of punch and die work, is often an absolute necessity. As a rule the use of springs is avoided whenever possible, but as there are so many cases where they are essential, often there is no alternative. Quite frequently the successful operation of a punch and die depends on the proper working of the springs, so that a great deal depends on the kind of spring that is used. This is particularly true when the space allowable for the spring is limited and, therefore, a spring must be used that will give the best results. For these and other reasons, the following may be of interest and value to those who occasionally have "spring troubles of their own."

When a spring is used in a hole or slot, it must be small



Correct and Incorrect Methods of inserting Pins for Springs in Sliding Parts

enough to allow for a free action. In no case should the spring bind in the hole or on the side of a slot. When determining the kind of spring to use for working slides in forming tools, etc., a good point to remember is that springs of small diameter will not give good results if the spring wire is too thick, because they will set and become useless in a short time; moreover such springs tend to give the slides too much resistance so that they will require a greater amount of pressure to push them forward. One of the most helpful kinks in the use of small spiral springs that are expected to do strenuous work in a limited space, is to use a double spring; *i. e.*, one spring inside the other, the outside spring being wound right-hand and the inside spring left-hand, to prevent the coils from interlocking. While this is not a new kink, it is one that ought to be used more than it is, as it greatly increases the life and pushing power of the spring.

Another spring trouble is frequently due to the fact that springs are not "set" before being put into place. All small springs that are used as push springs, should be set before using. This is done by forcing the coils of the springs tightly together at least two or three times. In this way the spring will be set to its working length. For instance, if a spring is not set and is put into place, after working a short time it will become set, which means that it has shortened in length and has thereby lost much of its pushing power. On the other hand, when a spring is set, more coils can be used in a given space, which adds greatly to the working strength and durability of the spring.

Another form of spring trouble is that sometimes due to broken springs. In the majority of cases this is due to an inferior grade of piano wire, as this is the material from which most small spiral springs are made. The best way to overcome this trouble is to use an A-1 grade of piano wire, for the very good reason that a set of tools that require too frequent attention on account of broken springs not only stops the production of the article for which the tools were made, but also requires the services of a die-maker to make the repairs; hence it pays to use only a good grade of wire.

Spring troubles are often caused when springs are used in connection with spring pockets in a vertical position, by not having the spring pockets deep enough, thereby leaving so much of the spring exposed that when it is compressed the exposed part bends to one side and becomes jammed. To overcome this trouble, the upper and lower holes or pockets, should not only be in proper alignment with each other, but should be drilled deep enough to give the spring plenty of support. It is a good plan to make the mouth of holes rounding in order to prevent the edges of the holes from catching between the spring coils.

Sometimes so much work is required of a small spring, that even if a double spring is used it does not always prove satisfactory, and we are compelled to do a little experimenting in order to find out just what kind of a spring will "do the trick." After the required spring has been found, it pays to make a note of the size of wire used, number of coils, etc., as shown in the following:

Springs used for No. 1289 Forming Tools

Outside spring (wound right-hand.)
Size of wire, 0.071 inch.
Size of spring-winding arbor, 0.257 inch.
Number of coils in spring, 14.

Inside spring, (wound left-hand.)
Size of wire, 0.043 inch.
Size of arbor, 0.155 inch.
Number of coils in spring, 18.

One of the quickest and best methods of winding small springs *by hand*, that the writer knows of, is to wind the springs in an ordinary lathe on a long arbor, by using a Best spring winder. This winder is so constructed as to allow it to be held by hand, and has adjustments so that any desired space can be obtained between the coils of the springs. The lathe can be run at a fair rate of speed and the springs wound with surprising rapidity.

In winding springs it always pays to wind a few more than are required, in order to form a general spring supply, which is often convenient and time saving.

In winding a spring that must fit in a hole or over a post, a winding arbor of the right size should be used, in order to avoid winding three or four different sizes of springs before the right size is found. The size can readily be determined, by using the table published in MACHINERY'S Data Sheet Supplement, April, 1913.

When spiral springs are used in connection with slides, the stud or pin against which the spring bears, should never be made as shown at *C* in the accompanying illustration (although it often is) for the reason that the pin is liable to work up and bear against the top plate, thereby causing the slide to stick. Two good methods for fastening the spring pin are shown at *A* and *B* as the pins cannot work upward.

Waterbury, Conn. CHARLES DOESCHER

* * *

The art of advertising is many-sided, and new phases are being added all the time. Some of these have unusual and striking features. Consider the ingenuity of the designer of a non-skid automobile tire who conceived the idea of making the raised part of the tire in the form of the letters NON SKID set diagonally. Every revolution of the tire prints the trademark reversed but readable many times when running over soft roads; on paving stones the print in water, mud or oil is often plainly visible. The user pays for the tire and prints the maker's advertisement thousands of times on roads and pavements before the tread is worn off.

SHOP AND DRAFTING-ROOM KINKS

INGENIOUS MEANS AND SHORT CUTS FOR SAVING LABOR AND MATERIALS

TAPER FINISHING TOOL

While trying to get accurate work from an old turret lathe, I hit upon an easy way of "holding size" on slightly tapered studs, etc. Forming tools were unreliable in maintaining diameters so we fitted a box-tool with a wide blade which would take in the entire surface to be turned. This was ground to a scraping edge and was set by a finished piece to take off a few thousandths which the forming tool was adjusted to leave. The feed for a tool of this kind should be quite coarse, in order to keep the edge in the cut.

Poughkeepsie, N. Y. H. W. Johnson

DRILL FOR CORED FLANGE HOLES

A drill that will outlast any standard twist drill or reamer for use in drilling out cored holes in cylinder flanges can be made from a worn-out pipe tap. The tap is first annealed and then turned to a diameter 1/32 inch larger than the size of the cored hole. Four flutes are next milled in it, after which the end of the drill is turned to an angle of 45 degrees. This end is then ground to form a good cutting edge and hardened half way up the flutes. The writer has used a drill of this type for a considerable length of time and has found it to work with entire satisfaction when lubricated with ordinary cutting oil.

Philadelphia, Pa. C. W. Carrigan

CRANKSHAFT TURNING CENTERS

Fig. 1 shows a convenient form of centers for turning the pins of single, double, triple and right-angle crankshafts. Fig. 2 shows a single crankshaft mounted in the centers and illustrates the method used in setting up the work for machining. For this purpose the centers are placed at the ends of the crankshaft and then placed upon a surface plate. By this means, the centers automatically align themselves with each other and the crankshaft is then brought to the required position by the use of an ordinary square. When the crankshaft has been located in the centers, it is secured in place by means of two set-screws.

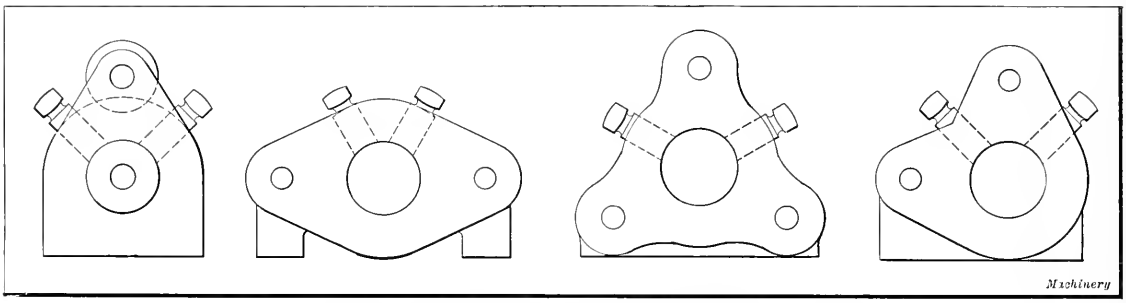


Fig. 1. Centers for turning Single, Double, Triple and Right-angle Crankshafts

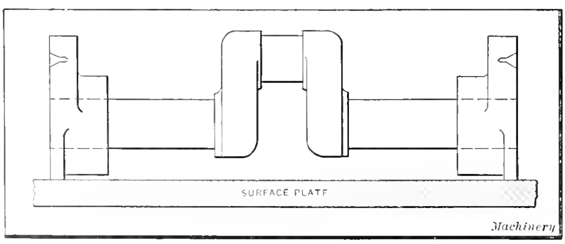

Fig. 2. Method of mounting Single Crankshaft in Centers

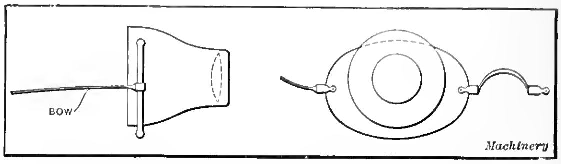
The square affords a satisfactory method of locating a single crankshaft in the centers, but in the case of double, triple or right-angle crankshafts a surface gage will be found necessary. Ordinarily, it is rather a difficult job to locate the centers on the crankshaft properly, but this is done automatically by the faces at the bottom which come into contact with the surface plate. If a surface plate is not available for this purpose, the table of an ordinary planer can be used with satisfactory results.

Milwaukee, Wis. Gus Luck

USE OF SPECTACLES FOR MAGNIFYING GLASS SUPPORT

Many toolmakers and machinists, who have to wear spectacles, experience more or less difficulty in putting on a watchmaker's eye-glass of the kind commonly used in the tool-room. Whenever they wish to use the eye-glass, it is necessary to first remove their spectacles or push them up onto the forehead. An easy and convenient way of avoiding this difficulty is to cut a slot of about the same width as the thickness of the spectacle lens in the rubber frame of the eye-glass. This slot is cut through to within about 1/8 inch of the opposite side, just enough rubber being left to give the necessary strength. When the eye-glass has been arranged in this way, it can be slipped over the spectacle lens as shown in the accompanying illustration, thus saving a considerable amount of trouble and loss of time.



Method of supporting Watchmaker's Glass on a Spectacle Lens

B. C.

FORMULA FOR SOLDERING SOLUTION

The following gives the formula for a solution which is very inexpensive to prepare and will be found a great improvement over the soldering acids generally used in machine shops. In addition to being an excellent soldering solution for brass, copper, tin and bronze, it may also be used as a flux for soldering galvanized iron. The union between the galvanized parts is perfect when this flux is used.

The method of preparing is as follows: Make a saturated solution of zinc chloride by dissolving as much zinc chloride as possible in water. Ammonium chloride (ordinary sal ammoniac) is added to this, the quantity being 1/10 part by weight. The solution should be thoroughly mixed before using.

A good paste for use where soldering acid would be objectionable is composed of the following ingredients: Ammonium chloride 25 per cent; alcohol (wood or grain) 25 per cent; common vaseline 50 per cent. The ingredients are thoroughly mixed before the paste is used.

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

PUTTY FOR EMBOSSING BRITANNIA WARE

G. P.—We are having trouble in "getting up" the detail embossing on britannia ware mirror backs which we make in large quantities. We think there is a "putty" or "slush" that is largely used in embossing such work under a drop hammer, which is placed on the reverse side of the blank to give extra pressure when struck by the force. Can anyone tell us what this putty is composed of?

RECHARGING PERMANENT MAGNETS

A. B.—I would like some information on recharging the permanent magnets of ignition magnetos for automobiles and motorcycles. Customers come to my shop to have their magnetos recharged, but I have not been able to handle the work successfully. I have wound coils for recharging and have followed the prescribed directions for magnetizing but with indifferent success. The magnetic flux would be very strong, but as soon as the current was shut off the magnet would be little or no stronger than before. I have annealed the magnets, thinking that by annealing and rehardening the original magnetic strength could be imparted again. Any information that the readers of MACHINERY can give me on this subject will be much appreciated.

TO COMPOSE THE INTEGERS FROM 1 TO 1000

H. M. L.—If given the problem of dividing $1000 into ten bags so that any integral sum from one dollar to $1000 inclusive can be paid out without opening any bag, how can the division be accomplished?

A.—Any integral sum between the limits of one and 1000 can be made up from the geometrical series 1, 2, 4, 8, 16, 32, 64, 128, 256 and the extraneous number 489. For example, compose the sum 255. $1 + 2 + 4 + 8 + 16 + 32 + 64 + 128 = 255$. Again compose 504. $1 + 2 + 4 + 8 + 489 = 504$. The sum of the series and 489 is 1000.

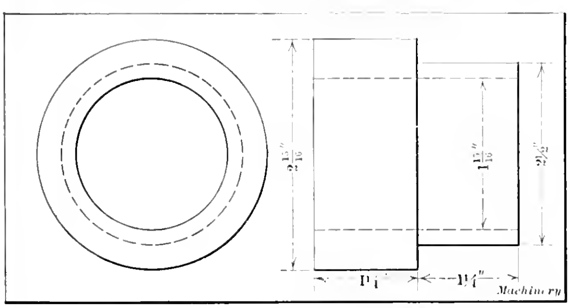
POLISHING HARD RUBBER—LAYING OUT POLISHED RUBBER PANELS

D. H. M.—(1.) Will you please tell me how to polish hard rubber to a buff or gloss finish? In turning or machining pieces for electrical work, they come from the machines in a dull finish. I would like to know how to put these small articles in a highly polished state. (2.) In laying off a highly polished, hard rubber panel, I paste a piece of plain paper on the surface and then lay out the various holes required but have trouble with the paper sticking to the rubber and injuring the polish. Will you kindly tell me what is the best adhesive to use to avoid the trouble?

A.—(1.) Hard rubber may be highly polished by the use of rottenstone and oil. (2.) Avoid the use of paper and adhesives and use instead, Chinese white diluted with water. Spread the diluted Chinese white on the rubber panel with a camel's hair brush. When it is dry, lay out your holes and lines. After the work is done, the Chinese white may be easily removed with water.

SHRINK VS. PRESSED FITS

J. B. F.—Is a shrink fit tighter than a driving fit, or is the supposed superiority of a shrink fit over a press fit only an old erroneous theory? For example, which method will fix



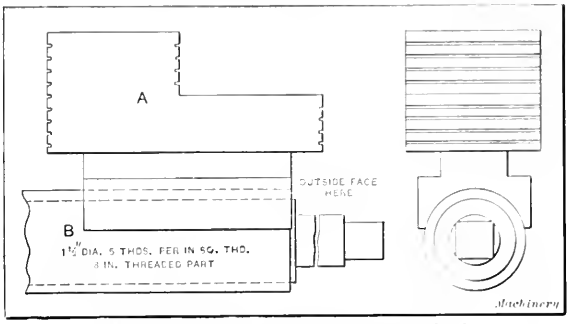
Piece to be shrunk or pressed on Shaft

the piece shown in the accompanying illustration most firmly on a shaft?

This is a practical question on which there is a difference of opinion. Discussion is invited from the readers.

COMPENSATING SCREW THREADS FOR HARDENING

W. B. T.—A lathe chuck jaw A is made of hardened tool steel and the square thread on the under side shrunk in pitch in hardening. The screw B is 1½ inch diameter, 8 inches long, left-hand pitch, five threads per inch, square thread. How



Hardened Lathe Chuck Jaw and Screw to be fitted

can I cut the thread so as to fit the hardened jaw in which the thread has shrunk 1/64 inch in pitch? I would like to have this problem submitted to MACHINERY's readers for reply.

W. B. T. evidently wants the details of a lathe compensating attachment with which he can change the pitch of a screw sufficiently to fit the shrunken hardened jaw threads. Details of such devices in use are solicited.

WORKING HOURS OF DRAFTSMEN AND MACHINISTS

J. W. B. P.—What are the standard working hours of draftsmen and machinists in American manufacturing centers?

A.—The working hours of draftsmen and machinists in representative shops in the principal manufacturing centers of the East and the West are given in the following table. The average number of working hours per week in twenty-five cities and towns is as follows: For draftsmen, 49 hours per week; for machinists, 52 hours per week.

SPRING-SUPPORTED CANTILEVER

M. M.—The following is a problem which has come up in connection with my work. I have attempted to solve it by several different methods but each method has yielded a different result. I would appreciate it if a correct solution of this problem could be published in the "How and Why" section of MACHINERY. What I desire to know is the deflection at the free end of the cantilever beam for a load of 500 pounds and also the stress at any point in the beam. Referring to the illustration, it will be seen that the cantilever is 20 inches long and supports a load of 500 pounds at its free end. The coil spring is located at a distance of 10 inches from the point of support and just touches the cantilever when the beam is unloaded. For the purpose of the problem, it will be sufficiently accurate to assume that the spring extends across the full width of the cantilever. The tension of the spring is such that it deflects one inch for each 220 pounds of load. The beam is made of steel and is 6 inches in width by 3/8 inch thick.

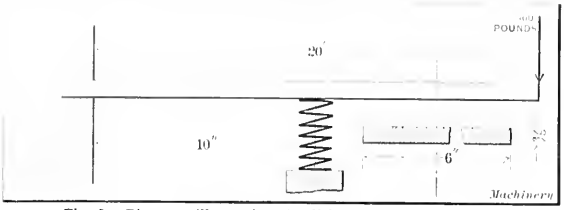

Fig. 1. Diagram illustrating Condition of Cantilever Beam supported by Spring

Answered by William L. Cathcart

A.—The neutral surface of a beam is the plane passing through the center of gravity and neutral axis of every cross-section of the beam. The elastic curve is the curve which the neutral surface assumes when the beam is bent. The deflection at any section of a cantilever beam is the vertical distance between the elastic curve at that point and a tangent to the curve at the support. For a cantilever of length l, having a load P at the free end, and taking the origin of the coordinates at the free end O, the equation of the elastic curve is:

$$6EIy = 3Pl^2x - Px^3 \qquad (1)$$

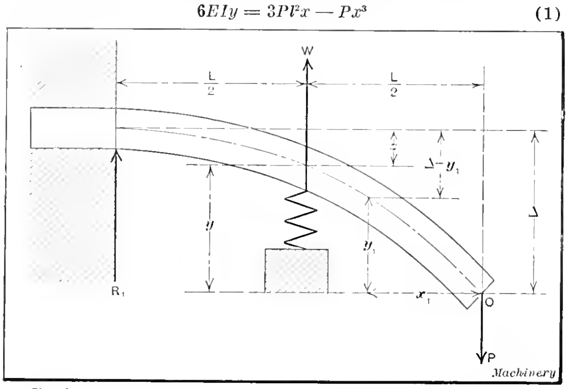

Fig. 2. Diagram illustrating Method of Procedure in solving Problem

The maximum deflection Δ, which is at the free end is:

$$\Delta = \frac{Pl^3}{3EI} \qquad (2)$$

where E = coefficient of elasticity = 30,000,000 and

$$I = \text{moment of inertia of section} = \frac{6 \times (3/8)^3}{12} = \frac{27}{1024}$$

The deflection at any other point, whose coordinates are x_1 and y_1, is determined by substituting the value of x_1 for x in Equation (1) and finding the value of y_1. The required deflection is then $\Delta - y_1$.

Let z inches be the vertical compression of the spring when the beam is bent by the load $P = 500$ pounds at the free end. Then as one inch of compression corresponds to 220 pounds of spring pressure, the upward thrust of the spring will be $W = z \times 220$ pounds. Now, if a force of W pounds acts at the middle of the beam and produces a deflection of z inches there, then a force of 2/5 W pounds = 2/5 × 220z = 88z pounds, acting upward at the free end, will also produce a deflection of z inches at the middle of the beam. This relation can be proved by comparing—by substitution in Equations (1) and (2)—the maximum deflection of a 10-inch beam, loaded at the end with W pounds, with the deflection at the middle of a 20-inch beam, loaded at the end with 2/5 W pounds. It will be found that the two deflections are equal. When P and W are acting simultaneously, the deflection due to P is downward while that due to W is upward. Hence, to find one relation for z we may take a beam having a load of (500 − 88z) pounds at the free end, and determine the maximum deflection for this load. Substituting in Equation (2):

$$\Delta = \frac{(500 - 88z)\ 20^3 \times 1024}{3 \times 30{,}000{,}000 \times 27} = \frac{256{,}000 - 45{,}056z}{151{,}875} \qquad (3)$$

From Equation (1) the value of y at the middle of the beam is:

$$y = \frac{(500 - 88z)\ 11{,}000 \times 1024}{6 \times 30{,}000{,}000 \times 27} = \frac{176{,}000 - 30{,}976z}{151{,}875} \qquad (4)$$

But $\Delta - y = z$. Therefore

$$\frac{256{,}000 - 45{,}056z}{151{,}875} - \frac{176{,}000 - 30{,}976z}{151{,}875} = z$$

$z = 0.48$ inch; $220z = 105$ pounds $= W$; $88z = 42$ pounds.

The deflection due to two or more loads acting simultaneously on a beam is equal to the algebraic sum of the deflections from these loads when acting singly. Hence, the deflection due to the load of 500 pounds acting downward at the end of the beam and the spring pressure of 105 pounds acting upward at the middle, is:

$$\Delta + \Delta' = \frac{500 \times 20^3}{3EI} - \frac{105 \times 10^3}{3EI} = \frac{(4{,}000{,}000 - 105{,}000)\ 1024}{3 \times 30{,}000{,}000 \times 27} = 1.64 \text{ inch} \qquad (5)$$

This result is subject to a slight correction, which will be referred to in a subsequent paragraph.

The stress at any section of a beam is given by the general formula:

$$M = \frac{SI}{c}$$

where M = the bending moment in the section under consideration;

I = moment of inertia of the section $= \frac{27}{1024}$;

c = distance of most remote fiber from neutral axis = 3/16 inch.

S = maximum section stress, pounds per square inch.

The bending moment M at any section of the beam is equal to the moment of the left reaction R_1 about that section, minus the algebraic sum of the similar moments of all loads to the left of the section. The left reaction, in this case, is equal to the algebraic sum of all loads on the beam or 500 − 105 = 395 pounds. For example, the bending moment at the section distant 15 inches from the support is

$$M = (395 \times 15) - (-105 \times 5) = 6450 \text{ pound-inches}$$

The stress at this section is

$$S = \frac{Mc}{I} = \frac{6450 \times 3 \times 1024}{16 \times 27} = 45{,}866 \text{ pounds per square inch}$$

Strictly speaking, the deflection at the end of the 20-inch beam, due to the spring pressure at the middle, should be increased (negatively) by the value of $kl \tan \theta$, in which $\tan \theta$ is the slope of the elastic curve at the spring and k is a fraction, in this case ½ as the spring is at the middle of the beam. With this correction, Equation (5) becomes:

$$\Delta + \Delta' = \frac{500 \times 20^3}{3EI} - \left(\frac{105 \times 10^3}{3EI} + kl \tan \theta\right) \qquad (6)$$

This gives a value of 1.58 inch instead of 1.64 inch as obtained by solving Equation (5).

The quantity $kl \tan \theta$ is here the difference between the deflection of the beam at the spring and the deflection of the end of the beam when the spring alone is acting. Its value is found thus:

$$kl \tan \theta = \frac{\frac{1}{2} Wl^3 \times \frac{1}{2}\,(1 - \frac{1}{2})^2}{EI} = \frac{1}{2} \times 105 \times 20^3 \times \left(\frac{1}{2}\,(\frac{1}{2})^2 \times \frac{1024}{30{,}000{,}000 \times 27}\right) = 0.06 \text{ inch.}$$

WOODS APPRENTICE INDUSTRIAL SCHOOL*

During the period that the Woods Engineering Co. has conducted its plant in Alliance, Ohio, an apprentice has never completed his period of indenture under the regular system. This is due to the fact that after a boy had served from one to two years of his time, he was able to obtain a more lucrative position in some other shop. This was usually done by misrepresentation, the boy claiming that he had completed his time and was a full-fledged machinist.

When a man, representing himself as a machinist, applies for a position, the foreman of the shop generally asks what class of work he is able to handle, and the answer will usually be that he is a lathe, planer or shaper hand or a fitter, erecter, etc. This shows that the majority of machinists have specialized in one line and are not in any sense full-fledged mechanics. The Woods Engineering Co. has found that apprentices from other shops who apply to them for positions have specialized or been kept on one class of work until they are reasonably proficient in that line, and often know very little of any other branch of their trade.

The Woods Engineering Company

APPRENTICE INDUSTRIAL SCHOOL

Schedule

(1) Applicants for apprenticeship must have reached the age of sixteen years and have sufficient education for entrance to first-class high school.

(2) The apprenticeship term shall cover a period of four years, during which time the apprentice must work under such shop rules and regulations as may be in force, and said four years shall be divided into eight (8) periods of 1,350 hours each, (about six months).

(3) Apprentice shall receive ten cents per hour to start and will be given an increase of one cent per hour, every period of 1,350 hours, (about six months). Apprentice shall be taken on six months trial. If at the end of six months it is agreeable to both apprentice and employer, the apprentice will be started in the shop industrial school course and will be credited with six months time on the apprenticeship term and be allowed one-half day each week on full pay to attend the Shop Industrial School. The school course is planned to extend over a period of three and one half years, but should the apprentice by aptitude and extra study complete the school course prior to the close of his apprenticeship term, he would be given credit for full school time. This would eliminate the school time for the balance of his apprenticeship term but he will be allowed double time with pay for all school time for which he is so credited, provided the time is put in in the shop.

(4) Overtime shall be counted in favor of apprentice, and all time absent shall be made up.

(5) Each apprentice shall be allowed the privilege of profiting by premium work or any other special system of pay or benefit in use in this plant.

(6) It is the pride of every first class machinist to possess a tool chest and a fine set of tools; with this idea in view each apprentice must purchase at his own expense, such small tools as he may require in the different departments, namely, a scale, calipers, hammer, surface gauge, etc.

(7) Each apprentice shall have the privilege of one week's vacation each year, without pay, at such time as may be mutually agreed upon one week in advance, and the loss of time need not be made up.

(8) Should the conduct or work of apprentice not be satisfactory to employer, he may be dismissed at any time without previous notice.

(9) To impress upon the apprentice the value of saving, the company, as agent will open a savings account with interest in the name of the apprentice, depositing to his credit $2.00 each month of his apprenticeship time in some good savings bank. No part of the bonus however, will be given to the apprentice until he has satisfactorily completed his four years apprenticeship, except that in case of death of apprentice, the full amount of the savings account on deposit at that time will be paid to his heirs or assigns.

(10) On completion of the shop school course and full apprenticeship term, the apprentice will receive the full amount of the savings account then to his credit, together with a diploma signed by proper officer of our company.

(11) The school proper will consist of a suitable school room and appurtenances, and the school course will include Technical machine shop practice. The school and shop work will at all times be directly under the supervision of a technical instructor who is thoroughly versed in actual machine shop practice.

(12) There is no charge of any kind whatever to the apprentice for school work, stationery, text books, or instruction.

....President

I have investigated the merits of The Woods Engineering Co. Apprentice Industrial School and have read the above Schedule governing same.

I approve the acceptance of the application of..........

....

and will render him every reasonable assistance in my power to complete the full course.

Signed

....

Schedule of Apprentice Industrial School adopted by the Woods Engineering Co., and Form on which the Student's Record is kept

It was felt that by training the apprentices by placing them in charge of an instructor, their efficiency would be increased in a way that would be beneficial to both the company and the boys. Considerable time was spent in investigating all of the schools of this nature that had come to the company's attention and the result of this investigation, coupled with the company's experience, has formed the basis of the industrial school for apprentices that was placed in operation in the shops of the Woods Engineering Co. on September 1.

The schedule which has been adopted by this company is reproduced herewith, and the following outlines the reasons which led to the adoption of the several articles which it contains. Article 1 was made necessary by the school laws of Ohio in regard to the age of boys who take a technical machine shop course. Article 2 was adopted as the result of the experience of other schools that claim to have demonstrated a four-year term to be necessary for the development of an all-around mechanic. The rate of payment outlined in article 3 was based on the rates allowed by other firms. It will be noticed that the apprentice is given an incentive to study out of school in order to shorten the apprenticeship term and receive double pay or 31 cents an hour for any school time that he eliminates in this way. By referring to the articles 4 and 5, it will be seen that the apprentice is given the same rights as the journeyman machinist so that he will not feel that he is being discriminated against. Article 6 was adopted with the view of developing pride in his work by having the apprentice own a part of the tools that he uses.

It was felt that every person should be entitled to some recreation each year, and as a result article 7 was adopted with the intention of making the apprentice feel that taking a week's vacation would not lengthen his apprenticeship term. It is believed that this tends to cheer the boys up and increase their interest in the work. Article 8 gives the employer the right to discharge any boy whose work is unsatisfactory. The provisions made in articles 9 and 10 add about one cent per hour to the wages received during the full term of apprenticeship and give a financial incentive for the apprentice to complete the full course. A brief description of the equipment of the school is given in article 11. The company was willing to adopt the provisions made in article 12 as it was felt that sufficient benefit would be derived from the increased efficiency of boys who went through this course of training.

The school is fitted up with desks, blackboards and the other necessary equipment for handling work of this kind. Six students were enrolled at the start and kept under the supervision of a technical instructor who is thoroughly versed in machine shop practice. It will be noticed that the company has not asked the apprentice to sign an agreement but has placed him strictly on his honor. A boy who is asked to sign any sort of an agreement realizes that he lacks experience in such matters and would probably feel some apprehension as to the outcome, not being able to realize the extent to which he would benefit by so doing. The company has, however, asked the boy's parents or guardian to sign a paper expressing their approval of his enrollment in the school. This was done in order to secure outside influence in making the boy complete his full term of apprenticeship.

* For further information on systems of apprenticeship see "A Modern Apprenticeship System," by A. J. Schneider, published in MACHINERY for June, 1913.

NEW CONNECTING-ROD GEAR FOR ENGINES AND PUMPS

An interesting and ingenious improvement in steam engine connecting-rod gear has been introduced by Mr. H. Williams of the Harvey Engineering Co., Glasgow. Instead of a single connecting-rod and crankpin, two connecting-rods and two cranks are used, in order to obtain a better movement for the reciprocating parts than is possible with a single rod, owing to its angularity. The arrangement of the Williams gear is shown by the accompanying diagram Fig. 1. The crosshead pin carries an oscillating link *A* which is connected by rods *B* and *C* to the two cranks. The latter are tied together by a tie-link *D*. The rods preferably cross at the inner dead center, as shown by the full lines, and they are open or parallel at the outer dead center.

In most of the gears hitherto made, the cranks have been set at an angle of 60 degrees, so that the link *D* is equal in length to the crank radius, and the centers of the connecting-rod pins on the oscillating link *A* are just a little greater than the crankpin centers. The two rods work side by side, somewhat like the eccentric rods of the Stephenson link motion. The centers of the connecting-rod pins on the oscillating link, follow horizontal figure-eight paths with the bottoms of the loops coming close to the center-line of the engine. With this arrangement, the crankpin circle is of larger diameter than the piston stroke. For example, in the engine illustrated in Fig. 2, the crankpin circle is 46 inches in diameter, whereas the piston travel is only 36 inches. This engine is a 200 H. P.

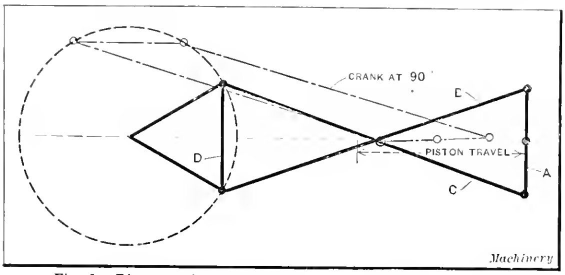

Fig. 1. Diagram of Williams Engine Driving Mechanism which employs Two Cranks and Two Connecting-rods

cross-compound condensing type, equipped with Corliss valves and using saturated steam at 120 pounds boiler pressure.

With this form of drive, the initial piston velocity is about 30 per cent less than with the ordinary type, assuming a constant angular velocity for the crank, but the maximum piston velocity is greater with the Williams gear, than with the ordinary connecting-rod. With the parts proportioned as previously stated, the crank moves through an angle of about 10 degrees before there is any appreciable movement of the piston. The effect of this slow initial movement is that the

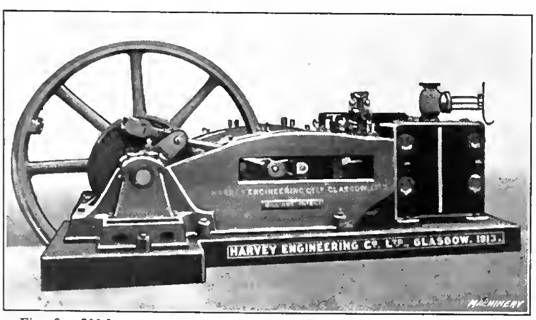

Fig. 2. 200-horsepower Engine equipped with Williams Driving Gear

acceleration of the reciprocating parts is more gradual as well as their retardation at the end of the stroke. As the result of this feature, the engine is said to run very smoothly and the difficulties of balancing the purely reciprocating parts have been gradually reduced. A 25 B. H. P. engine during a trial run, was bolted onto a structure of wooden beams which were ballasted on the ground but not otherwise held. In this position, the engine was run at various speeds and there was a remarkable absence of vibration. The 200 H. P. engine illustrated in Fig. 2, has been driving a weaving factory in Glasgow for several months and the speed of the looms has been increased 10 per cent over what was found possible with electric drive; the number of breakages has also been decreased.

The 25 B. H. P. engine previously referred to, was constructed for making comparative tests, it being arranged to run with either the Williams gear or the ordinary gear. The

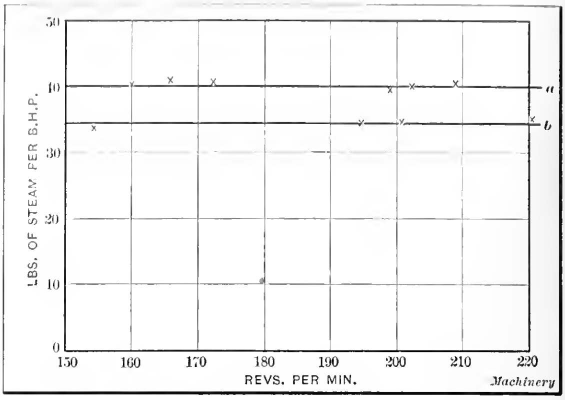

Fig. 3. Diagram showing Steam Consumption when using Single Crank, and when using Williams Two-rod Drive

frame valves and cylinder remained the same for both series of tests, the crankshaft and connecting-rod being the only parts changed. The engine was equipped with an ordinary D-slide valve and used saturated steam at about 75 pounds pressure. The exhaust was at atmospheric pressure. The exhaust steam was condensed and measured and the in-going steam was also measured with a steam meter. The results obtained from these comparative tests are shown in Fig. 3. Line *a* represents the steam consumption per brake horsepower for various numbers of revolutions, when using the ordinary single crank and connecting-rod. Line *b* represents the steam consumption per brake horsepower, when using the Williams gear. In this engine, the saving in steam effected by using the Williams gear was 15 per cent.

This new form of drive has also been applied to pumps with very satisfactory results. The "pause" at the ends of the stroke enables the valves to act without "slip."

INSPECTING WORK WITH LIMIT GAGES

The use of the fork and crescent types of limit gages manufactured by Wells Bros. Co., Greenfield, Mass., does away with the necessity of employing skilled mechanics to determine the perfection of a shop's product. Any man of ordinary intelligence can use these gages, as it is merely a matter of holding the piece of work loosely between the thumb and index finger, so that the constant force of gravity is alone responsible for carrying it between the contact points. As most mechanics know, the arrangement of these gages is such that the piece to be adjusted must pass between the upper pair of contacts but must be too large to go between the lower pair of contacts. The contacts can be set for different limits of tolerance. Where a practice is made of having the workmen test each piece as it comes from the machine, any error in the dimensions resulting from a change in the adjustment of the tool is immediately discovered, thus preventing a quantity of defective work from piling up.

Wells Bros. Co. and other firms who use these limit gages make a practice of having two sets of gages for each man; these gages are used on alternate days so that the chief inspector has one day in which to examine the gages which are not in use and see that they are accurately set. After completing this inspection, he fills the cavity behind the contact points with sealing wax which is marked with his private seal. This is of a conspicuous color and when the gages are in use in the shop the foreman is able to pass between the machines and see at a glance that each man's gage bears the inspector's stamp. This method of sealing the contact points makes it impossible for the men to tamper with the setting of the gages. The fork and crescent types of limit gages were fully described in the March, 1907 number of MACHINERY.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

UNIVERSAL SCREW MILLING MACHINE

The Universal Screw Cutting Co., 17th St., and Sedgley Ave., Philadelphia, Pa., has been engaged in cutting accurate lead-screws for a number of years, and has made a specialty of cutting screws of unlimited length. Special machines are used for this work, the design of which has been a carefully guarded trade secret. The company has recently decided to build these machines for the market, so that it is now possible for any factory to obtain a machine and cut its own screws by this process. The machine is the result of twenty years study of the subject of universal screw cutting, made by Mr. E. W. Crellin, mechanical engineer of the Universal Screw Cutting Co., and incorporates principles that have never been applied in the design of any other type of machine.

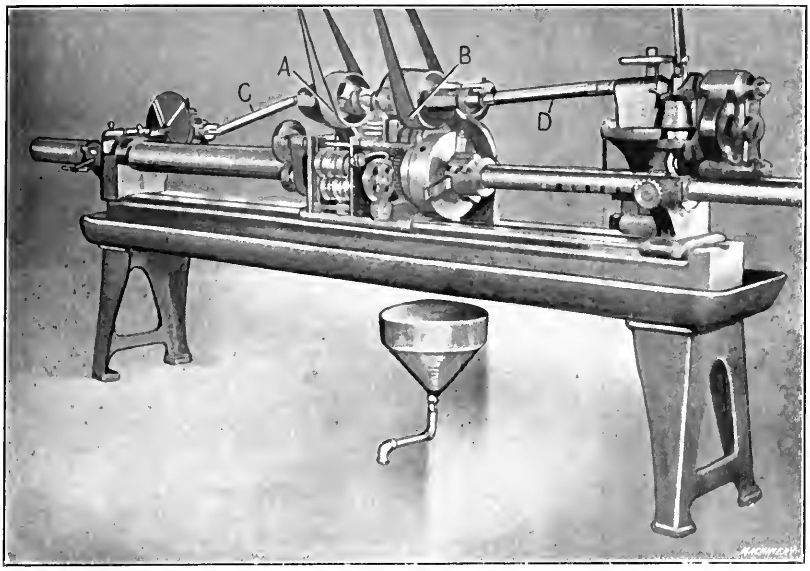

Fig. 1. The Universal Screw Milling Machine

The process is essentially a thread milling operation, but it differs from the established practice in that the work is held by a chuck, which grips it on the outside, and is supported near the point where the milling cutter operates by means of an expansion bushing or steadyrest. As the finished part of the thread passes beyond the head it is evident that the length of the screw which can be milled on this type of machine is unlimited. Another distinctive feature of the design is that the lead-screw is in direct line with the screw that is being milled.

The machine consists of three essential parts: the driving mechanism, the carriage and the cutter head. Referring to Fig. 1, it will be seen that there are two pulleys *A* and *B* located at the center of the machine. These pulleys transmit power to the driving mechanism through universal joints and the rods *C* and *D*.

Figs. 3 and 6 show rear and front views of the driving mechanism. Referring to the front view (Fig. 6), it will be seen that the rod *C*, connected to the driving pulleys *A* and *B*, transmits power to the shaft *D* on which the friction roll *E* is mounted. This friction roll drives the friction disk *F*. In order to provide for varying the speed at which the machine is operated, the screw *G* and crank *H* are provided. By turning the crank, the roll *E* is made to move in or out on the friction disk *F*, thus varying the rate of transmission as desired. In addition to the convenience of this friction drive in varying the rate of transmission, a further advantage is secured on account of the ability of the friction to slip in case the mechanism of the machine is subjected to excessive strain. This avoids the possibility of the machine or work being damaged from this cause.

The rear view of the driving mechanism is illustrated in Fig. 3, where it will be seen that the shaft on which the friction disk *F* is mounted, transmits power through the worm *I* and the worm-wheel *J* which surrounds the lead-screw. A key on the inside of this worm-wheel fits in a spline in the lead-screw, thus causing the latter to rotate. The lead-screw rotates in the split nut *L* and as the position of this nut is fixed at the end of the machine, the rotation evidently results in a longitudinal movement of the lead-screw. The hand-screw *M* shown in Fig. 3 provides for engaging or disengaging the lead-screw nut *L* and taking up any wear which may develop in it.

Fig. 4 shows a detail view of the carriage, the chuck which holds the work and the gear-box. A gear is secured to the end of the lead-screw, and power is transmitted through the gear-box from this gear. By making the necessary changes, the longitudinal movement of the carriage obtained from the lead-screw can be adjusted to obtain the desired pitch for the screw that is being milled. The first and last gears of the train in the gear-box are splined to a shaft which rotates in

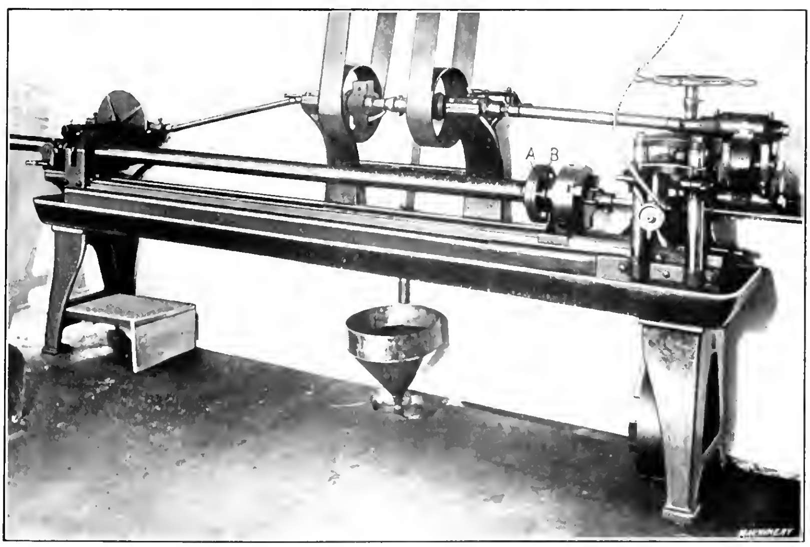

Fig. 2. Duplicating Machine requiring Individual Lead-screws for Different Pitches

flanged bearings that are clamped to the carriage. This is the means by which connection with the carriage is effected, and an idea of the arrangement will be obtained by reference to Fig. 4, in which the last gear of the drive through the gear-box is shown at E. This gear is fastened to a rotating cylinder to which the chuck is attached. The plate G is secured to the end of this cylinder, and it will be seen that this plate is graduated to conform with graduations around the plate H. The purpose of these graduations is for cutting multiple threads; by this means it is possible for the work to be indexed

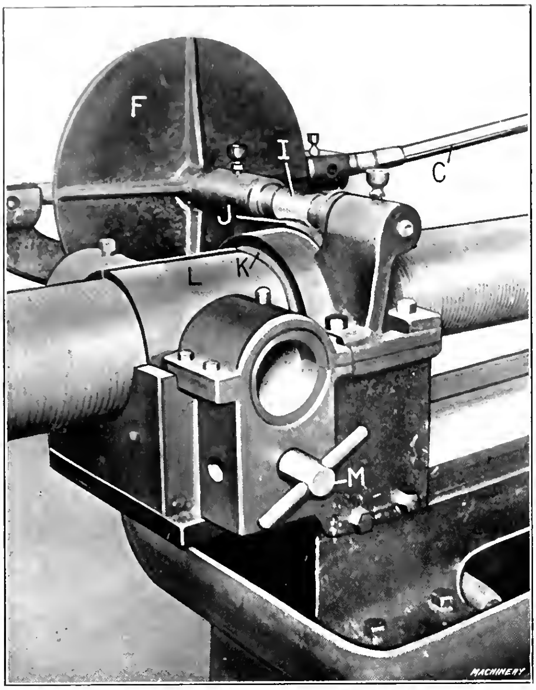

Fig. 3. Rear View of Friction Drive for Lead-screw showing Method of Transmission

through the required part of a revolution to enable it to be set ready for starting subsequent cuts after the first cut has been completed. The plate H is secured to the back of the chuck that holds the work. In order to hold the work positively and prevent it from slipping on the chuck, an auxiliary

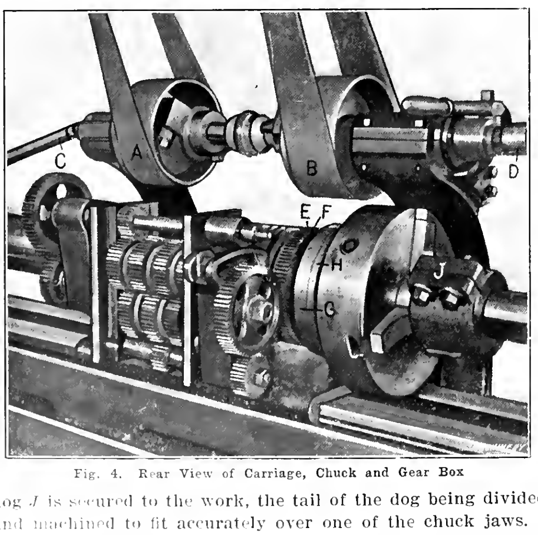

Fig. 4. Rear View of Carriage, Chuck and Gear Box

dog J is secured to the work, the tail of the dog being divided and machined to fit accurately over one of the chuck jaws.

It was stated in a previous paragraph that power is transmitted to the cutter head by means of shaft D, connected to driving pulleys A and B. A detail view of the head is shown in Fig. 5, where it will be seen that shaft D transmits power to a bevel gear H, from which the drive is through the bevel gears I and J to the horizontal shaft K. From this shaft power is transmitted through spur gears to the arbor E upon which the cutter F is mounted. It is evident that the bevel gears H, I and J enable the cutter head to be swiveled about a central pivot 90 degrees to the right or left of the center

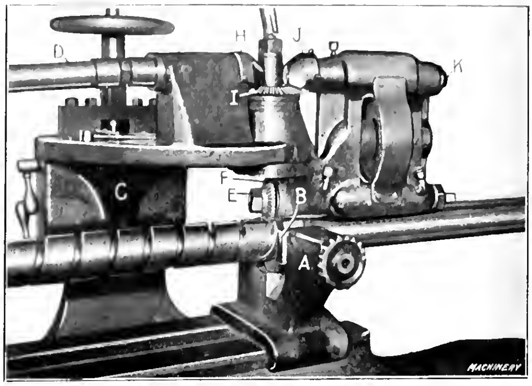

Fig. 5. The Cutter Head, showing Drive and Method of supporting Work

in order to have the cutter F set at any required angle. The work is supported by the bushing B carried in the anvil A, which is secured to the right-hand end of the machine, and the cutter head is further supported by the bracket C which is secured to the bed plate of the machine.

The work is fed to the cutter—in either the right- or left-hand direction—by means of the rotation of the lead-screw in the nut L at the left-hand end of the machine, which was described in connection with Fig. 3. The length of a single cut is limited by the traverse of the carriage along the bed of the machine, but for work of a greater length the chuck can be released, the nut disengaged, and the carriage run back to its original position. The nut is next reengaged and the chuck retightened. After this, the machine is ready to continue milling the thread and this operation can be repeated as

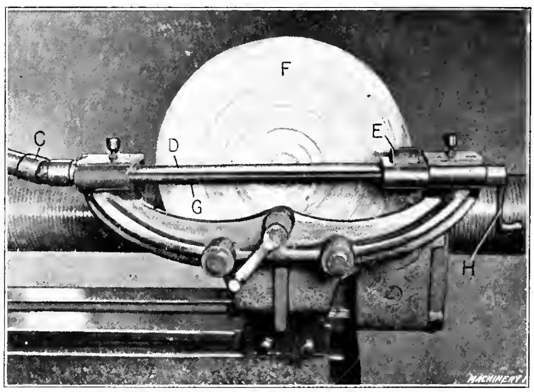

Fig. 6. Front View of Friction Drive for Lead-screw

many times as is necessary to finish the work. While the position of the carriage is being changed, care should be taken to clamp the work securely in the bushing B in order to prevent altering the relative positions of the cutter and the work.

For milling multiple threads it is obvious that the work must be run through the machine the same number of times as there are threads; for instance, a double thread would be run through the machine twice.

It has already been explained that on the machine shown in Fig. 1, a standard lead-screw is used in connection with change gears, which gives the required pitch on the screw that is being milled. A simpler form of screw cutting machine is illustrated in Fig. 2. Referring to this illustration, it will be seen that the change gear box is eliminated and different lead-screws are used for milling threads of the various pitches that are produced on the machine. The same arrangement of index plates for use in the production of multiple threads is

used on both types of machines. In the duplicating machine shown in Fig. 2, the index plate *A* is screwed onto the end of the lead-screw while the plate *B* is secured to the back of the chuck in a manner similar to that described in connection with the gear-box type of machine. It is a relatively simple matter

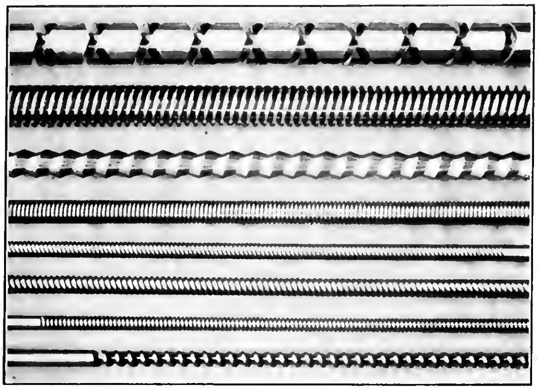

Fig. 7. Examples of Work done on Universal Screw Cutting Machines

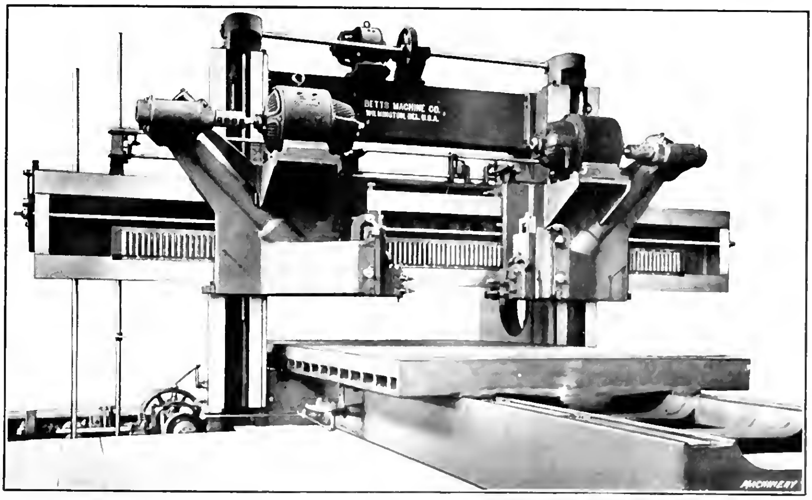
to change the machine for cutting various pitches, it being merely necessary to screw off the index plate and then remove the lead-screw and replace it by one of the desired pitch.

It is obvious that the accuracy of the work is dependent upon the perfection of the lead-screw, and the Universal Screw Cutting Co. has facilities for producing extremely accurate lead-screws for use in the machines. These lead-screws are machined on a larger size of the type of machine described in this article. A very severe test of the accuracy of a thread consists of splitting a section of the lead-screw along its axis and then fitting the threads on the two halves together. Any slight error will make it impossible for the threads to mesh properly, but the process used by the Universal Screw Cutting Co. has been developed to a point where this test can be conducted with satisfactory results.

BETTS CROSS PLANER

A special 120 by 84 inch cross planer which was built for the Commonwealth Steel Co., St. Louis, Mo., is shown in the accompanying illustration. This machine was designed to plane steel frames for passenger cars, but it was felt that at some future date it might be desirable to use it for regular classes of planer work, in addition to the special purpose for which it was built. With this idea in mind the design was worked out in such a way that by substituting a standard cross-rail in place of the special one shown in the illustration and by making a few other minor changes, the machine would be adapted for regular classes of planer work.

Referring to the illustration it will be seen that the two saddles on the cross-rail are equipped with slides set at right angles to the rail, and regular planer heads are mounted on these slides. A 25-horsepower reversing Westinghouse motor is mounted on each of the saddles and transmits power through spiral gears and the rack which is bolted to the cross-rail. The heads work toward each other and are electrically controlled in such a way that one head waits until the other has completed its stroke before reversal takes place.



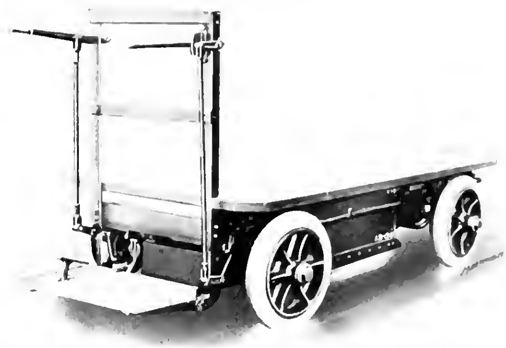
Special Betts Planer built for the Commonwealth Steel Co.

Two table speeds are provided, one of which gives a quick movement of about 20 feet per minute and the other a variable movement for feeding the work to the tool after each stroke. The mechanism for this purpose will be seen at the base of the machine, power being provided by a 7½ horsepower Westinghouse compound-wound motor. The vertical feed for the heads is also obtained from this mechanism, the control being obtained by the tripping dogs which engage a latch on the feed plate. Perfect control is obtained by means of the handle which is shown on the vertical shaft at the left-hand side of the machine, this shaft being connected to the master switch. Pendant switches are also provided.

The planer was built under specifications which required it to be capable of taking two cuts ½ inch deep with a ⅛ inch feed at a speed of 30 feet per minute in steel castings. When the machine was placed in operation, it was found that its actual capacity was considerably in excess of this figure. The Betts Machine Co., Wilmington, Del., is the builder of this special planer.

HUNT INDUSTRIAL TRUCK

A storage battery industrial truck which has been designed by the C. W. Hunt Co., Inc., New York City, is shown in the accompanying illustration. Practically any sort of material



Hunt Storage Battery Industrial Truck

can be handled on this truck, and as it does not run on tracks it can be taken from floor to floor in the elevator or run up into a box car that is being loaded. The capacity is for approximately 4000 pounds, and with this load a speed up to 5 miles an hour can be obtained. The battery has a capacity for a full day's work. Either Edison iron and nickel cells or Exide lead cells can be used. These cells are encased in a steel battery box that is suspended by springs from the cross members of the truck frame. The entire section of the top of the truck over the battery box is removable so that the batteries are readily accessible.

The motors used on these trucks are especially designed for

use in connection with storage batteries, and drive the wheels through cut steel gearing. The gearing is enclosed in an oil- and dust-proof case. Ball and roller bearings are used throughout. It will be seen that the operator's platform is located at the front of the truck. The right-hand lever is used for steering and the left-hand lever controls the motor. The brake is actuated by the foot treadle. When not in operation, the truck is automatically locked.

J. N. LAPOINTE DOUBLE BROACHING MACHINE

The distinctive feature of the broaching machine which forms the subject of this article is that two operating screws and work heads are employed. The sliding heads carried by the operating screws are of the standard form and the design of the machine is such that one head is being returned while the other is engaged on the cutting stroke. This does away with the necessity of waiting for the head to return, so that the operator is kept busy at all times and the output of the machine is materially increased. As it is possible to disengage one of the operating screws, the machine can be changed into the equivalent of a single broaching machine, if desired.

Both operating screws are provided with individual trips so that a very close adjustment of the length of stroke can be obtained. Two forward speeds are available and two operating levers are provided so that the operator can control the machine from either side. A Brown & Sharpe pump and oil reservoir are provided in the base of the machine. The reservoir is readily accessible through an opening at the rear of the machine and the pump is of ample size to deliver a liberal supply of lubricant to the broaching tools. Two flexible tubes are provided at the front end of the machine for the purpose of directing the cutting compound to the desired place. At the rear of the gear case there are two tubes which cover the operating screws; these tubes act as safeguards and also prevent oil from dropping off the screws onto the driving belts.

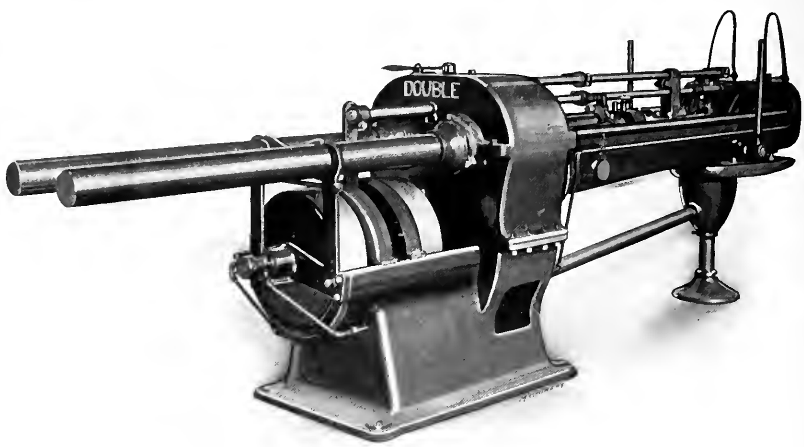


Fig. 2. Rear View of Lapointe Double Broaching Machine

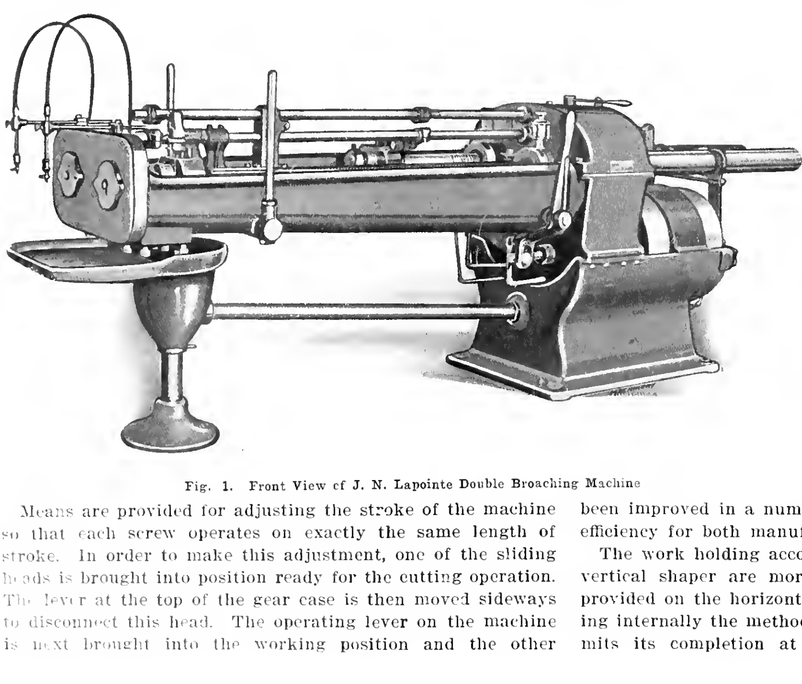

Fig. 1. Front View of J. N. Lapointe Double Broaching Machine

Means are provided for adjusting the stroke of the machine so that each screw operates on exactly the same length of stroke. In order to make this adjustment, one of the sliding heads is brought into position ready for the cutting operation. The lever at the top of the gear case is then moved sideways to disconnect this head. The operating lever on the machine is next brought into the working position and the other sliding head is moved to a position corresponding with the extreme of the stroke that is required. The stops are then set in this position and the stops for the other head are brought exactly in line with them. The lever on top of the gear case is then shifted to bring the first head into operation.

The principal dimensions of the machine are as follows: Travel of sliding heads on low speed, 3 feet per minute; travel of sliding heads on high speed, 6 feet per minute; size of driving screws, 2 3/4 inches diameter, 2 pitch; maximum stroke, 54 inches; floor space occupied, 3 by 16 feet; net weight of machine, 4800 pounds. The machine has a capacity for broaching holes up to 3 inches square. This machine is a recent product of the J. N. Lapointe Co., New London, Conn.

PRATT & WHITNEY VERTICAL SHAPER

The usefulness of the vertical slotting machine is greatly curtailed through its lack of adaptability, and on this account many shops find it difficult to keep their vertical slotters supplied with work. The customary method of supporting the tool on these machines is also a drawback in that the overhang of the tool makes it practically impossible to produce accurate work; and furthermore, the machine cannot be operated with any degree of rapidity. Another disadvantage of the tool support on the vertical slotter is that the tool does not free itself on the return stroke. By dragging over the work, the cutting edge is soon destroyed, and this results in a serious loss of time owing to the frequent intervals at which grinding is necessary. With a view of overcoming these difficulties, the Pratt & Whitney Co., Hartford, Conn., has brought out the 10½-inch vertical shaper illustrated in Fig. 1. This machine is adapted for the classes of work handled on both the vertical slotting machine and the horizontal shaper. It is similar in design to the smaller machine of this type which was briefly described in the January, 1912, number of MACHINERY, but the present machine has been improved in a number of ways which add greatly to its efficiency for both manufacturing and tool-room work.

The work holding accommodations on the Pratt & Whitney vertical shaper are more flexible in application than those provided on the horizontal shaper; for instance, when operating internally the method of holding the work invariably permits its completion at one setting. The same statement

applies to many classes of external work, as in the planing of an irregular shaped die-punch, where the entire periphery may be finished at one setting. The swiveling ram-head that is a distinctive feature of the vertical shaper, also permits two or even four sides of certain work to be planed at one setting, which insures the work being parallel. Furthermore, concave, convex or irregular surfaces which are very difficult to machine on the horizontal shaper, are handled with the greatest ease on the vertical shaper by means of the rotary table. Another decided advantage is that when working to a line, as in the case of die work, the cutting tool always enters the work where the line is scratched; whereas, on the horizontal shaper, it leaves the work on the scratched line, breaking away the chip and making it impossible to follow the line accurately. The feature of angular adjustment for the ram is also an advantage on a large variety of work, especially in the working out of dies, as the desired clearance can be obtained. As another point in favor of the vertical shaper, it might be mentioned that the working strains on the machine when in operation tend to hold all such parts as knees and slides together, which is directly conducive to maintaining the accuracy—while in the horizontal shaper, these strains are exactly opposite and are detrimental to accuracy and stability. The proportions of the Pratt & Whitney vertical shaper are ample to assure stability, and sufficient power is provided to meet every requirement. While the stability and power of the machine are adequate for the severest service on manufacturing work, this vertical shaper is a precision tool in every particular. Attention is also directed to the method pursued in meeting the various operating requirements, all of which are constructed and located with a view of affording the greatest possible convenience in operating the machine.

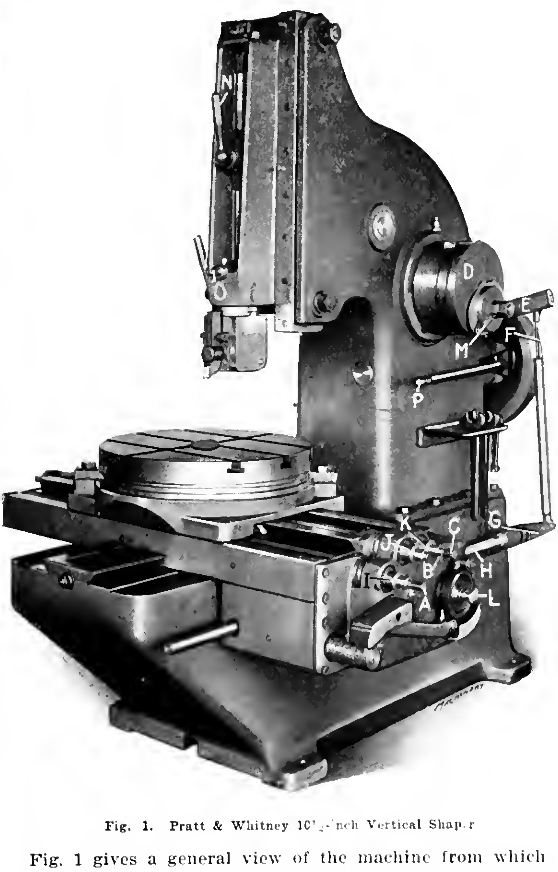

Fig. 1. Pratt & Whitney 10½-inch Vertical Shaper

Fig. 1 gives a general view of the machine from which it will be noted that the rotary table forms a very important part of the construction. It is substantially mounted, liberal dovetail bearings with taper gib adjustment being provided whereby the proper relation between the bearing surfaces may be easily maintained. Both hand and power feeds are provided, the means of controlling which have been worked out very satisfactorily and are worthy of special mention. The entire mechanism is self-contained in a compact unit attached to the saddle at the right-hand side of the machine. The transverse feed is controlled through the shaft A; longitudinal feed through the screw B; and rotary feed through the shaft C. Power is transmitted to the feed mechanism through the cam D which operates oscillating arm E. The desired rate of feed is obtained by adjusting shaft F, the power being transmitted

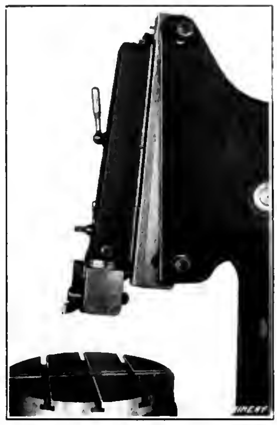

Fig. 2. Angular Adjustment of Ram

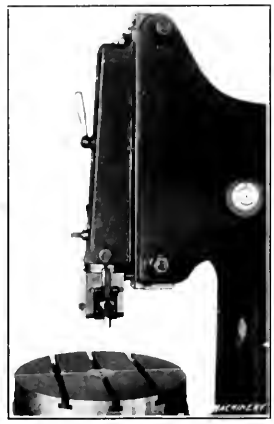

Fig. 3. Ram Head swiveled through 90 Degrees

through crank G and shaft H, to the feed pawl and ratchet clearly shown in the illustration. The various power feeds are engaged through the sliding pinions I, J and K. As shown in the illustration, these pinions are in the outward position, making the power feed inoperative. They are advanced to the inward position for engaging the power feed by hand, and are made of suitable form so that this may be easily accomplished. The power feed is operative in either direction and is controlled through the knob L which operates a clutch, the knob being pushed in or pulled out according to the direction desired. This mechanism gives a very rapid feed action which takes place when the ram is at the extreme upper point of its travel. As the tool is clear of the work at this point, it is not subjected to additional pressure on the return stroke, which results when feeding against the cut. A crank wrench is used for operating the hand feed, the ends of the shaft being squared for this purpose. Micrometer dials are provided, by means of which the various feeds may be very accurately controlled. The periphery of the rotary table is also graduated in degrees. The entire feed mechanism is enclosed, and means have been provided whereby the various feed-screws are absolutely protected against chip interference.

The mechanism for actuating the ram is driven by means of powerful worm gearing, and with this exception it is quite similar in design to the method used on the Pratt & Whitney horizontal shaper. The mechanism is so constructed that it forms a perfect counterweight for the ram; and thus a free, easy running action is obtained. Four speed variations are provided by means of a four-step cone, a very quick return being obtained through the mechanism previously referred to. Any desired length of stroke is readily obtained, the graduated dial M being provided for this purpose. The position of the ram may be changed by releasing binder N and adjusting the screw through shaft O. The ram may be stopped and started entirely independently of the countershaft by means of a friction clutch controlled through lever P. The important feature of angular adjustment to the ram is clearly shown in Fig. 2. This is accomplished by mounting the ram in an independent bearing, the upper part of which is pivoted on a trunnion which enables the bearing, together with the ram, to be swung on an angle. Suitable graduations in degrees are provided for obtaining the required setting. The ram bearing fits in the upright for its entire length and is made considerably longer than the ram, so that the ram is adequately supported even when the maximum length of stroke is used.

Special attention is directed to the method of holding the

tool. As will be noted, a style of toolpost is used which does not project beyond the cutting edge of the tool; consequently it passes directly over the work without interference. In order to accomplish this result the tool is secured from the back, the traditional set-screw which has always been a source of inconvenience on this type of machine having been done away with. The toolpost is carried in a clapper by means of which the same action is obtained as on the horizontal shaper or planer, which permits the tool to clear the work on the return stroke. The clapper is mounted in such a manner as to obtain this result, the force of the cut driving the clapper rigidly against the head. Cases may occur when exceptionally long tools must be used on internal work, where it would be advantageous to bind the clapper solid with the head; and means have been provided whereby this may be easily accomplished.

The ram-head is so designed and mounted in the ram that it is practically as stable as the ram itself, and it may be swiveled to four different positions, one of which is shown in Fig. 3. This feature enables the operator to adjust the tool to the most advantageous position, and as previously mentioned, permits planing two or even four sides of certain classes of work at one setting. In planing the different sides of the work, the rotary table is clamped stationary by means of two binders provided for this purpose. The ram-head is then swiveled to the desired position and either the longitudinal or transverse power feed utilized depending upon the position of the ram-head. This head permits the use of very short tools, especially on external work where practically no overhang is necessary; thus the tool in operation is dependent upon the ram for its stability rather than on the tool itself.

The maximum stroke of the ram is 10½ inches; the diameter of the rotary table, 24 inches; the longitudinal travel, 25 inches; and the transverse travel, 22 inches. The maximum distance from the table to the under side of the ram is 22 inches; and from the table to the under side of the ram bearing, 12½ inches. The net weight of the machine is 5700 pounds.

BARNES 22-INCH SELF-OILED DRILL

The illustrations show a 22-inch upright drill that is a recent product of the Barnes Drill Co., Inc., 814 Chestnut St., Rockford, Ill. This is a heavy-duty machine particularly adapted for severe classes of manufacturing work. One of the distinctive features of the design lies in the provision of a geared pump which supplies oil to all of the bearings and gears of the machine with the exception of the spindle sleeve. A belt-driven pump is also provided on the outside of the machine which supplies lubricant to the work. The machine is all geared with the exception of the short belt used for driving the outside pump, and if desired, a chain drive could be substituted for this belt. Power is provided by a 10-horsepower motor and transmitted through a Morse silent chain drive.

There are eight changes of speed which are obtained by levers within easy reach of the operating position. The spindle may be stopped by placing the shifter lever in a neutral position or by throwing out the clutch gears. With direct drive, the available speeds are 575, 456, 367, and 233 revolutions per minute; and with the back gears in, the available speeds are 144, 114, 92 and 58 revolutions per minute. Ten changes of geared feed are provided which are indicated on an index dial plate. These feed changes are 0.003, 0.005, 0.009, 0.013, 0.017, 0.020, 0.025, 0.041, 0.065 and 0.093 inch per revolution. Heat-treated cut-steel gears are used in the feed box and these gears are flooded with oil. A safety collar protects the machine from being damaged through over-load.

An idea of the capacity of this machine may be obtained from the results of a test which was made with a machine installed at the Foundry and Machine Exhibition in Chicago. A 13/16 Celfor high-speed steel drill was driven at 575 revolutions per minute with a feed of 0.041 inch per revolution. Operating under these conditions, a 2-inch bar of cast iron was drilled through in five seconds, which means that the drill was cutting at a rate of nearly 24 inches per minute. The capacity of the machine is for drills from ½ to 2 inches, and a 2-inch drill can be driven at 144 revolutions per minute

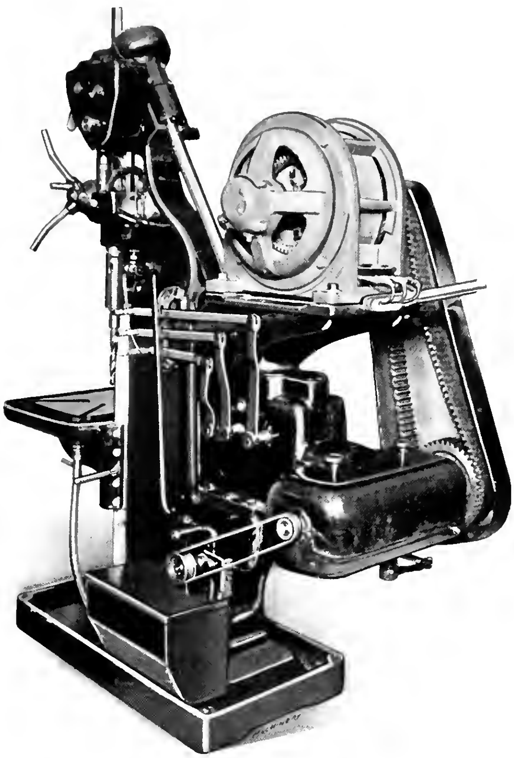

Fig. 1. Barnes 22-inch Drill equipped with Morse Silent Chain Drive

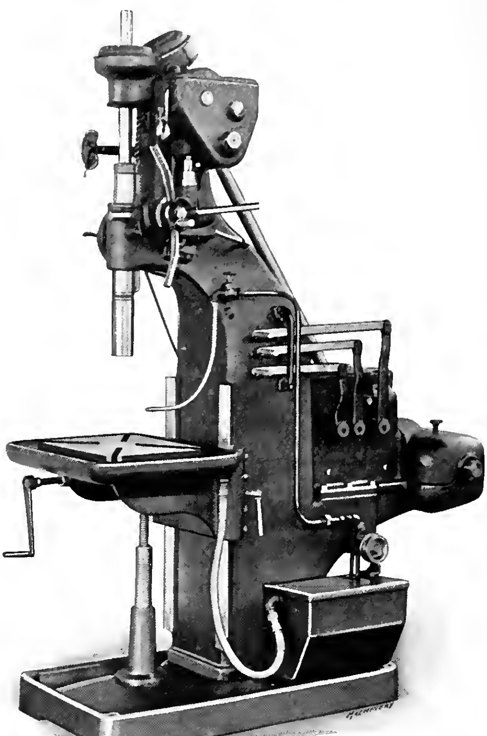

Fig. 2. Front View of Barnes 22-inch Drill

with a feed of 0.025 inch per revolution. The important dimensions of the machine are as follows: Height, 85 inches; distance from center of spindle to face of column, 11 inches; spindle travel, 14 inches; size of table, 14 by 20 inches; vertical travel of table, 23 inches; floor space occupied, 31 by 65 inches; weight of machine without motor, 2620 pounds.

LANGELIER TWO-SPINDLE OPPOSED DRILL

The Langelier Mfg. Co., Providence, R. I., has added to its line a two-spindle machine for drilling watch pendants of the form shown in Fig. 1. Although particularly designed for this class of work, the drill could be used for machining a variety of classes of work where it is necessary to drill, counterbore, or ream holes from opposite sides. An idea of the capacity of the machine may be obtained from the fact that an output of twenty of these German silver pendants per minute was obtained. Holes that do not lie on the same center-line may be produced with this machine by setting one spindle at a greater distance from the frame than the other. When there are several holes to be drilled on each side, the spindles of the machine may be equipped with the multiple heads of this company's manufacture.

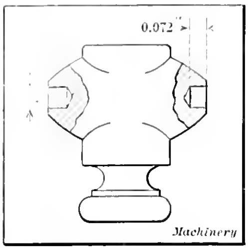

Fig. 1. Watch Pendant drilled by Machine

As it is only necessary for the attendant to insert the pieces to be drilled in the jaws of the jig, a boy or girl of ordinary ability should be able to produce satisfactory results. The jig locates the work in the proper relation to the drills and it is merely necessary to depress the foot treadle, which operates the feed mechanism. The jig is opened and closed automatically by the U-shaped yoke that is fastened to the upper side of a piston operated by compressed air under 30 pounds pressure. A piston valve of special design controls the flow of air to the piston this valve being operated from the treadle rod. The exhaust air from the cylinder which operates the jig jaws is utilized to blow the chips away and keep the jaws clean, so that each piece of work is accurately seated. The faces of the jig jaws are machined so that they fit accurately around the work to be drilled.

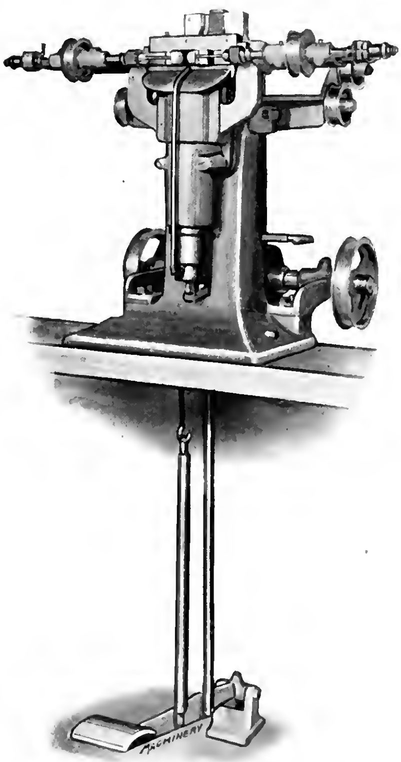

Fig. 2. Langelier Two-spindle Opposed Drill

The spindles are of hardened and ground steel and are arranged for either No. 1 Jacobs or No. 11 Skinner chucks for drills up to 7/32 inch in diameter. An adjustment of 1 inch is provided, and stops are arranged to enable the depth of drilling or counterboring to be accurately regulated. The settings cannot be accidentally changed and require no attention from the operator. After each drilling operation is completed, the spindles are withdrawn by springs located inside the drill frame, and the finished piece drops into a suitable receptacle. Bronze and steel thrust washers and ball thrust bearings are used on each spindle. The spindles are relieved of the tension of the driving belts by means of phosphor-bronze bushings in the drill frame bearings. These bushings extend to almost the middle of the spindle driving pulleys, just enough space for the driving collar being left uncovered by the ends of the bushings. The hub of each driving pulley runs on the projections of these bushings which take the tension of the driving belts, thus relieving the spindle from strain. This construction insures sensitiveness, ease of feed and return, and complete freedom even if the belts are unusually tight.

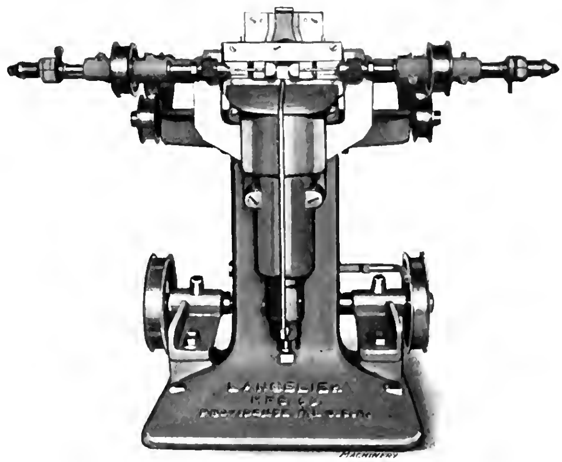

Fig. 3. Nearer View of Langelier Opposed Spindle Drill

The total feed of the spindles is two inches, and the feed is accomplished by causing the cam roll on each drill frame yoke to move in contact with the double inclined plate cam, which will be seen projecting above the center of the machine. Th proper amount of feed is obtained by adjusting stops on the yoke, which is connected to the treadle rod. Each spindle is driven at about 2900 R.P.M. The driving pulleys are located on the base of the machine at the rear; these pulleys are 6 inches diameter by 3/4 inch face and run at 1200 R.P.M. Tight and loose pulleys 5 inches in diameter by 1 1/2 inch face, are also located at the rear of the machine, and are provided with a hand belt shipper. When desired, the machine can be provided with motor drive.

WORCESTER LATHE

The Worcester Lathe Co., 134 Gold St., Worcester, Mass., is now building the 11-inch lathe illustrated in Fig. 1. It will be seen that the head of this lathe is provided with a four-step cone pulley and it is single back geared. The speeds obtained are in geometrical progression and range from 14 to 280 revolutions per minute. The spindle is of 60 carbon steel and runs in cast-iron ring oiling bearings; it is No. 4 Morse taper and has a hole one inch in diameter to adapt the lathe for operation on bar work. The tailstock is of the cut-away pattern and has adjustment to provide for turning tapers. The tailstock is secured to the bed by a single bolt and has an

ample bearing surface on the vee and flat ways on the bed. The carriage bears on the vee at the front of the bed and the flat surface at the rear. It is gibbed under both bearing surfaces. The toolpost is of the ring and wedge type and is suitable for turning tools ½ by 1 inch in size. A compound tool-block is also provided which is graduated in degrees and may be easily set by loosening a single bolt. This block can be quickly removed when it is desirable to use the plain tool-block in its place. The usual form of dial graduated to 0.001 inch is provided on the cross feed screw. The apron is of the worm-driven type and the power cross feed is engaged by means of a pull knob.

The lead-screw is only used when the machine is engaged on thread cutting operations. Three changes of feed are obtainable in the gear box and other combinations of three

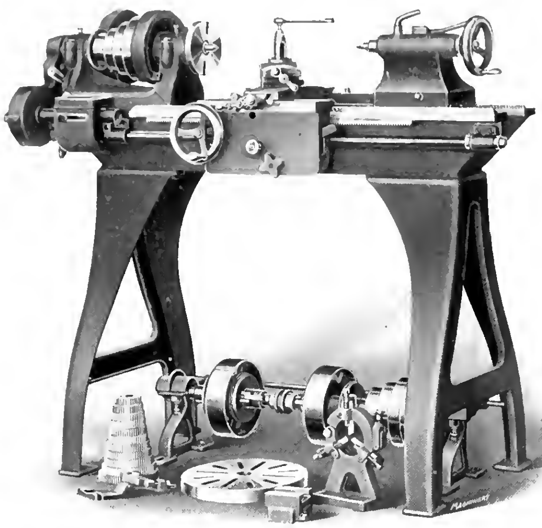

Fig. 1. Worcester Eleven-inch Lathe

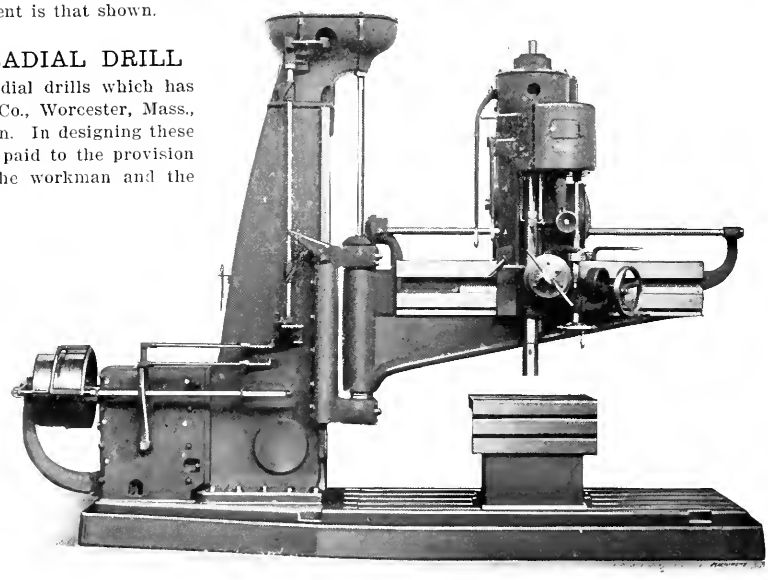
changes may be obtained by adjusting the gearing on the machine. The machine can be arranged for cutting metric pitches. The countershaft used is of the flat disk friction type with ring oiled bearings. The bed is rigidly braced by cross tie members. The regular equipment is that shown.

REED-PRENTICE HEAVY RADIAL DRILL

The 6-foot size of a line of heavy radial drills which has been brought out by the Reed-Prentice Co., Worcester, Mass., is shown in the accompanying illustration. In designing these machines, particular attention has been paid to the provision of safety devices which protect both the workman and the machine from injury. All gears are encased in guards which are cast integral with the machine. The counterweight is so constructed that it is impossible for it to drop in the event of the chain breaking. Safety stops are used to prevent the saddle from feeding too far in either direction, thus protecting the gearing from damage. Particular attention has also been paid to the lubricating system in order to insure long life for all wearing parts.

The speed box is located behind the post to which it is bolted. The speed range obtained is adequate for all ordinary working conditions. Four speeds are provided in the speed box—any one of which may obtained while the machine is running, and if desired while the drill is actually under cut. The clutches are so arranged that it is impossible to engage conflicting ratios, as it is necessary for both levers to be in the operating position in order to start the machine.



Reed-Prentice Six-foot Heavy Pattern Radial Drilling Machine

The upper portion of the post is cast so as to provide for encasing the driving gears as well as the saddle raising gears. By means of the vertical rod at the side of the post, the saddle raising gears may be engaged. The arrangement of the gearing is such that the down feed is twice as fast as the up feed. The arm is mounted in a bearing provided with

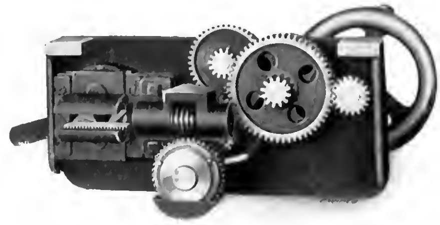


Fig. 2. Apron of the Worcester Lathe

ball thrust collars at the lower end to facilitate swinging it easily. The sliding head is assembled as a complete unit before being placed on the arm, the horizontal arm shaft being located by means of jigs and fixtures which insure perfect alignment of the shaft. Two speed mechanisms are provided in the head which give a slow speed with ample power for heavy work and high speed for light work. This arrangement relieves the strain on the shaft in both cases. These two speeds are multiplied by the four changes in the speed box to give a total of eight speeds without the back gears and sixteen speeds with the back gears.

The tapping attachment is always available for use and is controlled by a lever located at the right of the head directly above the arm. An important feature of these machines is the introduction of helical cut gears which reduce vibration and noise to a minimum. The machines are either built with ball bearings throughout or with bronze bushed bearings. The ball bearing drills can be operated with a power consumption of about 50 per cent of that required for machines with plain bearings. These machines are built in 2½, 3, 4, 5, 6 and 7 foot sizes.

NIAGARA TRIMMING PRESS

The trimming press shown in the accompanying illustration is a recent product of the Niagara Machine & Tool Works, Buffalo, N. Y. This machine was built for trimming drop-forgings, but a press of this type would also be adaptable for the manufacture of various kinds of hardware, automobile and bicycle parts, and for heavy sheet metal work. Where a trim-

ming press is built with the flywheel and pulley adjoining the main gear, and with an outboard support for the overhanging part of the shaft, a considerable amount of space is occupied. This is objectionable for a press that is to be used for trimming drop-forgings, as it is desirable to have the press located as close to the drop hammer as possible. The independent outboard bearing also makes it difficult to keep the driving shaft in the proper alignment and there is likely to be trouble with the bearings where such a construction is employed. As the bearings are located close to the bed of the press, they are also likely to be subjected to undue wear by particles of dirt and scale finding their way into them. The pulley and flywheel are also in the operator's way and must be carefully guarded to prevent accident.

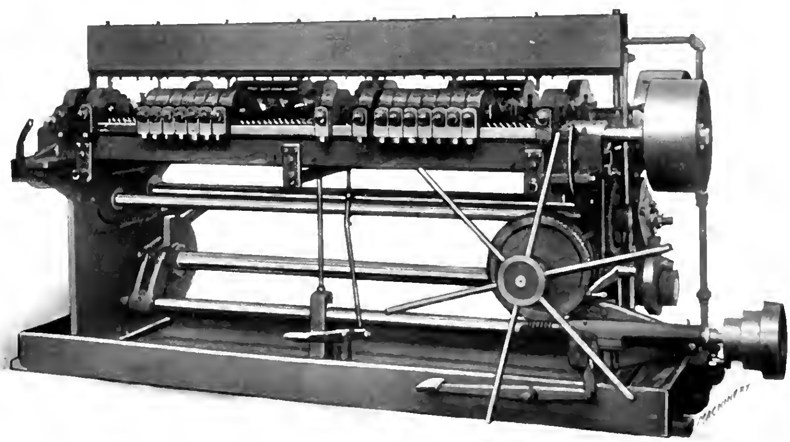
Niagara Press for trimming Drop-forgings

These disadvantages have been eliminated in the new Niagara trimming press. It will be seen that the flywheel, pulley and backshaft are mounted at the top of the machine, where they are out of the operator's way and where the bearings are not exposed to scale and dirt. The necessity for an outboard bearing is also eliminated, thus making the machine self-contained. The press occupies a minimum amount of floor space, is accessible from all sides, and can be located very close to the drop hammer. The motion of the press is controlled by an automatic jaw clutch equipped with a gravity disengaging device. The inner slide is provided with a dovetail recess for use in mounting, trimming and forming dies. The outer slide receives its motion from an eccentric keyed to the main shaft. Both the outer slide and the bed have a recess machined in them which provides for mounting adjustable holders for cutting-off tools. These trimming presses are built in different sizes; they are equipped with either a single or double crankshaft and with straight or gap housings. The smallest sized machine weighs 5000 pounds and the largest, 60,000 pounds.

MOLINE TOOL CO.'S DUPLEX PIPE DRILLING MACHINE

The Moline Tool Co., Moline, Ill., has recently added to its line the duplex pipe drilling machine illustrated herewith. It will be seen that this machine embodies the characteristic features of design that have been worked out by this company. The feed is actuated by a cam and can be quickly changed to adapt the machine for drilling through one wall of the pipe or through both walls, as desired. It will be evident from the illustration that the drill heads are arranged on opposite sides of the pipe. This arrangement enables holes to be drilled very close together. For example, using heads 2 inches in width and feeding each drill through both walls of the pipe, it is possible to drill holes with only 1 inch between centers. When the holes to be drilled are not closer than the width of the heads, a great saving of time can be effected by setting the drills on one side of the pipe opposite those on the other side. With this arrangement, both walls of the pipe can be drilled in the time that would ordinarily be required for drilling one hole, and no time is lost in feeding the drills through the gap.

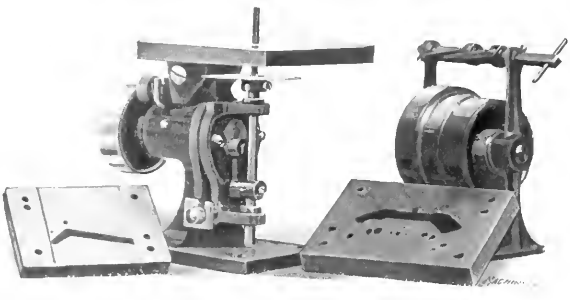
When the pipe is only drilled through one wall by each drill, a smoother product is obtained, as all fins and burrs are on the inside and there is nothing to injure the hands of the man who is to handle the product. The operation of the machine is expedited through the use of an automatic clamping jig which is operated by a cam. Where holes are to be drilled through both walls from each side of the pipe, the drills are not only lubricated from the outside but also by forcing a stream of lubricant through the pipe that is being operated upon. This is unnecessary where only one wall of the pipe is being drilled. The spindles of the machine are hollow and adjusting screws are provided to set the drills to exactly the desired point. Machines of this type can be built in any length up to 10 feet and equipped with any number of heads to suit the requirements of different classes of work. When so desired, hand feed can be substituted in place of the power feed used on the machine shown in the accompanying illustration.



Moline Duplex Pipe Drilling Machine

PATTEN BENCH FILING MACHINE

Mr. E. L. Patten of 4011 Shenendoah Ave., St. Louis, Mo., is now manufacturing the bench filing machine shown in the accompanying illustration. The operating table of this machine can be adjusted to any desired point over an angle of 15 degrees, in either direction from the horizontal, and rigidly locked in the desired position. Similarly, the file carrier can be adjusted up to 15 degrees, in either direction from the vertical, and locked in position. These adjustments of the table and file carrier are obtained by screws and make it possible to obtain any required angle for die work, thus doing away with the necessity of filing by hand. The working parts of the machine are protected by guards which keep the filings from working their way into the bearings. All bearings are made of liberal size and means of adjustment are provided to take up wear in those bearings upon which the pressure is high. These filing machines are made in two styles, known as Nos. 1 and 2. The No. 1 machine is fastened to the bench and driven by a countershaft. The No. 2 machine is equipped with a sub-base and is driven by a direct-connected motor. This makes it a complete unit.



Patten Bench Filing Machine

HORTON DRILLING AND TAPPING CHUCK

The E. Horton & Son Co., Windsor Locks, Conn., is now manufacturing the quick change collet chuck shown in the accompanying illustrations. These chucks are adapted for both drilling and tapping operations. The drill or tap is held in a collet and in order to mount the tool in the chuck ready for use, it is merely necessary to grasp the knurled collar and hold it back against the rotation of the spindle. This causes a pair of retaining dogs to be drawn back into the body of the chuck so that the collet can be slipped into place. The knurled collar is then released and the action of a spring forces the dogs inward, so that they engage a groove in the collet and secure it in the chuck.

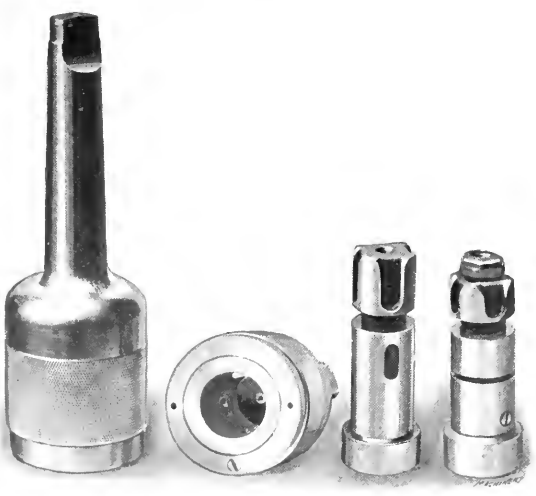


Fig. 1. Horton Chuck and Drilling and Tapping Collets

Fig. 1 shows the chuck and the collets used for drilling and tapping; and Fig. 3 shows a cross-sectional view of the chuck and tapping collet and also a drilling collet. These illustrations, in connection with the following description, will make the principle upon which the chuck operates quite clear. When the knurled collar *A* is held back, the pilots on the retaining dogs *B* move in contact with cam surfaces which cause the dogs to be drawn back into the body of the chuck. The collet is then pushed up into the chuck where it is centered by means of the tool steel plug *D*. The squared ends of the collet are engaged by the studs *E* which afford positive drive. When the knurled collar *A* is released, the retaining dogs *B* are forced inward by the action of spring *C* and engage in the groove machined in the body of the collet.

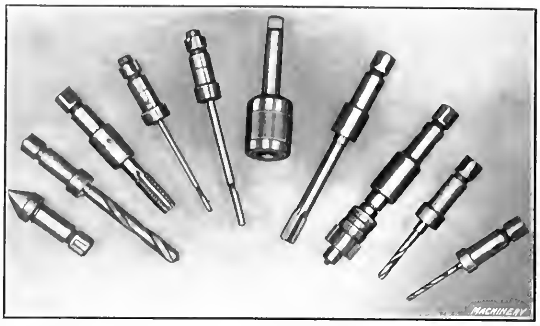

Fig. 2. Examples of use to which Horton Chuck can be put

The collet is made 0.015 inch smaller than the bore of the chuck and the design is such that the collet floats in a way which assures the desired alignment for tapping or reaming. As the collet is positively held in the chuck by the retaining dogs, there is no danger of it dropping out and causing tools to be broken. Another feature of this arrangement is that the chuck can be used for counterboring the under side of a hole or for similar operations. Where there are a number of operations to be performed on a single piece, the necessary tools can be mounted in individual collets and the change of tools can then be made with great rapidity.

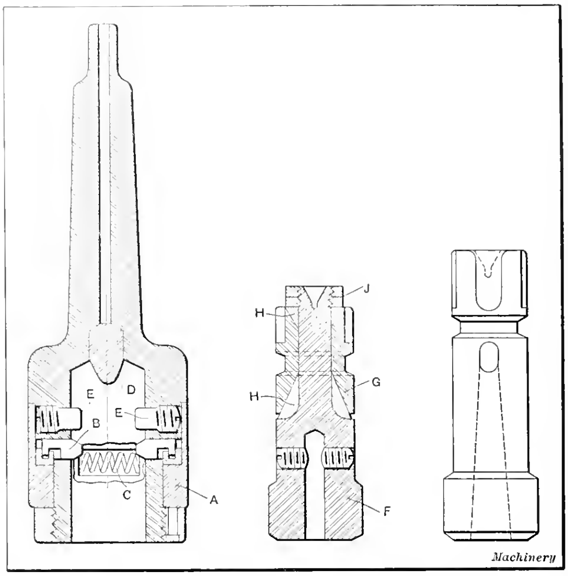

Fig. 3. Cross-sectional View of Chuck and Tapping Collet

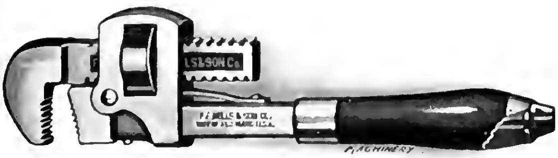
Referring to the cross-sectional view shown in Fig. 3, it will be seen that the tapping collet consists of a body *F* and sleeve *G*. Conical fiber frictions *H* are located between the body of the collet and the sleeve, and by adjusting the nuts *J* any desired tension may be obtained. In this way, the frictions will slip in the event of the tap binding, preventing the tool from being broken. The parts of the chuck are held together by means of the adjusting nut at its lower end. It will be seen that this nut is split and fitted with a binding screw which

holds it securely in place. There are no projecting parts on the chuck which can injure the man who is operating it. All studs and other parts subjected to severe strain are of hardened steel in order to provide ample wear. This chuck is the invention of Mr. Oscar F. Bergsten of Worcester, Mass.

F. E. WELLS STILLSON WRENCH

The Stillson pattern pipe wrench illustrated herewith is a recent product of F. E. Wells & Son Co., Greenfield, Mass. This wrench is similar to the familiar style of Stillson wrench, the distinctive feature being that the jaw has been materially

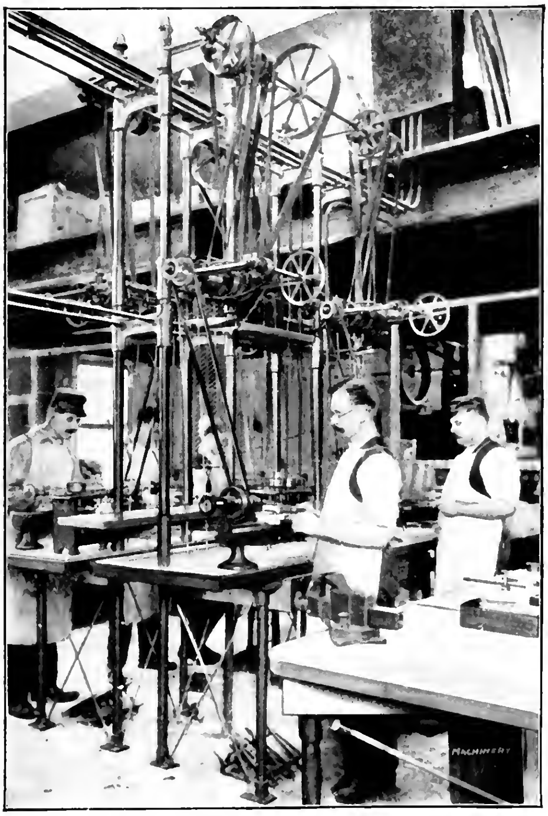


F. E. Wells Stillson Wrench with Heavy Jaw and Double Ferrules on Handle

strengthened at the angle, which is the point where the greatest strain is experienced and where the jaw is most likely to break. It will also be seen that double ferrules are provided on the handle which keep the wood from splitting. These improvements add materially to the durability of the tool.

HARDINGE UNIT SYSTEM OF OVERHEAD WORKS

A unit system of overhead works adapted for use in connection with bench lathes, milling machines and sensitive drill presses, has recently been brought out by Hardinge Bros., Inc., 4201 Ravenswood Ave., Chicago, Ill. This equipment



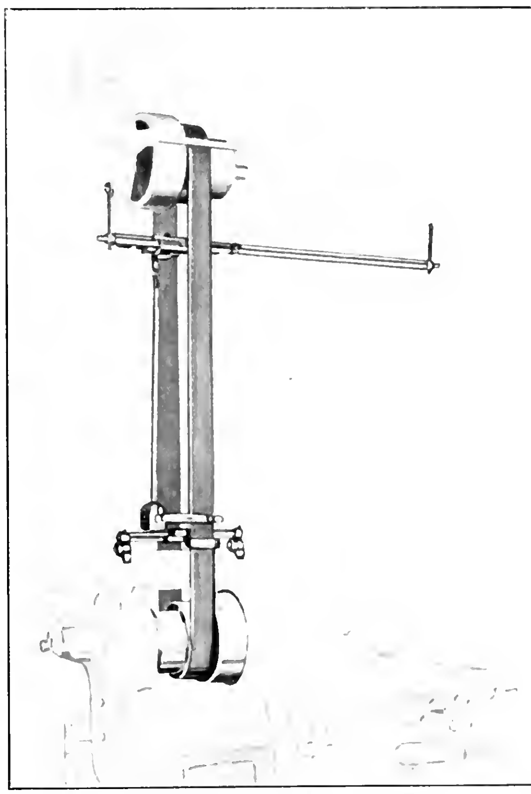
Hardinge System of Unit Overhead Works

differs from the countershaft stand formerly built by this company in that it is not dependent upon the height of the ceiling, the present design constituting a complete unit which occupies a minimum amount of floor space. It will be seen from the illustration that there are four sets of uprights which are made from 1¼-inch iron pipe. Each pair of uprights is held together by means of three yokes which effectually eliminate vibration.

The unit is driven by a one horsepower motor which is mounted on a platform supported by the two middle sets of uprights. This motor has a pulley on each end of its shaft, these pulleys being belted to the main countershafts which drive the machines on the benches at each side of the stand. The countershafts which drive the individual machines on these two benches are driven from the two main countershafts, and adjustment is provided in the individual countershafts for regulating the belt tension. The unit shown in the accompanying illustration has two lathes located on the right-hand bench, while the bench to the left carries one lathe, a drill press and a hand milling machine. Of course the arrangement of units can be modified to meet the requirements of different shops.

LE BLOND MECHANICAL BELT SHIFTER

The R. K. LeBlond Machine Tool Co., Cincinnati, Ohio, is now manufacturing a mechanically operated belt shifter that is particularly adapted for use on milling machines, lathes and other cone-driven machine tools. This device consists of two racks, one of which is mounted on the headstock of the machine and the other on the countershaft. A belt shifter is



LeBlond Mechanical Belt Shifter for Milling Machines, Lathes and other Cone-driven Machine Tools

secured to each rack and in order to shift the belt from one step on the cone pulley to an adjacent step in either direction, it is merely necessary to turn a crank handle through one complete revolution. This crank operates two pinions that are in mesh with the racks, the connection being through bevel gears and a telescopic shaft, the length of which may be adjusted for different heights of ceilings.

The two racks and belt shifters are fixed relatively to each other and one shifter acts one-half revolution of the crank in advance of the other. In this way, one belt shifter throws the belt from one step on the machine cone to the next smaller step by turning the crank through one-half revolution: the other belt shifter then comes into action and the remaining half revolution shifts the belt on the countershaft cone pulley

from one step to the next larger step. If a reduction of speed is desired, the crank is turned in the reverse direction and the steps just referred to will then be reversed. As the crank is always turned through one complete revolution, the operator becomes accustomed to reaching for the handle in the position that it always assumes. The operation of this belt shifting device is such that the belt is automatically locked in position and cannot be shifted except by turning the crank. Stops are also provided in both directions which make it impossible to throw the belt entirely off the cone pulleys. It is stated that belts are longer lived where this shifting device is used because they are held in place and cannot curl up against the edges of the adjacent step of the cone pulley. For this reason, wider belts can also be used on a cone pulley with steps of a given width. It is such a simple matter to shift a belt in this way, that a mechanic will always operate his machine at the proper speed.

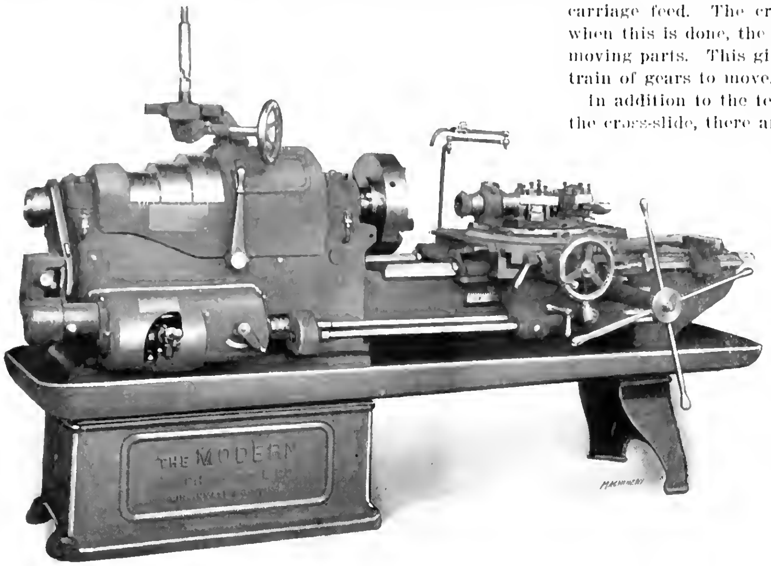


Fig. 1. Modern Flat Turret Lathe equipped with a Cross-slide

"MODERN" FLAT TURRET LATHE

In the July, 1912, number of MACHINERY, the flat turret lathe manufactured by the Modern Machine Tool Co., 4657 to 4659 Spring Grove Ave., Cincinnati, Ohio, was illustrated and described. A new machine has recently been brought out by this company which is built along the same general lines that were followed in the design of the preceding lathe. The important feature of the present machine lies in the provision of a cross-slide upon which the turret is mounted. This cross-slide is provided with ten stops which may be used to locate the turret when moving in either direction, the maximum cross travel being 7 inches. The stops may be used for one tool or in any combination for a series of tools, being engaged by a series of plungers located at the front of the carriage. All of these plungers are operative from any location of the slide. The center position is automatically and positively located by means of a taper locking bolt on the head end of the carriage, which is disengaged when the cross-feed is used. The cross-slide has a bearing surface of 195 square inches on the carriage and is equipped with a long, narrow dovetailed guide to prevent cramping. It has a taper gib which provides for taking up wear and a parallel gib for holding the slide down.

The graduations for obtaining accurate adjustment of the cross-slide are located on the periphery of the handwheel on the cross-feed screw. The cross-slide has independent feed in both directions and the feeds may be engaged while the machine is in operation. The feed is started, stopped or reversed by means of a single lever and is entirely independent of the carriage feed. The cross-feed can be operated by hand and when this is done, the screw and two bevel gears are the only moving parts. This gives an easy action as there is no heavy train of gears to move.

In addition to the ten stops for regulating the movement of the cross-slide, there are twelve independent stops for controlling the longitudinal movement of the carriage. Two of these stops are available for each of the six tools that are carried in the turret. The turret is a circular plate 18 inches in diameter with the lock bolt located close to the edge of the turret. It will be seen from the illustrations that the head and bed of this lathe are cast in one piece to insure the greatest possible rigidity. The bed is supported on a three-point bearing. The head is friction back geared, the gears being located inside the bed under the spindle. The carriage is gibbed to the outer edge of the bed by flat gibs and has a bearing for its entire length on the vees of the bed.

The feed-box provides eight positive geared feeds ranging from 0.005 to 0.085 inch and these feeds are operative in either direction. All gears are made of steel. Referring to the head of the lathe it will be seen that a belt shifter is used which is operated by a handwheel. The design of this shifter is such that one turn of the wheel moves the belt from the center of one step on the pulley to the center of the adjacent step. The principal dimensions of the machine are as follows: Swing over vees, 20 inches; swing over carriage, 16 inches; swing over turret, 6 inches; maximum travel of carriage, 26 inches; maximum travel of cross-slide, 7 inches; diameter of hole in spindle, 2⅜ inches. The speed range provided on this lathe is from 18 to 350 revolutions per minute; the machine occupies a floor space of 4 by 11 feet; and the net weight is 6150 pounds.

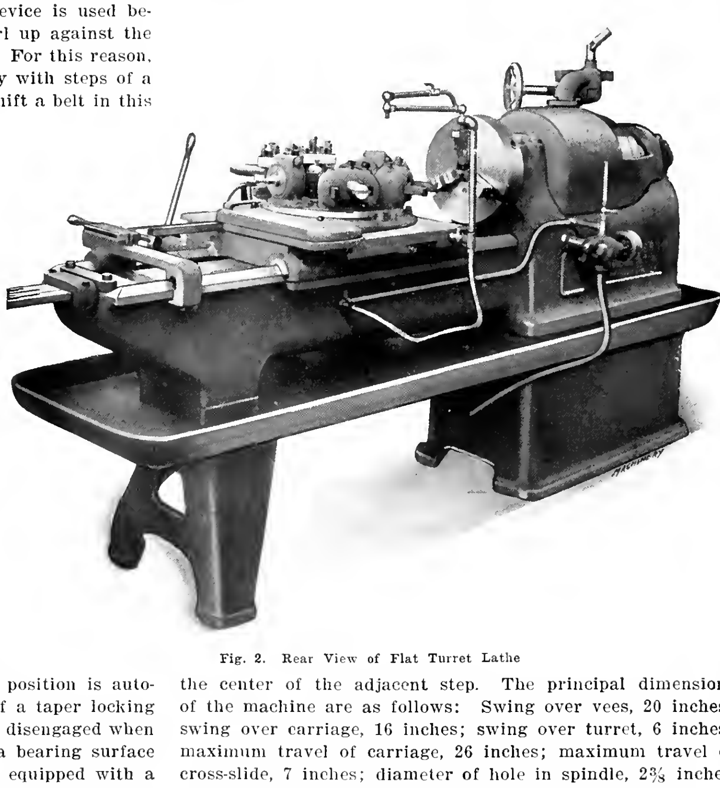

Fig. 2. Rear View of Flat Turret Lathe

HARRINGTON MULTIPLE RADIAL DRILL

Edwin Harrington, Son & Co., Inc., Philadelphia, Pa., are now building the multiple radial drill shown in Fig. 1. Five of these machines were recently built for use in drilling boiler plates in locomotive shops, and machines of this type could also be used to advantage on various other classes of work. It will be seen that there are four radial arms mounted on a single cross-rail, and lateral power traverse is provided for these arms by a $7\frac{1}{2}$ horsepower motor which runs at 750 revolutions per minute. This movement is provided in addition to the in and out and radial movements of the arms and spindles. A larger view of one of the drill heads is shown in Fig. 2, from which the design will be more clearly understood.

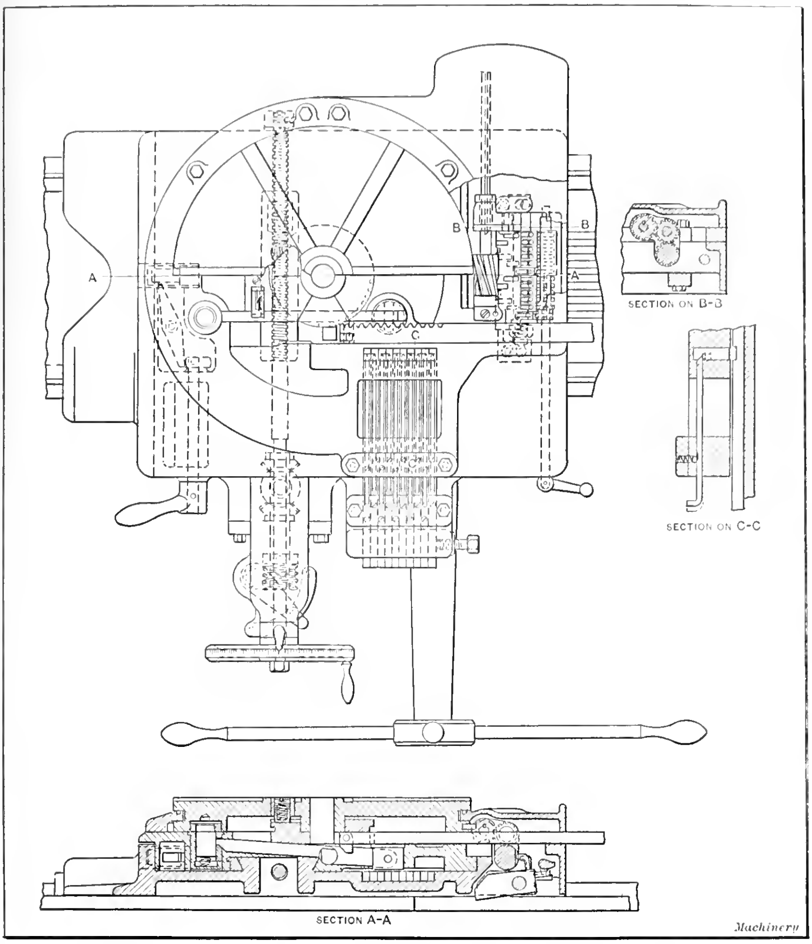

Fig. 3. Longitudinal and Transverse Stop Mechanism of Modern Flat Turret Lathe

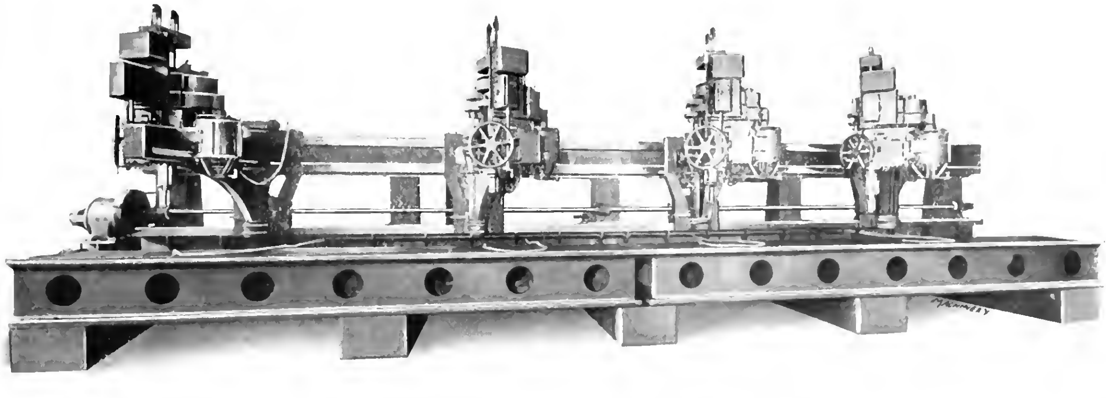

Fig. 1. Harrington Multiple Radial Drill for drilling Boiler Plates

The spindle heads have adjustable steel rollers running on a wide track at the top of the arm, which provides for easy movement of the head by means of the handwheel and worm through which this movement is controlled. The $7\frac{1}{2}$ horsepower variable speed motors which drive the heads are mounted behind the arms, and the controller handles are brought down behind the traverse wheels. The spindles are forged from high-carbon steel and run in large diameter sleeves. Ball bearings are provided to receive the drilling thrust. Three selective feed changes are provided, the feed being driven by gears from the spindle through a safety friction clutch. A positive tooth clutch controlling the feed worm can be operated by hand or by means of an automatic trip. Hand feed is effected by means of a wheel on the worm shaft.

The arms are of heavy box section and are mounted on the saddles by means of roller and ball-thrust trunnion bearings. The binders on the top trunnions are operated by air supplied through hose connections to valves on the spindle heads. The saddles have a long bearing surface on the top rail to prevent tipping and are supported against the lower rail where the drilling thrust is received. The power traverse gearing carried on each saddle permits independent motion in either direction by means of a double clutch located between bevel gears. The motor for driving the traverse operating shaft is located at the left-hand end of the machine at the base. The cross-rails are carried by five box section uprights which are supported by a cast-iron base running parallel with the cross-rail. Five cast-iron sub-bases support both the cross-rail and the table, these bases being located below the floor level. The table is made in two parts which are joined at the center to make one continuous surface. Three T-slots run the full length of the table and a channel is provided which drains the oil back to the tank in the base of the machine. Cutting fluid is supplied by a motor-driven pump which delivers it to each spindle through flexible hose.

The range of the machine can be judged from the follow-

ing dimensions: Shortest distance between spindles with arms straight, 4 feet; greatest distance between spindles with arms straight, 40 feet; vertical traverse of spindles, 15 inches; greatest distance of spindle to table, 28 inches; shortest distance of spindle to table, 13 inches. In and out move-

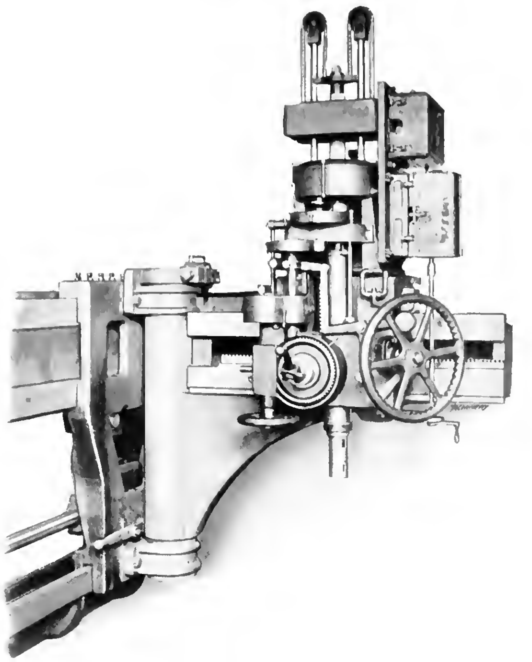

Fig. 2. View of One of the Heads of the Harrington Drill

ment of head on arm, 30 inches; spindle speeds, 75 to 300 R. P. M.; feeds per revolution, 0.005, 0.009 and 0.015 inch per revolution. Size of table, 40 feet by 2 feet 6 inches; floor space occupied by machine, 9 feet 9 inches by 43 feet 4 inches; weight of machine including motors, 85,500 pounds.

FRANKLIN MOORE "IMPERIAL" CHAIN HOIST

A new chain hoist which has just been put on the market by the Franklin Moore Co., Winsted, Conn., incorporates some interesting features in its design and construction, as the accompanying illustrations show. One commendable feature of this hoist is that there are no iron castings interposed between the points where the load is applied and suspended. The "load end of the hoist" comprises three sheet-steel disks which are held together by through bolts and nuts and separated by spacing bushings. The load is carried directly on the casehardened load-shaft passing completely through the three steel plates, and the sprockets on which the chain is held are keyed to it. The load-shaft runs in roller bearings located at each side of the chain sprocket. The roller bearings are held in outer bearings which are both recessed into and riveted to the steel plates. This construction reduces friction to a minimum and at the same time provides a means for keeping the hoist in repair at all times.

The construction of this hoist, referring particularly to the 1-ton size illustrated, and starting at the point where the power is applied at the handwheel by the chain, is as follows: The handwheel shown to the left in Fig. 1, which is an iron casting, is operated by the chain shown, and is fitted to the handwheel shaft, which is provided with a right-hand square thread having a lead of 5/8 inch. This handwheel shaft passes completely through the hoist and is both casehardened and ground. Bearing up against the handwheel is a cast-iron friction gear, these two surfaces being separated by a galvanized iron disk. The opposite side of the friction gear contacts with a leather washer, which is held on a cast-iron friction disk, this being keyed to the handwheel shaft. The large friction gear meshes with a small ratchet gear (the ratio being 4 to 1), which has five internal ratchet teeth in which a casehardened steel pawl drops as soon as the operator releases his pull on the hand-operating chain. This pawl is longer than the diameter of the shaft in which it is fitted (and also the hole in the gear) so that it is impossible for the ratchet gear to slip owing to the pawl not seating properly. It is not spring controlled, but is thrown into lock by the action of the friction gear itself.

The handwheel shaft, as previously mentioned, passes entirely through the three sheet-steel disks, and on its outer end has teeth cut in it to form a pinion. This pinion meshes with two large intermediate gears, one on each side, these, in turn, being keyed onto the extended shoulders of two intermediate pinions. These pinions mesh with the load-gear which is keyed to the load-shaft, the latter also passing through the three sheet-steel plates. The load-shaft which carries the chain sprocket is located in cast-iron bearings on the outer end where no load is taken, and on the inner end is supported by roller bearings, as previously mentioned. The other bearings for both the load and handwheel shafts are made from cast iron and are held in and riveted to the sheet-steel plates so that they can be replaced when worn.

This design of hoist is built in sizes ranging from ½ ton to 20 tons capacity. The sheet-steel plates which form one of the important parts are made from disks varying in thickness from 3/16 to 5/16 inch, depending on the capacity of the hoist. All gears in the power side of the hoist are made of special gear steel, and these are enclosed in a drawn sheet-steel cover, making the entire mechanism dust-proof, increasing the lightness and at the same time making it unbreak-

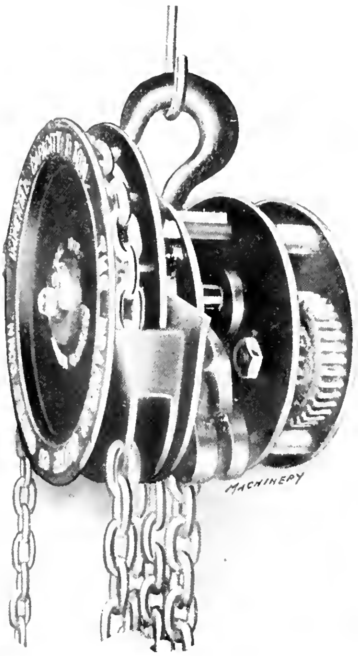

Fig. 1. The Franklin Moore "Imperial" Chain Hoist

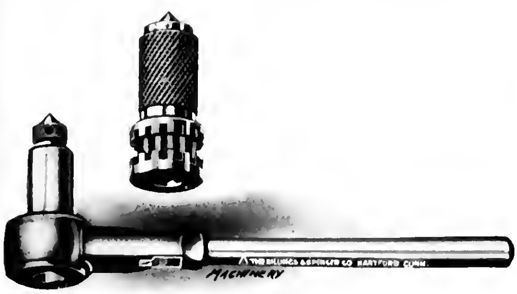
Fig. 2. Hoist under 2000 Pounds Test

able. All gears run in grease, and as they are enclosed in a dust-proof cover need no attention. The chain is guided over the sprocket by rollers providing a free and smooth action.

Another important feature in connection with this hoist is the reversing key which is designed in such a manner that wear on the friction can be easily compensated for. This key has a square hole and fits on the square end of the handwheel shaft. As the frictions wear, the position of this key can be changed by simply removing the nut and turning the key around one-quarter turn.

BILLINGS & SPENCER DOUBLE-ACTING RATCHET

The double-acting ratchet shown in the accompanying illustration is a recent product of the Billings & Spencer Co., Hartford, Conn. This tool is known as the No. 0 size and is intended for light work. The distinctive feature of the design lies in the ability to change the sockets quickly and easily without requiring the use of a wrench or any other tool. This



Billings & Spencer Double Acting Ratchet

ratchet is provided with two removable sockets for handling taper and square shank drills. The taper socket is No. 1 Morse taper and has a capacity for twist drills from 1/16 to 1 9/32 inch. The square socket takes bit-stock, twist drills. The tool is drop-forged and all working parts are hardened.

BROWN HAND-OPERATED CRANE

The Brown Hoisting Machinery Co., Cleveland, Ohio, is now manufacturing the hand-operated traveling crane illustrated in Fig. 1. It will be seen that the cross member of this crane consists of a single I-beam which is supported at both ends by a truck frame of cast steel. The I-beam is of standard size and its lower flange serves as a track for the trolley to run on. The I-beam rests on two planed surfaces at the center of each truck frame, to which it is securely bolted. The truck frame is of light construction; it is so designed that no undue strains are put on any member and the load is equally distributed on the wheels. The simplicity of the construction makes it possible to erect this crane very quickly and it can be used where there is little overhead room.

It will be seen that each truck frame is carried by two wheels and that a bearing is provided on each side of the wheels. These bearings are secured to the frame by means of U-bolts. For cranes of 1/4 to 1 ton capacity, bronze-bushed bearings are used, the bearings being scored to insure efficient lubrication. Larger cranes are equipped with roller bearings of the type shown in Fig. 2, which make the operation of the crane very easy. The provision of a bearing on both sides of the wheel keeps it exactly perpendicular, regardless of any side pressure which may be exerted on the wheel flange; this distributes the wear evenly over the bearings and

Fig. 1. The Brown Hand Operated Crane

insures satisfactory operation. Each crane is equipped with a "squaring shaft" connected to one wheel on each truck. The arrangement of this shaft will be readily understood by referring to Fig. 1 and its use insures a uniform travel of both the truck frames and prevents undue strains on any part of the crane.

Cranes with a capacity of from 1/4 to 1 ton, with spans not exceeding 20 feet, are not provided with a travelling mechanism. Such cranes are propelled by pushing or pulling on the load. Cranes of larger capacity are equipped with a hand

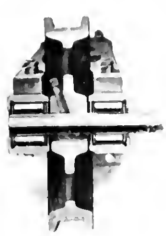


Fig. 2. Roller Bearing

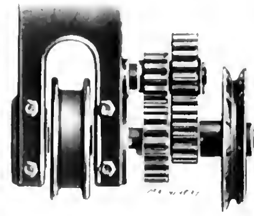

Fig. 3. Traveling Reducing Gears

traveling chain and sprocket wheel which is clearly shown at the left-hand side of Fig. 1. The larger sized cranes are fitted with traveling reducing gears of the type shown in Fig. 3; these gears reduce the amount of pull required on the hand traveling chain to move the crane along the runway. These cranes are equipped with either a plain or geared Brownhoist steel plate trolley and with a Yale & Towne triplex chain block or a Brownhoist electric hoist as desired.

TILTON ENDLESS WOVEN BELTS

The Tilton Mills, Tilton, N. H., are now manufacturing a line of endless woven belts. These belts are suitable for a

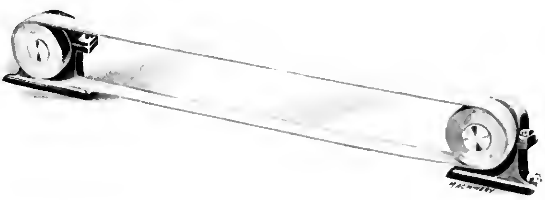

Fig. 1. A Small Size of Tilton Endless Woven Belt

variety of purposes, but the smaller sizes have been found particularly well adapted for driving high-speed machinery,

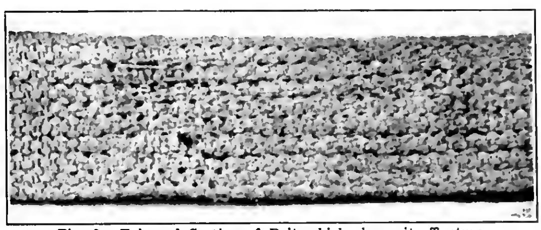

Fig. 2. Enlarged Section of Belt which shows its Texture

owing to the absence of any seams or joints. A case in point is the Rivett internal grinder, upon which the Tilton belts have been used to very good advantage. These machines are driven at angular speeds up to 25,000 revolutions per minute, and operating under such conditions the woven belts give perfectly satisfactory results.

This line of endless woven belts comprises sizes up to 15 feet in circumference by 3 inches width. The belts are made in from 1 to 6 ply and the individual layers of the belt are stitched together. One of the Tilton endless belts is shown in Fig. 1 and an enlarged section of the same belt is illustrated in Fig. 2. A good idea of the texture and way in which the belts are stitched will be gathered from the latter illustration. In conclusion, it may be mentioned that these belts are treated in such a way that they are not in the least affected by moisture or oil.

DAVIS-BOURNONVILLE NO. 2 OXYGRAPH

The Davis-Bournonville Co., 30 Church St., New York City, has added to its line of mechanically guided cutting torches, the No. 2 oxygraph, here shown. This machine is adapted for a variety of cutting operations of the kind usually handled on a vertical slotting machine or horizontal shaper and does the work much faster than a cutting tool. The machine is provided with a substantial bed for holding heavy steel plates or forgings and there is an extension at the rear which supports the pantagraph motion that guides the cutting torches. The double pantagraph frames are made of steel tubing and all joints are provided with ball bearings. A horizontal bar is secured to the pantagraphs at the points opposite their pivots on the vertical supports. The tracing wheel which governs the movement of the torches is attached by a sliding block to any position on this bar according to the pattern or drawing to be followed and the required position of the torches. One or more torches are attached to the bar by similar sliding blocks. The illustrations show the tracing wheel at about the middle of the bar and a torch on each side making duplicate cuts.

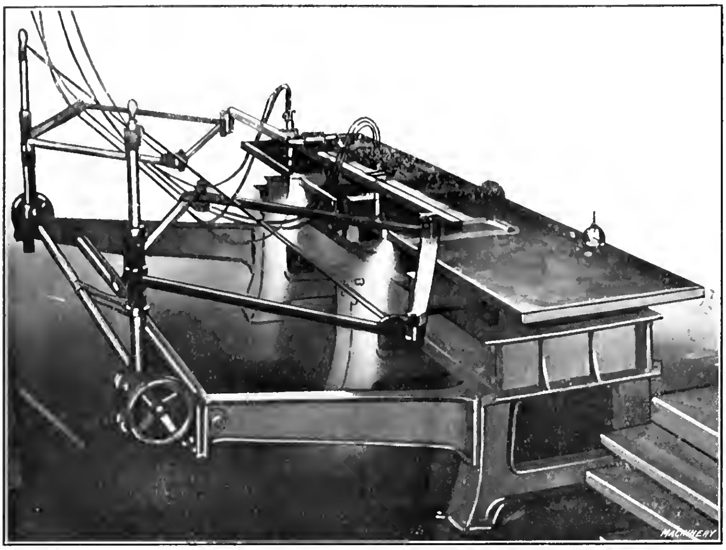

Fig. 1. Davis-Bournonville No. 2 Oxygraph showing Vertical Adjustment for Pantagraph Motion

The tracing wheel is driven by a small electric motor which can be connected to an ordinary lamp socket on either alternating or direct current. This motor is provided with a centrifugal governor for regulating the speed at which the torches move over the work. The drive is taken from the motor by means of a worm on the end of the spindle which meshes with a worm-wheel on a vertical shaft. Another worm at the lower end of this vertical shaft meshes with a worm-wheel on the shaft which carries the tracing wheel. A full size drawing of the cut that is to be made is placed under the tracing wheel; the tracing wheel follows the outline on the drawing and causes the torch or torches to follow a similar path over the work. The most irregular outlines can be easily followed. The speed at which the machine cuts is from 3 to 12 inches per minute, according to the thickness of the work, and in addition to the centrifugal governor on the motor further means of adjustment are provided by three worm-wheels having 95, 50 and 30 teeth, respectively. The motor is supported on a pivot and may be swung around so that the worm is brought into the required position to mesh properly with any one of these wheels.

The torches used are the regular No. 640 two-hose machine cutting torches manufactured by the Davis-Bournonville Co. Vertical adjustment of the torches is obtained by means of a pinion operated by a thumb-screw which meshes with a rack cut in the body of the torch. Referring to Fig. 1, it will be seen that the entire pantagraph motion can also be adjusted vertically by means of a handwheel at each end of the machine. These handwheels operate pinions which mesh with rack teeth cut in the vertical supports, and provide a movement of 12 inches. Any further adjustment that is necessary is then obtained by regulating the height of the torches with the thumb-wheels. The latter adjustment is particularly convenient on certain classes of work where the thickness varies, so that it is necessary to adjust the height of the torch while cutting. During the operation of this machine, witnessed by MACHINERY's representative, a 1-inch plate was cut at the rate of 10 inches per minute. There was a little slag left on the cut surface, but a few taps with a wrench knocked this off and left the surface of the metal perfectly clean.

The torches use oxygen and acetylene on the high pressure positive mixture principle. They have a normal capacity for cutting work up to 6 or 8 inches in thickness. For work over 6 inches thick, oxygen and hydrogen may be advantageously employed. A cut may be made at any point over a surface 42 by 84 inches in size without shifting the torch on the bar. By shifting the torch or by using two torches, the area over which a cut can be made is increased to 42 by 168 inches. Where duplicate work is being done or where two similar cuts are to be made in a single piece the output of the machine is greatly increased by using two torches simultaneously. An example of this kind is shown in the accompanying illustrations where a steel side frame for an electric locomotive is being cut. A convenient feature of this machine in handling heavy work is that the pantagraph motion can be pushed back from the table. This leaves space for the use of a traveling crane.

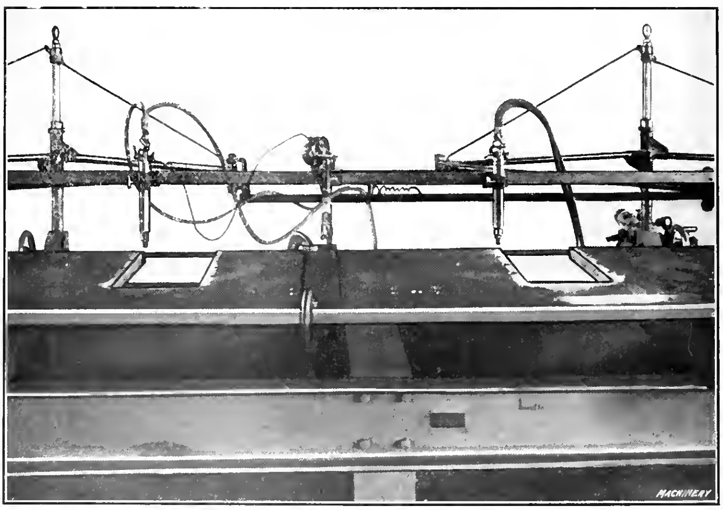

Fig. 2. Front View of No. 2 Oxygraph making a Duplicate Cut

DETRICK & HARVEY DUPLEX FLOOR BORING MACHINE

The Detrick & Harvey Machine Co., Baltimore, Md., has recently brought out a duplex floor boring machine for boring and drilling the frames of heading machinery, and for similar classes of work. Referring to the illustrations, it will be apparent that this machine consists of two horizontal boring machines and a bed plate upon which the work is mounted. One of the boring machines is a standard No. 2 floor boring

machine and the other is a standard No. 0 machine of the same type, the two machines being set at right angles to each other. The runways of each machine are bolted to the bed plate, the size of which may be varied to meet the requirements of individual cases. The illustrations show the bed plate raised from the floor in order to provide for bringing the spindles down close to it. Work can be bored at a single setting; and milling, drilling and tapping operations can be completed on four sides with but one additional chucking.

All of the fast and slow movements of both machines are controlled by levers which are so located that they are conveniently operated from the respective platforms, the arrangement being such that the different movements are non-conflicting. The spindles of the machines are forged from high-carbon steel and are driven from the front or working end. All of the gearing is of steel or bronze and no belts are used.

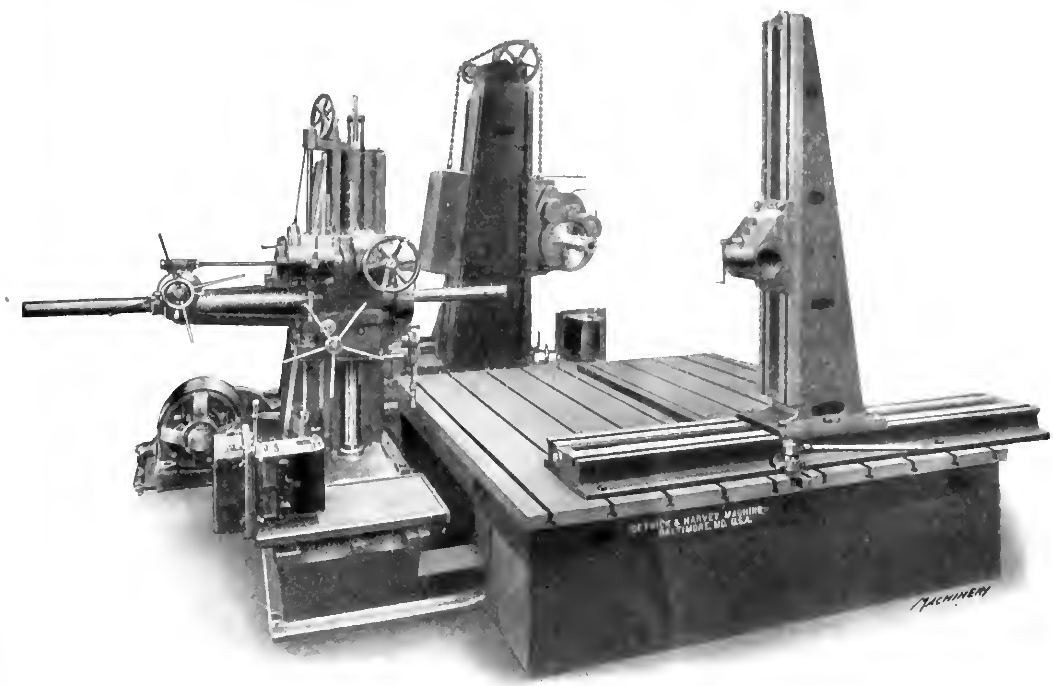

Fig. 1. Front View of Detrick & Harvey Duplex Floor Boring Machine

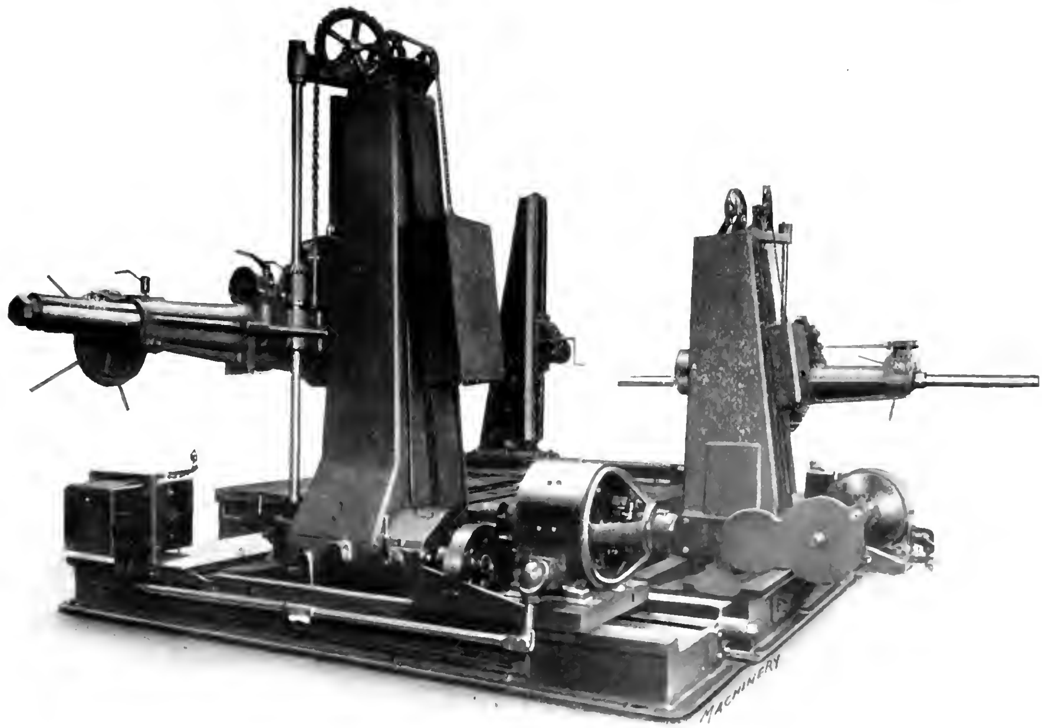

Fig. 2. Rear View showing Arrangement of Motor Drive

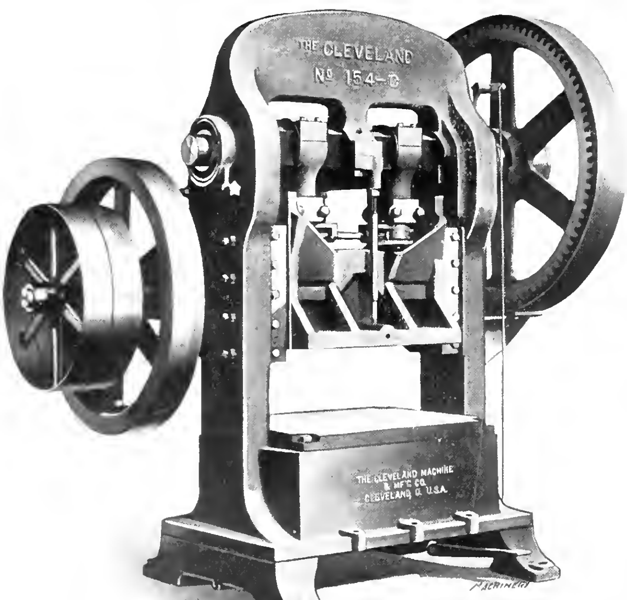
When so desired, the No. 2 machine can be equipped with a large faceplate for attaching facing heads. The total weight of the machine is approximately 37,300 pounds.

The principal dimensions of the No. 2 machine are as follows: Vertical travel of the spindle saddle on the column, 60 inches; continuous feed, 36 inches; spindle diameter, 5 inches. The horizontal travel of the column on the runway and the size of the work bed may be varied to suit different requirements. The machine is equipped with automatic milling feeds, outboard support for the boring bar, and permanent electric wiring for the motor drive. The equipment includes a General Electric ten horsepower variable speed motor for operating on direct current.

The spindle of the No. 0 machine has a travel of 40 inches on the column. The travel of the column on the runway may be varied according to requirements. The spindle is 3½ inches in diameter and has 24 inches continuous feed. The spindle can be brought down to within about 13 inches of the work bed. This machine is also provided with permanent electrical wiring for the 6 horsepower direct-current variable speed motor which forms part of the equipment.

CLEVELAND DOUBLE CRANK PRESS

The double crank-geared power press, illustrated herewith, is one size of a line of presses of this type which have recently been added to the line of the Cleveland Machine & Mfg. Co., Cleveland, Ohio. In designing these machines, particular care was given to the elimination of all weak points. The weak part of the housing, which is around the shaft bearing, has been heavily reinforced; the arch and bed are of extra deep section; and the slide is reinforced to eliminate deflection when using large forming or embossing dies. Knockout rods are attached to the center bearing cap for ejecting formed and drawn parts from the upper die. When so desired, the bed of this press is fitted with a drawing attachment which



Cleveland Double Crank Press

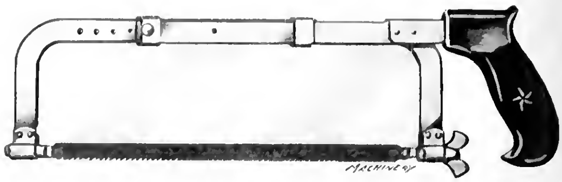
also serves as a knockout device for ejecting work from blanking and forming dies.

These presses are equipped with either a positive clutch or a multiple disk friction clutch, and the clutch may be either automatically or hand operated. The friction clutches are generally used on the larger presses, particularly those that have a long stroke. The gear and pinion are covered with a cast-iron guard. These presses are built in nine sizes and each size is built in several different widths.

MILLERS FALLS HACKSAW FRAME

The tool shown in the accompanying illustration is a recent product of the Millers Falls Co., 28 Warren St., New York City, and is known as their No. 1011 Star hacksaw frame. It will be seen that this saw is provided with a pistol grip, which is very convenient to use, and the frame of the machine is made of a nickel plated steel section 3/16 by 11/16 inch in size. The frame is double at the middle of the back, where the greatest strain comes.

It will also be seen that the blade is tightened by means of a wing nut and stud. This wing-nut is located under the

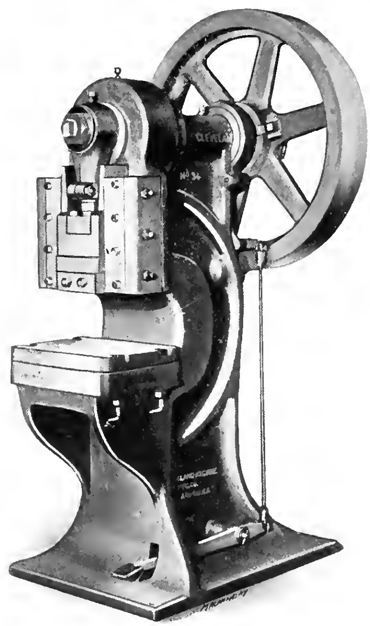


Millers Falls No. 1011 Hacksaw Frame

handle of the saw so that it does not reduce the stroke, as it would do if the nut were located at the opposite end of the frame. The depth of the frame is 3½ inches and it has a capacity for blades from 8 to 12 inches in length. The method by which the adjustment is made will be readily understood from the illustration, where it will be seen that a scale facilitates setting the frame for different lengths of blade.

CLEVELAND POWER PUNCH

The power punching press illustrated in this connection is a recent product of the Cleveland Machine & Mfg. Co., Cleveland, Ohio. The characteristic features of this machine



Cleveland Power Punch

may be briefly outlined as follows: The face of the frame across the gibs is unusually broad to provide for the use of V-gibs; this also makes room for a large area at the base of the slide to support the upper die or punch. The connection is a bronze bushed steel casting and the diameter and length of the pin bearing is larger than where the eccentric adjustment is employed. The adjustment of the slide is also greater than can be conveniently obtained with an eccentric bushing and the design is such that the adjustment will not slip

under the heaviest load. Two clutch points are regularly furnished in the flywheel so that the clutch is engaged every half revolution.

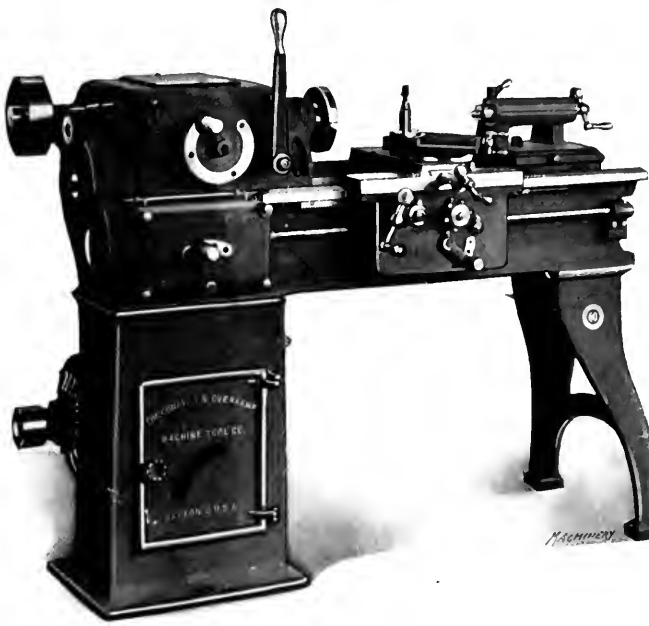
These machines are built in seven sizes, either plain or geared, and are particularly adapted for use in the manufacture of hardware, locks, cutlery, typewriter parts, etc. The principal dimensions are as follows: Bed area, 14 by 20 inches; opening in bed, 9 by 12 inches; distance from bed to slide with the stroke and adjustment up, 9½ inches; stroke of slide, 1½ inch; weight of machine, 5000 pounds.

CONOVER-OVERCAMP HIGH-SPEED LATHE

The Conover & Overkamp Machine Tool Co., Dayton, Ohio, recently built the high-speed geared head lathe shown in the accompanying illustration for use in the Fort Wayne plant of the General Electric Co. It will be seen that the machine is equipped with a single pulley drive and an all-geared head; the machine shown in the illustration is arranged for individual motor drive, although it may be driven from a countershaft with equally good results. There are four geared speed changes. The drive is through a friction clutch located in the headstock, by means of which the lathe may be started, stopped or reversed without paying any attention to the motor.

This machine was designed to operate at 1500 revolutions per minute, which is probably a higher spindle speed than has ever been obtained in an all-geared head lathe. But this is not the limit. During tests to which this lathe was subjected in the Conover & Overkamp shops, the spindle was run at angular speeds up to 3500 revolutions per minute, and at this remarkably high speed, the gears ran without noise. It was also found that the machine could be started, stopped or reversed by means of the friction drive in the head, when running at 3500 revolutions per minute. Lubrication is effected by the splash system, whereby all of the journals in the head and the main spindle bearings are efficiently oiled. Felt wipers are also employed to assist in distributing the oil to the best advantage.

The vertical lever is employed to start, stop or reverse the spindle and the radius plate provides for obtaining either of the four speed changes that may be desired. These changes can be made while the machine is running at its maximum speed. There are also four changes of positive geared feed. The apron is of a standard type. This machine is built for handling small chucking work that may be handled at high speed, as well as for regular turning operations. As previously stated, the particular machine shown in the illustration was built for use in the Fort Wayne plant of the General Electric Co., but the Conover & Overkamp Machine Tool Co. is now building these machines as a regular product.



Conover-Overkamp High-speed Lathe

CORRECTION

An illustrated description of the Nilson four-slide wire forming machine was published in the October issue of MACHINERY. In this article, the statement was made that the cut-off slide of the machine is kept in contact with the lever C by means of a stiff, spiral spring. This statement was made in error. Instead of using a spring, the cut-off slide is kept in contact with the lever C by means of a link fastener at the back of the cut-off slide which connects with the lever.

NEW MACHINERY AND TOOLS NOTES

Machines for Worm Drives: Grant Engineering Co., Detroit, Mich. Two special machines for use in the manufacture of worms and worm-wheels used in automobile transmissions.

Storage Battery Truck: Atlas Car & Mfg. Co., Cleveland, Ohio. A storage battery truck adapted for carrying stock and finished product about in industrial plants. The battery is located in a box at the forward end of the truck.

Three-jaw Air Chuck: Hannifin Mfg. Co., Chicago, Ill. An air operated lathe chuck of the universal type which has independently adjustable jaws. By using a double-acting air cylinder the chuck can be used for both internal and external work. It is made in five sizes ranging from 8 to 18 inches.

Automatic Tube Straightening Machine: Sleeper & Hartley Co., Worcester, Mass. A machine of the swager type for straightening tubing. The work is fed through a rotating die by means of a set of rolls driven by worm-gearing. A second set of rolls grips the work on the opposite side of the die and assists in drawing it through.

Draftsman's Chest: American Drafting Furniture Co., Rochester, N. Y. A chest provided with drawers and compartments of different sizes which are suitable for holding scales, triangles and the different instruments used by draftsmen. The case is covered with leatherette and the fronts of the drawers are of solid mahogany.

Tapping Machine: Peerless Drill Co., Rockford, Ill. A tapping machine of similar design to the 12-inch bench drill which was illustrated in the September issue of MACHINERY. The tapping mechanism is operated by the same lever that controls the feed of the spindle for drilling. The capacity is for holes up to ¾ inch in diameter.

Cold Saw: Newton Machine Tool Works, Inc., Philadelphia, Pa. A cold sawing machine which has a capacity for cutting round stock up to 6½ inches in diameter at one cut. Larger sized bars can be cut by turning them. The machine is adapted for the use of any type of saw blade 22 inches in diameter, although high-speed steel solid or inserted tooth blades are preferable.

Rod-boring Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. A duplex machine designed for boring operations on connecting-rods. It is equipped with two 10 horsepower motors which give direct speeds of 400 to 1200 revolutions per minute. The spindle speeds are 40 to 120 revolutions per minute, and, with the back gears in, from 12 to 36 revolutions per minute.

Vertical Slotting Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. An eccentric-driven slotting machine for heavy forge work which is especially designed for operations on railway frogs and switches. The machine is used for making the angular cuts on the individual parts and for cutting fillets and key slots in the different members. This slotting machine can also be used for taking square cuts on rails.

Hobber and Cutter Grinder: Lees-Bradner Co., Cleveland, Ohio. A machine especially designed for grinding hobs and radially relieved cutters. This grinder has a traversing work slide with a swiveling table mounted on it. The travel of the slide is controlled by a crank handle. Cross adjustment of the wheel is provided at right angles to the movement of the slide.

Cold Saw: Lea Equipment Co., Wyoming and Stenton Aves., Philadelphia, Pa. A cold sawing machine equipped

with sprocket drive. The machine has centralized control and an interesting form of feed mechanism. Machines of this type are built for either belt or motor drive and have a capacity for cutting round stock ranging from 5 to $10\frac{1}{2}$ inches in diameter.

Portable Crane: Canton Foundry & Machine Co., Canton, Ohio. A portable crane adaptable for a variety of purposes in machine shops. The main frame of the crane is of cast iron and stands on a reinforced base. The hook is a drop-forging and the wheels on which the crane runs are mounted in roller bearings. The total height of the crane is 5 feet 8 inches and it is capable of lifting loads up to 3000 pounds through a distance of 4 feet 6 inches.

Hacksaw Machine: W. Robertson Machine & Foundry Co., Buffalo, N. Y. A motor-driven machine designed for cutting steel I-beams, angles and other sections. The machine is equipped with a device for raising the frame on the idle stroke, thereby eliminating the drag on the teeth. A tank is provided underneath the bed, in which the cutting compound is held. The machine is designed to operate at from 90 to 95 strokes per minute.

Machine Vise: Brown Engineering Co., 133-135 N. 3rd St., Reading, Pa. A universal machine vise provided with deep jaws to assure the vertical alignment of the work. The rear jaw swivels so that four different faces can be presented to the work at any angle. Supplementary jaws are arranged to be bolted to the top faces of the vise jaws for holding work of irregular shape. Long pieces of work can also be extended down through the base of the vise through a hole provided for this purpose.

Thread Chasing Attachment: Fitchburg Machine Works, Fitchburg, Mass. A chasing attachment for use on the "Lo-swing" lathe which makes it possible to finish pieces on which threading is to be done at a single setting. The essential parts of the attachment consist of the driving mechanism fastened to the headstock end of either carriage and the chaser which can be mounted at any point on either of the two carriages. The attachment has a capacity for threads up to $1\frac{1}{4}$ inch in length on work from $\frac{5}{8}$ to $3\frac{1}{2}$ inches diameter.

Safety Device: Morgan Construction Co., Worcester, Mass. Two safety devices for use on wire drawing blocks. The first of these devices consists of a safety loop through which the wire passes on its way to the die. A kink or loop—irrespective of whether it has caught the operator or not—catches in this safety loop and stops the machine, thus protecting the operator or machine from injury. Another safety device has been applied which stops the block instantly if the wire breaks, thus preventing the loose end from thrashing around as it would do if the block continued to revolve.

Special Machines for Automobile Work: Grant Engineering Co., Detroit, Mich. These machines were especially designed for machining the spiders for the differential gearing used in automobiles. One machine takes the rough forging, bores the center hole and faces both sides by a single operation. The second machine has two spindles which carry tools for automatically roughing and finishing the arms of the spider. There is also a drilling spindle which drills and centers the end of each arm ready for the grinding operation. The third machine is a duplex grinding machine for finishing the spiders by grinding.

Casehardening Compound: Kasenit Co., 21 State St., New York City. Kasenit is a compound for casehardening malleable iron, cast iron or steel, that has recently been introduced into this country from England. The characteristic properties of this material are the rapidity with which it enables casehardening to be conducted, and the fact that it is non-poisonous. This material is adapted for use in open fires, and it can be used in this way without giving off any injurious fumes. In casehardening with kasenit, a case of ordinary depth can be obtained in a few minutes and a deeper penetration is easily obtained by using this material in the usual method followed for pack-hardening. Under ordinary conditions no special equipment is necessary, as a blacksmith's hearth, a gas jet or a blow pipe work satisfactorily. The work is heated uniformly to a bright red and then dipped or rolled in the kasenit powder, which melts and spreads itself uniformly over the surface. The work is then reheated to a bright red and plunged in clean cold water. This gives the article a uniformly hard surface. If a deeper case is required, the work is reheated a second time before quenching. Three grades of this material are manufactured which are adapted for extra rapid work, for ordinary conditions of casehardening and for pack-hardening.

An International Exposition will be held in London, in 1914 to celebrate the centenary of peace between the United States and Great Britain, being the anniversary of the signing of the Treaty of Ghent. The executive offices of the Anglo-American Exposition for the United States are in the Woolworth Bldg., New York City.

ERECTING A TOLEDO CRANE

A 50-ton Toledo electric traveling crane was recently installed in the power house of the Omaha Electric Light and Power Co., Omaha, Neb. This crane is equipped with two 25-ton trolleys, and owing to the limited clearance above the rails of the runway, it was necessary to use box section girders of the goose-neck type. When the power plant was originally equipped, a hand-power crane was installed, but the increasing demands made upon this station led to the provision of additional equipment, which was far beyond the capacity of the hand-power crane. For this reason the 50-ton electric traveling crane was ordered from the Toledo Bridge & Crane Co., Toledo, Ohio.

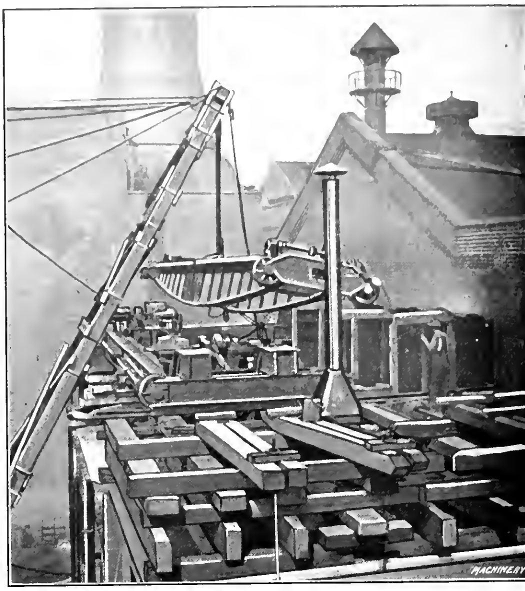

Fig. 1. End View showing New Crane on Temporary Runway

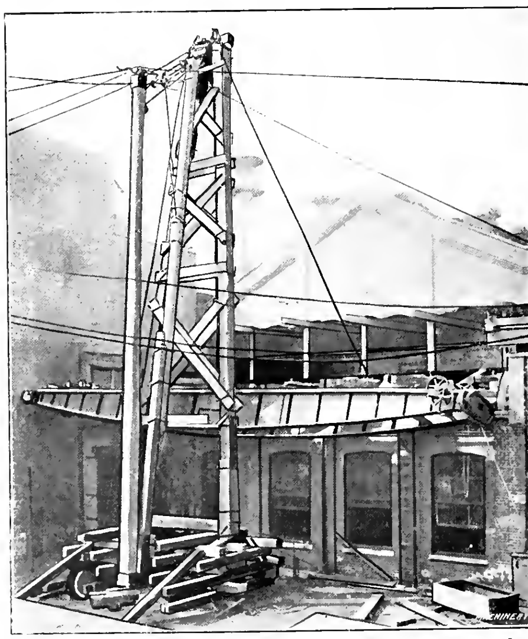

Fig. 2. New Crane inside Building and Old Crane being lowered to the Ground

The removal of the old crane and substitution of the electrically operated crane in its place led to the development of a rather ingenious method. The front end of the building in which the power plant is installed is taken up by the boiler

equipment, and there was no way that the crane could be brought in at the side of the building. This made it necessary to remove a section of the wall at the rear end of the power house in order to remove the old crane and bring in the new one. A temporary extension of the crane runway was built out through this breach and the wall was shored up with posts and jackscrews to support the shoring timbers. The new electric crane was assembled on this temporary runway with the exception of attaching the operator's cage.

After the assembling had been completed, the inside posts supporting the shoring timbers were removed, and the old crane was brought up against the center posts. The inside posts were next replaced, after which the center posts were removed to enable the crane to be passed out. The middle posts were then put back into place and the outer posts removed to allow the crane to move on. The old crane was then lifted out of the way by means of a derrick, after which the new electric crane was moved into the building by reversing the method of procedure followed with the old crane. The operator's cage was then attached, which put the crane into condition for use. The credit for this method of installation is due to Mr. A. C. Anderson, general superintendent of the company.

SOCIETY OF AUTOMOBILE ENGINEERS

Cycle cars formed the subject of discussion at the meeting of the Metropolitan Section of the Society of Automobile Engineers held in New York City on November 30. The animated discussion concerning the advisability of introducing cycle cars in this country shows that the subject is one that is attracting considerable interest in automobile circles. The argument was advanced that the motorcycle, on one hand, and the cheap automobile, on the other, covered the need for a motor-driven vehicle in a way which left no room for the successful introduction of an intermediate type.

The cycle car was developed in Great Britain to take advantage of the low vehicle tax made possible by coming within certain limits of weight and piston displacement. There has been a great variety in the design of these little cars, but their distinctive features are that they have a narrow tread, light weight and are provided with wheels having wire spokes. The original cycle cars were of very simple construction, but the tendency has been to continually add to their equipment until the most approved designs now have most of the facilities of a modern automobile. Cycle cars are built with either three or four wheels—although modern practice is strongly in favor of four-wheel vehicles.

Experience seems to show that the cycle car is unsuited for rough roads owing to its narrow tread and the inability of a four-wheel vehicle to pick its path as a motorcycle can. This forms one of the strongest arguments against the cycle car, the claim being made that it is unsuited for use on American roads, which are decidedly inferior to those of Great Britain. Furthermore, the claim is advanced that a satisfactory form of cycle car cannot be built for less than $500 and that at such a price it has nothing to commend it as compared with the Ford runabout.

The arguments in favor of the cycle car are that it is much cheaper to operate, it being possible to run a cycle car from 40 to 50 miles on a gallon of gasoline. The cycle car is also cheaper to garage, and as it accelerates more rapidly than an automobile it can move faster through conjested districts where it is necessary to stop at frequent intervals.

Taking the opinion expressed at the meeting the Metropolitan Section as representative, it appears that if there is a field for the cycle car in America, it is limited to cities and suburbs where the presence of good roads is assured. It also appears that a cycle car must have most of the facilities of an automobile in order to give satisfactory service. This means that there is little difference in price between a cycle car and a cheap automobile, the advantage of the cycle car lying in the possibility of reducing the cost of operation. One speaker stated that the appearance of a cycle car should be that of a modern automobile viewed through the wrong end of a telescope.

DETERMINING THE RATE OF PRODUCTION

BY C. W. HINMAN*

A most deceiving arithmetical problem, in shop and factory, is to find correctly how many pieces are actually being finished per hour, when the rate per hour is known for several machining operations on the same piece. As a simple illustration, suppose a piece is being milled at the rate of 125 pieces per hour and is then drilled at the rate of 280 pieces per hour. What is the completed output per hour?

One generally finds that the finished output per hour is really considerably less than what he had supposed, and there lies a mistaken idea whereby some firms actually lose money when figuring on a job.

125 pieces per hour is 1 piece in $\frac{1}{125}$ of an hour, and 280 pieces per hour is 1 piece in $\frac{1}{280}$ of an hour. Adding the fractions and reducing to the lowest terms we have, 1 piece, finished complete, in $\frac{81}{7000}$ of an hour. Then, in one hour, as many pieces can be finished complete as $\frac{81}{7000}$ are contained in 1 or $\frac{7000}{81}$ times = 86.4 pieces. From this we deduce the following formula in which X = one rate per hour and Y = the other rate per hour.

$$\text{Complete finished output per hour} = \frac{XY}{X+Y}$$

Rule.—The *product* of the two rates per hour divided by the *sum* of the two rates per hour, is the complete output per hour. This is a very easy rule to remember. Also, in general, when any number of rates per hour are known, on one piece, use the same rule, treating the operations in pairs, until the final operation is performed.

DECEMBER MEETING OF THE A. S. M. E.

The annual meeting of the American Society of Mechanical Engineers will be held in the Engineering Societies Bldg., New York City, December 2-5. Papers will be presented on boilers and their operation; cement; enameling; fire protection, with special reference to turbo-generators, oils and the novel use of sprinkler systems; gas measurement; gas power engineering; lineshaft bearings; machine tools; management; properties of steam; rope drive; steel railway cars; textiles, covering mill engineering; and vacuum cleaning. The Grashof medal will be presented to George Westinghouse, past president and honorary member. The medal was conferred upon Mr. Westinghouse by the Verein deutscher Ingenieure at Leipzig on the occasion of the joint meeting of the two societies there last June. Excursions to many manufacturing plants and places of interest in and near New York City have been arranged for. The customary reunion will take the form of a German dinner to be held at the Deutscher Liederkranz, Thursday evening, December 4.

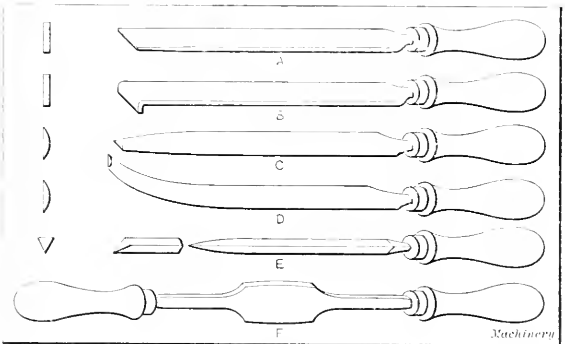
SCRAPERS AND HAND SCRAPING

When correcting errors on flat or curved surfaces by hand scraping, it is desirable, of course, to obtain an evenly spotted bearing with as little scraping as possible. When the part to be scraped is first applied to the surface-plate, or to a journal in the case of a bearing, three or four "high" spots may be indicated by the marking material. The time required to reduce these high spots and obtain a bearing that is distributed over the entire surface depends largely upon the way the scraping is started. If the first bearing marks indicate a decided rise in the surface, much time can be saved by scraping larger areas than are covered by the bearing marks; this is especially true of large shaft and engine bearings, etc. An experienced workman will not only remove the heavy marks, but also reduce a larger area; then, when the bearing is tested again, the marks will generally be distributed somewhat. If the heavy marks which usually appear at first are simply removed by light scraping, these "point bearings" are gradually enlarged, but a much longer time will be required to distribute them.

The number of times the bearing must be applied to the journal for testing is important, especially when the box or bearing is large and not easily handled. The time required to distribute the bearing marks evenly depends largely upon one's judgment in "reading" these marks. In the early stages of the scraping operation, the marks should be used partly as a guide for showing the high areas, and instead of merely scraping the marked spot the surface surrounding it should also be reduced, unless it is evident that the unevenness is local. The idea should be to obtain first a few large but generally distributed marks; then an evenly and finely spotted surface can be produced quite easily.



Different Forms of Scrapers commonly used

The proper distribution of the bearing marks on the finished surface depends somewhat on the class of work. For flat surfaces which must be very accurate, all the marks should be approximately the same size and evenly distributed. In locomotive work, the bearing marks on driving-wheel boxes should indicate a heavier bearing in the "crown," or top of the box, than on the sides. Split bearing boxes such as are used for engine connecting-rods, should also be scraped in this way. If the heaviest bearing were left at the sides, a slight heating of the journal would be more likely to greatly increase the friction and cause excessive heating.

In the accompanying illustration, the different forms of scrapers commonly used are shown. The flat scraper *A* is almost invariably used for plane surfaces. For ordinary purposes, the scraper blade is about 3/16 inch thick, 1 to 1¼ inch wide and is drawn out at the point to a thickness of about 1/16 inch. The cutting end is made as hard as possible and is rounded slightly, in grinding, so that the outer corners will not score the surface being scraped. The grinding should be done, preferably, on a wet grindstone, the edge being finished with an oilstone. The hook scraper *B* is also used on flat surfaces. It is preferred by some workmen for obtaining a fine, smooth surface and can be used, occasionally, in narrow spaces where there would not be room enough for a straight, flat scraper. Straight and curved scrapers of the "half-round" type are shown at *C* and *D*. These are used for scraping bearings, etc., the sides forming the cutting edges. The curved type *D* is more convenient to use on large half-bearings, as it is held at an angle and the scraping is done by the curved edge. The "three-cornered" or "three-square" scraper shown at *E* is also used to some extent on curved surfaces. When the end is beveled, as shown in the detail view to the left, this form of scraper is convenient for producing sharp corners or for "relieving" them slightly.

The two-handled scraper shown at *F* is an excellent form for scraping bearing boxes and all curved surfaces which are so located that this type can be used. This style of scraper does not seem to be in general use, although it is much superior to the forms shown at *C* and *D*, especially for large work. The straight or curved half-round type works very well on soft bearing metals such as babbitt metal, but on brass or bronze it cuts slowly and, as soon as the edge is slightly dulled, considerable downward pressure is necessary. The type *F* requires very much less effort on the part of the workman, and it will cut rapidly. As there are two handles instead of a single handle at one end, the blade can be pressed against the work with little exertion. This form of scraper is largely used in railroad shops, for the heavy scraping required on driving-wheel boxes and in fitting the large connecting-rod brasses now in use. The sides are sometimes ground slightly concave to give the cutting edges "rake," by holding them against the face of the grinding wheel.

The marking material commonly used in connection with scraping operations is composed of a mixture of red lead or Venetian red and oil. The Venetian red is finer than the red lead, and is preferable for accurate work. It is important to keep the marking material in a covered box in order to exclude all grit or chips.

The scrapers used in the U. S. Navy for fitting bearings, etc., are made in sets of four. The Navy specifications are as follows:

One half-round, 10 inches long, 1 inch wide, with two cutting edges. One "mill" 8 inches long, 0.8 inch wide and 0.135 inch thick, with two ends and four side cutting edges. One "three-square," 8 inches long, ⅝ inch width of triangular side, with three cutting edges. One "three-square," 6 inches long, ½ inch width of triangular side, with three cutting edges. These scrapers are made from uncut file blanks, the terms "half-round," "mill," etc., corresponding to the shapes used for files.

F. D. J.

CONVENTION OF THE NATIONAL FOUNDERS' ASSOCIATION

The seventeenth annual convention of the National Founders' Association was held in the Hotel Astor, New York City, November 19-20. The former president, O. P. Briggs voluntarily retired and was succeeded by W. H. Barr of the Lumen Bearing Co. Otto H. Falk was elected vice-president, and J. M. Taylor, secretary. During the convention a number of interesting papers were presented, dealing more particularly with labor troubles, the prevention of accidents and workmen's compensation. A list of the different papers follows: "Union Lawlessness," by George F. Monaghan, general attorney for the National Founders' Association; "Erie Strike," by Thomas E. Durban, Erie City Iron Works; "Birmingham Strike," by W. D. Tynes, Hardie-Tynes Manufacturing Co.; "Anxiety Caused by Practical Business Problems—Publicity a Possible Solution," by Henry M. Leland, Cadillac Motor Car Co.; report of the committee on safety and sanitation; "A Review of the Work for the Past Year and What the Committee Proposes for the Coming Year," by M. W. Alexander, chairman; "Workmen's Compensation—How the Different State Laws have operated," by Staunton B. Peck, Link-Belt Co.; C. H. Gifford, American Blower Co., and H. P. MacDonald, Snead & Co. Iron Works.

Many a man will expound to his wife the doctrine that good things never come cheap, and then he will hunt all over the country for the lowest-priced tool he can find for his shop.

COATING STEEL AND IRON WITH GLASS

A paper on the art of enameling or coating steel and iron with glass will be presented by Raymond F. Nailler, of Elyria, at the December meeting of the American Society of Mechanical Engineers. Mr. Nailler briefly traces the history of the art of enameling from early times. Enamels are used for artistic or decorative purposes and for sanitary reasons. The most familiar class of enamel work is cooking utensils, these being of the so-called agate or granite ware class. The second class is enamel signs and a third class is large tanks, kettles, evaporators, pipes, etc., used in the preparation of food stuffs. The first step in enameling metals is the preparation of the enamel. This must be done very carefully as purity of the raw material of the enamel is absolutely necessary. Three general methods are employed in applying the enamel to metallic surfaces. The first, applicable to small pieces only, is known as dipping, the piece being dipped into the enamel and the excess shaken off leaving a thin coating. The second method, known as slushing, consists of pouring the prepared enamel over the surface and allowing it to drain. The third method and principal one used on large pieces consists of spraying the finely ground enamel onto the metal surface by means of a compressed air atomizer. The pieces are fired in furnaces of various designs. The temperature required varies with the nature of the enamel and in cases of high silicon acid-proof enamels reaches as high as 2500 degrees F. The chemistry of enameling is somewhat complex and not altogether fully understood. Production of first-class white enamel either for cast iron or sheet metal depends at present, on the use of tin oxide. Efforts have been made to substitute less expensive substances but with indifferent success. In the preparation of foods in factories there is a constantly increasing demand for larger pieces of enameled steel apparatus in the form of pans, kettles, tanks, pipes, etc. Enamels for these purposes should be acid-proof.

* * *

THE PRICE OF MONOPOLY

Some figures published by the *English Mechanic and World of Science*, relating to coal prices in England, provide food for the thoughtful mind. These figures give an idea of the price that the community and its industries must pay to monopoly, and show that the increased cost of living is not entirely due to increased wages, as has been claimed by many. When the miners' dispute in Great Britain was settled about a year and a half ago, the Mining Association decided to advance the price of coal sixty cents a ton. This was done in the face of the fact publicly declared by Sir Arthur Markham, who held a large interest in mining properties, that the granting of all the miners' demands did not increase the cost of mining more than eight cents a ton. It may be interesting to note in this connection that the British papers recently told of one mining company in South Wales paying a sixty per cent dividend, as was also done by another company in Durham, England. Of course, there is no need of going to England to meet with this condition, except for the fact that it is, as rule, more difficult to obtain accurate facts about the doings of large monopoly interests in this country than abroad. Exact figures, such as here quoted, are not easily obtained, although both manufacturers and individual consumers of any product under monopoly control, are well aware of the same conditions. It is a well-known fact that in this country also, an increase in the wages of the coal miners of a few cents a ton has caused a permanent increase of twenty-five or fifty cents a ton to the consumer. We do not believe that conditions of this kind are in the interest of the manufacturers of this country any more than they are in the interest of the smaller consumers of monopolized products; nor are such conditions necessary.

* * *

It has been found by experiments that the difference in power that can be transmitted by the same belt in damp and dry weather may vary as much as 50 per cent especially if the drive is a vertical one; that is, if in general, the pulleys are placed in an unfavorable position.

CUTTING METAL UNDER WATER

A German engineer, Herr A. Heckt, has designed a burner, according to the *Scientific American*, which makes it possible to use the hydrogen-oxygen flame for cutting metals under water. The burner consists of a bell-shaped head which is screwed onto an ordinary burner and which allows the flame to continue to burn below the water in a supply of compressed air. This process has been so improved of late that the cutting of metals under water is claimed to be effected almost as quickly as above the surface. At tests recently made with the new apparatus at the harbor of Kiel, before prominent engineers and representatives of the German government, a diver went down into the sea to a depth of about 16 feet, and, after boring a hole into an iron bar $2\frac{1}{2}$ inches square, cut off the bar in about thirty seconds. An iron sheet $\frac{3}{4}$ inch thick was drilled through and cut for a distance of one foot in ninety seconds.

PERSONALS

M. G. Doll has been made general sales manager of the Bury Compressor Co., Erie, Pa.

Robert J. Anderson, vice-president of James Anderson & Sons, makers of "Conus" oil cups, Sidney, Ohio, sailed on the *Amerika*, November 22 for a business trip to Sweden.

G. F. Collister, for three years assistant to the general superintendent of the Cleveland Twist Drill Co., Cleveland, Ohio, has taken charge of the tool steel department of the Betz-Pierce Co., of Cleveland.

Heinrich J. Freyn, formerly consulting engineer of the gas engine department of the Allis-Chalmers Mfg. Co., Milwaukee, Wis., recently joined the H. Koppers Co., of Chicago in the capacity of third vice-president.

W. M. Corse, works manager of the Lumen Bearing Co., Buffalo, N. Y., has resigned to become general manager of the Empire Smelting Co., Depew, N. Y., on January 1, 1914. H. P. Farrock, sales manager, will assume Mr. Corse's duties as superintendent, combining the two offices.

R. G. Williams, who read a paper "Safety Devices used in connection with Grinding Wheels" before the New Haven meeting of the A. S. M. E., November 21, has been promoted from the position of assistant research engineer of the Norton Co., to the position of safety engineer.

James H. Herron has tendered his resignation as general manager of the National Machine Tool Builders' Association to take effect January 1, 1914. Charles E. Hildreth, well known to the members of the association for his able secretarial work in past years, has been appointed to the position.

Charles E. Thwing, formerly sales manager of the Whitcomb-Blaisdell Machine Tool Co., Worcester, Mass., and prior to that connection treasurer of the Draper Machine Tool Co., of Worcester, has started in business for himself as a manufacturer of engine lathes under the name of the Worcester Lathe Co. For the present, the lathes will be made by the Whitcomb-Blaisdell Machine Tool Co.

S. H. Reck, secretary and treasurer of the Rockford Drilling Machine Co., Rockford, Ill., manufacturer of upright drills, gang drills and lathes, has sold his interest in the business to William Nelson, president, who now becomes sole owner. Mr. Reck expects to make his home in Cincinnati, Ohio, where he will engage in business, the nature of which has not yet been determined.

K. R. Odman of Stockholm, Sweden, is at present in the United States as special representative of *Svenska Teknologföreningen* (Society of Swedish engineers) to arrange for a delegation of the society to take part in the International Engineering Congress to be held in San Francisco, 1915. In addition, Mr. Odman is endeavoring to arrange for a convention between the Swedish engineers who will visit this country in 1915, and the great body of engineers of Swedish birth who permanently live in this country.

* * *

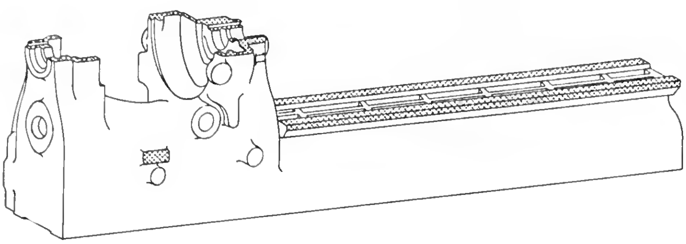
OBITUARIES

E. C. Dove, a well-known manufacturing machinist lately connected with the Lima Locomotive Corporation, Lima, Ohio, in an official capacity, died in Lima after a week's illness.

John D. Jones, died suddenly while at work November 15, aged seventy-four years. He established the old Anderson Mfg. Co., now known as the National Machinery Co., of Tiffin, some years ago.

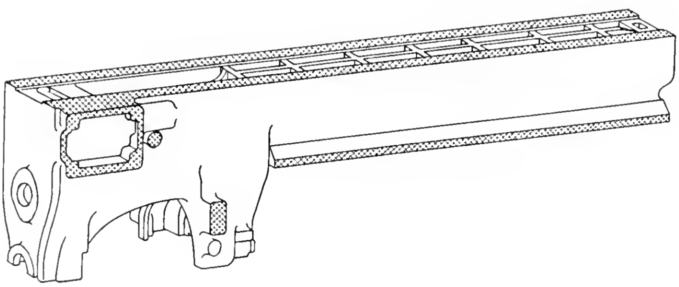
Ashmead Gray Rodgers, for twelve years superintendent of the Carborundum Co.'s plant at Niagara Falls, N. Y., died October 23 as the result of injuries sustained through an

We Saved Four and One-Half Hours On Each of These Castings



This demonstrates the superiority of the milling machine for this class of work.

Are there not jobs in your shop on which an equal saving could be made?



These castings are Screw Machine Beds. Twelve different settings are required in milling them, but the facility of making the settings and the advantages of gang milling and fast operation enable a substantial saving in time to be made. A bed is first inverted and clamped in a fixture. The bottom is milled, the bed turned over and clamped directly to the table of the machine, when the top is finished. The remaining surfaces at the sides are finished with a face mill. A gang of cutters is used for milling the ways of the bed, so that once these cutters are accurately set the ways milled are exact duplicates in width and distance between. Work similar to these castings is common to nearly all manufacturing shops, as, for example, machine beds or tables, bases or frames of engines, pumps and compressors, crank cases or similar parts. No doubt if you look around your shop, you will find at least a few examples of this class of work.

Send us blue prints of any such work and let us aid you in securing maximum production.

READ PAGE 69

automobile accident October 5. Mr. Rodgers had many friends and acquaintances throughout the mechanical and chemical world who will sincerely feel the loss of a man of his pleasing personality, democratic ways and general capabilities in his chosen line of work. Mr. Rodgers was born in Albany, N. Y., in 1872. Prior to his connection with the Carborundum Co., as superintendent, he was superintendent of the Eddy Electric Co., Hartford, Conn. He was a member of the American Chemical Society, Engineers' Society of New York, Chemists' Club, Niagara Club, University Club, Country Club of Niagara Falls and several other scientific and social organizations.

Everete F. Morse of the Morse Chain Co., Ithaca, N. Y., died at his home in Ithaca, November 11, aged fifty-six years. When Mr. Morse was only sixteen years old he patented an improvement on the horse-drawn hay-rake and made good use of the earnings of his first invention to supplement other efforts to give him an education. He attended Cornell University in 1875 and after being out for several years, graduated with the class of 1884 as a mechanical engineer. After spending some time at Algona, Iowa, where he was manager of a flax mill, he returned to New York State and settled at Trumansburg. Here in 1893 he patented the Morse rocker-joint bicycle chain and in conjunction with his brother, Frank L. Morse, founded the Morse Chain Co., and began the manufacture of bicycle chain. The novel mechanical principle embodied in this chain and its high efficiency attracted immediate attention and eventually secured for the company a profitable business which lasted until the phenomenal slump in the bicycle trade about 1897. Meantime, his brother, F. L. Morse, who has been the active manager of the Morse Chain Co. for the past thirteen years, developed the present type of silent chain for power purposes, and in 1906 built the new plant where the business has grown from small beginnings to its present proportions. At the time of his death, E. F. Morse was a director and secretary of the Morse Chain Co., but for some years past he had devoted himself very largely to his heat gage interests and to various public duties in which he was most active and efficient. The Morse thermo gage invented by Mr. Morse and patented about 1900 is an ingenious device for the measurement of high temperatures, especially of steel and other metals. This invention won him much distinction at home and abroad, having been adopted by the United States and the German bureaus of standardization. In recognition of the high mechanical merit of the rocker-joint chain and thermo gage, Mr. Morse was awarded medals by the Franklin Institute of Philadelphia.

COMING EVENTS

December 2-5—Annual meeting of the American Society of Mechanical Engineers. Headquarters, Engineers Bldg., 29 W. 39th St., New York City. Calvin W. Rice, secretary.

December 11-20.—First International Exposition of Safety and Sanitation under the auspices of the American Museum of Safety, 29 W. 39th St., New York City. Dr. William H. Tolman, director. Safety and health in every branch of American industrial life—manufacturing, trade, transportation on land and sea, business and engineering, in all of their sub-divisions, will be represented at this exposition. Exhibits from Europe and other foreign countries will be admitted free of duty by special act of Congress. European employers have cut their accident and death rate in half by a persistent campaign of safety. There are twenty-one museums of safety in Europe, and all these will contribute to the American Exposition.

December 29-31—Seventh Annual Convention of the American Society of Agricultural Engineers, Chicago, Ill. Great Northern Hotel, headquarters. I. W. Dickerson, secretary, Urbana, Ill.

May 1-October 31 (1914)—Anglo-American Exposition, London, England to celebrate the centenary of peace between the United States and Great Britain. American executive offices: Woolworth Bldg., New York City. Charles J. Kiralfy and Albert E. Kiralfy, commissioners general.

September 20-25 (1915).—International Engineering Congress, San Francisco, Cal., in connection with the Panama-Pacific International Exposition. W. F. Durand, chairman, Foxcroft Bldg., San Francisco, Cal.

SOCIETIES, SCHOOLS AND COLLEGES

Worcester Boys Trade School, Worcester, Mass., has begun the publication of a small weekly named "Occasional Suggestions." The object of this little publication is to present the principles underlying the methods of the school. The first number contains very readable essays in mathematics by E. P. Neal and C. B. Price.

International Correspondence Schools, Scranton, Pa. Catalogue of the International Library of Technology, listing reference libraries of the following subjects: advertising, architecture, automobiles, business, chemistry, civil engineering, commercial law, concrete engineering, designing and illustrating, electrical engineering, electrotherapeutics, locomotive engineering, mechanical engineering, mechanical drawing, mining and metallurgy, navigation, poultry, refrigeration, salesmanship, sanitary engineering, shop practice, structural engineering, telegraph and telephone engineering, textiles. The catalogue gives tables of contents of each volume of 113 volumes covering the leading trades, professions and industrial sciences and containing about 55,000 pages. The volumes are six by nine inches, averaging 525 pages and 243 illustrations each. The books on any subject can be highly recommended to those in need of the information they contain.

National Association of Purchasing Agents was organized at the Hotel McAlpin, New York City, October 16. H. T. Leeming of Thomas A. Edison, Inc., was elected temporary chairman and Elwood B. Hendricks, the organizer, temporary secretary and treasurer. Mr. Hendricks is the son of S. E. Hendricks, president of the Hendricks-Sullivan Corporation, publishers of Hendricks' Commercial Register. The temporary headquarters of the association is at the Hotel McAlpin. The association will be devoted entirely to the interests of purchasing agents and buyers and will have sub-associations in all sections of the country. Some of the objects are: (1) The formation of the purchasing agents and buyers into a national body; (2) Mutual acquaintanceship and the resulting privilege of exchanging ideas and opinions; (3) The standardization of purchasing routine and methods; (4) The investigation and certification of new appliances and materials; (5) The improving of existing methods for the diffusion of market information; (6) The gathering and dissemination of data relating to the subject of buying; (7) The standardization of specifications. All communications should be addressed to E. B. Hendricks, P. O. box 1106, New York City.

NEW BOOKS AND PAMPHLETS

Pyrometer Testing and Heat Measurements. 19 pages, 7 by 10 inches. Published by the Department of Commerce, Bureau of Standards, Washington, D. C., as Circular No. 7.

Permissible Explosives. By Clarence Hall. 11 pages, 6 by 9 inches. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Technical Paper 52.

Portable Electric Mine Lamps. By H. H. Clark. 13 pages, 6 by 9 inches. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Technical Paper 47.

Commercial and Agricultural Organizations of the United States. 125 pages, 6 by 9 inches. Published as Senate Document 1109 of the 62d Congress, Third Session, Washington, D. C.

Heavy Oil as Fuel for Internal-Combustion Engines. By Irving C. Allen. 36 pages, 6 by 9 inches. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Technical Paper 37.

Safety in Tunneling. By David W. Brunton and John A. Davis. 19 pages, 6 by 9 inches. Published by the Department of the Interior, Washington, D. C., as Miners' Circular 13 of the Bureau of Mines.

Manufacture of Lime. By Warren E. Emley. 130 pages, 7 by 10 inches. Illustrated. Published by the Department of Commerce, Washington, D. C., as Technologic Paper of the Bureau of Standards No. 16.

First-Aid Instructions for Miners. By M. W. Glasgow, W. A. Raudenbush and C. O. Roberts. 66 pages, 6 by 9 inches. Published by the Department of the Interior, Bureau of Mines as Miners' Circular 8.

The Analysis of Black Powder and Dynamite. By Walter O. Snelling and C. G. Storm. 80 pages, 6 by 9 inches. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Bulletin 51.

Proposed Regulations for the Drilling of Gas and Oil Wells. By O. P. Hood and A. G. Heggem. 28 pages, 6 by 9 inches. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Technical Paper 53.

Apparatus for Gas-Analysis Laboratories at Coal Mines. By George A. Burrell and Frank M. Seibert. 24 pages, 6 by 9 inches. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Technical Paper 14.

The Commercial Trend of the Producer-Gas Power Plant in the United States. By R. H. Fernald. 93 pages, 6 by 9 inches. One folding plate. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Bulletin 55.

The Prevention of Waste of Oil and Gas from Flowing Wells in California. By Ralph Arnold and V. R. Garfias. 15 pages, 6 by 9 inches. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Technical Paper 42.

Directory of Clay Products Manufacturers in the United States Comprising Manufacturers of Common Brick, Pressed Brick, Face Brick, Fire and Silica Brick, Paving Brick, Tiles, Pottery. 142 pages, 6 by 9 inches. Published by L. L. Longdon, Oxford, Ohio. Price, $2.50.

Proceedings of the Twenty-first Annual Convention of the Traveling Engineers' Association. Edited by W. O. Thompson. 371 pages, 5¾ by 8½ inches. Published by the Association. W. O. Thompson, secretary, Buffalo, N. Y.

The proceedings of the convention held at Chicago August 12-15, 1913, include papers and discussions of technical interest to the railway men connected with the operating and motive power departments.

Standard Regulations for Manufactured Gas and Gas Service. 170 pages, 6 by 9 inches. Published by Department of Commerce as Circular No. 32 of the Bureau of Standards, Washington, D. C.

This circular supersedes Circular No. 32 first edition entitled "State and Municipal Regulations for the Quality, Distribution and Testing of Illuminating Gas." The importance of established standards for illuminating gas to municipalities and all gas consumers is obvious.

Cranes and Hoists. By Hermann Wilda. Translated from the German and adapted to British practice by Charles Salter. 168 pages, 4½ by 6¼ inches. 399 illustrations. Published by Scott, Greenwood & Son, Ludgate, E. C., England and D. Van Nostrand Co., New York City. Price $1.25 instead of $1 as quoted in the review appearing in the November number.

Harper's Wireless Book. By A. Hyatt Verrill. 185 pages, 5¼ by 8 inches. Illustrated. Published by Harper & Bros., New York City. Price $1.

This book for amateur wireless electricians tells how to use wireless electricity in telegraphing and telephoning and the transmission of power. It explains electromagnetic waves and tells how to build and use wireless apparatus, telegraphs, telephones, etc. An appendix contains tables and standards useful to the worker.

Harper's Beginning Electricity. By Don. Cameron Shafer. 275 pages, 5¼ by 8 inches. Illustrated. Published by Harper & Bros., New York City. Price $1.

The book, as the title indicates, is intended for amateurs, boys and others who wish to make simple experiments in electricity and to learn more about electrical phenomena. It treats of static electricity, galvanic electricity, batteries, magnetism, permanent and electro-magnets, induction coils, the telegraph, telephones, generators, motors, electric light, and the history of electricity. An electrical dictionary is included, defining many of the common electrical terms.

Shop Sketching. By Joseph W. Woolley and Roy B. Meredith. 102 pages, 6 by 9 inches. 122 illustrations. Published by the McGraw-Hill Book Co., Inc., New York City. Price, $1.

This book is made up of the instruction papers used in the extension division of the University of Wisconsin and is presented as a course of instruction for apprentices and mechanics who need more knowledge of drawing. It contains seven chapters as follows: Principles of Mechanical Drawing; Screws and Screw Fastenings; Sections; Assembly and Detail Drawings; Gearing; Isometric Drawing; Freehand Drawing. The book is in no sense a treatise on mechanical drawing, but is intended to make shop men familiar with the principles of mechanical delineation and able to read working drawings.

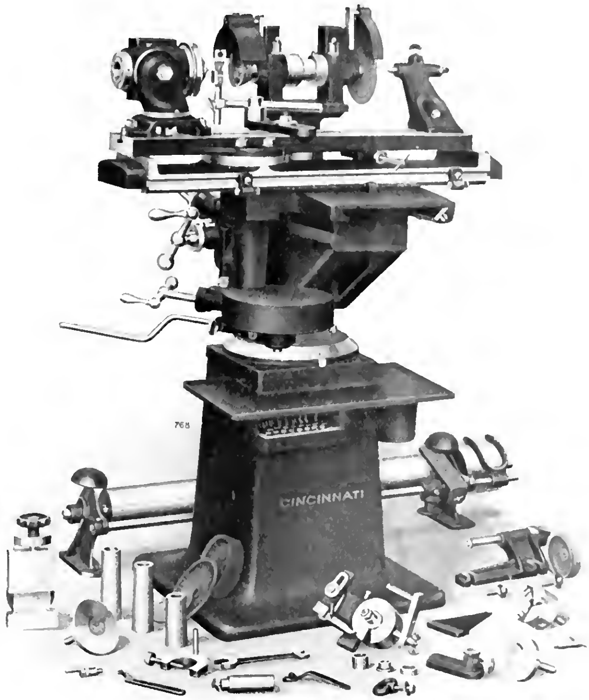
Jigs and Fixtures. By Fred H. Colvin and Lucian L. Haas. 168 pages, 6 by 9 inches. 391 illustrations. Published by the McGraw-Hill Book Co. Inc., New York City. Price $2.

The development of interchangeable manufacturing of guns, sewing machines, typewriters, engines, automobiles and hundreds of other products depends on jigs and fixtures as the most important accessories of manufacturing equipment. The variety of jigs required to suit the multitude of shapes to be machined, the accuracy with which they have to be constructed and the designing of them to be efficient and convenient in use, test the best skill of tool designers and toolmakers. The contents of the book comprise: Tool-room systems; various kinds of jigs; jig locating means; standard bushings; details of jigs; clamps and clamping methods; milling fixtures; pneumatic fixtures; advantages of lap jigs; designs and materials for gages; external and internal thread gages; manufacturing gages; and machine vise jaws and mandrels. The work is one that should be appreciated and found useful by tool designers, toolmakers and machinists generally.

Formulas in Gearing. 225 pages, 6 by 9 inches. Published by the Brown & Sharpe Mfg. Co., Providence, R. I. Price, $1.50.

This well-known work on gearing was first published in 1900. It has passed through five editions

The New Cincinnati No. 1½ Cutter Grinder



(Patented Rights fully Reserved)

Takes work 10" diameter 17" long. Has 16" table travel—9½" cross and 7¼" vertical.

Will grind High Power face mills up to 12" in diameter and Standard face mills up to 16" diameter; formed cutters up to 5½" diameter, using a 4" diameter grinding wheel.

It is in every way as handy as our well-known No. 1 Grinder, but is much heavier and more rigid, as the illustration shows.

The following features produce quick and accurate results:

1. A vertical movement which can be adjusted and clamped without disturbing any other settings.
2. A swiveling or angular adjustment of the knee and table through a complete circle about the column which is entirely independent of all other settings.
3. A slow screw feed for cylindrical, internal and some classes of surface grinding.
4. A quick lever feed for all sharpening operations.
5. A conveniently located feed lever which the operator can set to that position handiest for the work being ground.
6. A large swiveling headstock which receives the shanks of end mills, face mills, etc., holding them for the sharpening operations just as they are held in the milling-machine spindle.
7. As graduated dial on the headstock spindle from which the clearance angle for cutters may be read direct. No clearance tables or diagrams are needed.
8. A Gear Cutter Sharpening Attachment which grinds the teeth equally, straight and radially and also *feeds the cutter to the grinding wheel radially.*
9. A single, universal tooth rest, the blade of which forms a solid support for all cutter sharpening.
10. A dial reading in degrees and also a dial reading in inches per foot for angular and taper work.

Ask for descriptive matter showing how these things have been accomplished.

THE CINCINNATI MILLING MACHINE CO.

CINCINNATI, OHIO, U. S. A.

into the sixth enlarged edition. Forty-two pages have been added, the additional matter including a table of prime factors from 10,000 to 100,000 and a new table giving the chordal thickness of gear teeth and the distance from the chord to the top of the tooth. The tables for bevel gears giving the diameter increment, the apex distance to the pitch line, angles of edge and angles of face have been extended. Additions have also been made to the tables giving the number of cutters for use in cutting bevel gears. The subject is dealt with essentially from the draftsman's standpoint and covers the principles of spur gearing, spur gearing formulas, bevel gearing, worms and worm-wheels, spiral gearing, internal gearing, bevel gear cutters, indexing, gearing of lathes for screw cutting, tooth parts, solution of triangles, trigonometrical tables, angles for gashing worm-wheels, and the subjects before mentioned.

The Resistance of Guns. By Leone Compaye and Pietro Malavat. 262 pages, 7 by 10 inches. Illustrated. Edited by Carlo Pasta, Piazza Castello, 22 Turin, Italy.

Captain Hector Bravetta of the Italian Royal Navy, well known to students of naval matters on account of the many articles contributed to technical reviews in Italy and abroad, has translated and united in one volume three important memoirs on the resistance of guns which engineers Leone Coupaye and Pietro Malaval of the French Naval Artillery had published in French. Mr. Coupaye points out that it is absolutely impossible to build guns having purely elastic deformations greater than the elastic limit of the metal of which the internal tube is made, and that the limit is about nine-tenths of the elastic limit. This is true whatever system of manufacture be adopted, and applies to both built-up and wire-wound guns. The elastic limit of a gun is very limited. If the metal forming the internal tube, for instance, possesses an elastic limit of 40 kilograms, a gun of normal thickness will become permanently deformed under a pressure of 3600 kilograms per square centimeter. The work is published in Italian.

Scientific American Reference Book of 1914. By Albert A. Hopkins and A. Russell Bond. 597 pages, 5½ by 7½ inches. 1000 illustrations. Published by Munn & Co. Inc., New York City.

This comprehensive reference book is indispensable to the business man as it will answer all sorts of questions that may come up in the course of affairs. The work is divided into two sections, Part I containing statistical information and Part II scientific information. Under statistical information are statistics on population and social relations; farms, foods and forests; mines and quarries; manufacture; commerce; mercantile marine; railroads; the Panama Canal; telegraphs and cables; wireless telegraphy; telephone statistics of the world; post office affairs; patents, trade-marks and copyrights; armies of the world; navies of the world; aviation. In Part II on scientific information are chapters on chemistry; astronomy and time; meteorology; machine elements and mechanical movements; geometrical constructions; weights and measures. The division of the matter into parts and chapters and the index make for easy reference to any matter treated.

Working Drawings of Machinery. By Walter H. James and Malcolm C. Mackenzie. 143 pages, 6 by 9 inches. 220 illustrations, 21 folding plates. Published by John Wiley & Sons, Inc., New York City. Price $2 net.

The authors are, respectively, assistant professor of mechanical engineering and instructor in mechanical engineering of the Massachusetts Institute of Technology, and the book was written to meet the needs of the second and third year students studying drawing in the Institute. The aim has been to give correct conception of the character and purpose of a working drawing and to suggest the relation between a pictorial drawing of an object and its orthographic projection. The plan was also to illustrate good, modern drafting-room practice. The contents comprise discussion of general principles, conventional representations, dimensioning and describing, sketching, scale detail drawing, general drawing, design drawings, diagrammatic drawings, mechanical pictorial drawings, etc. The book should be found generally useful to draftsmen. The appendix contains a number of tables of machine details, such as bolt heads and nuts, cap screws, machine screws, standard threads, Acme threads, washers, cotter pins, taper pins, tapers, keys, etc.

NEW CATALOGUES AND CIRCULARS

James Anderson & Sons, Sidney, Ohio. Circular of the "Comus" oil cups for all purposes.

Standard Tool Co., Cleveland, Ohio. Catalogue No. 21 of drill chucks and circular of the "Shield" brand high speed drills.

American Can Co., 104 So. Michigan Ave., Chicago, Ill. Catalogue of sheet metal presses, wire working machinery and die shop equipment.

Richard W. Jefferis Co., Camden, N. J. Folder of Jefferis pressed steel lockers, wardrobes and shelving for offices, shops and factories.

Fosdick Machine Tool Co., Cincinnati, Ohio. Circular illustrating and describing new style No. 0 horizontal boring, drilling and milling machine.

W. W. Blakely, 100 Leicester Court, Detroit, Mich. Circular of the "Common Sense" adjustable boring tool for use on lathes, boring machines and drilling machines.

Billings & Spencer Co., Hartford, Conn. Circular describing the Billings & Spencer No. 0 double-acting ratchet which is provided with two removable sockets for taper and square shank drills.

Brown Hoisting Machinery Co., Cleveland, Ohio. Catalogue E of Brown hoists, grab buckets, slag buckets, contractor's grab buckets, shovel buckets and various kinds of tubs.

Millers Falls Co., Millers Falls, Mass. Circulars of automatic boring tool No. 15, "Star" hacksaw frame No. 11½ and "Star" hacksaw frame No. 1011 having pistol grip.

Walden Mfg. Co., Worcester, Mass. Circular of "Walden Worcester" wrenches comprising ratchet wrenches, combination sets for automobiles, offset wrenches, tee-handle wrenches, etc.

Hess-Bright Mfg. Co., Front St. and Erie Ave., Philadelphia, Pa. Booklet on ball bearings for axle lighting generators, showing details of railway car equipment for generating electricity used for lighting cars.

Index Visible, Inc., Times Bldg., New York City. Circular of a visible card index system, the cards being mounted on vertical aluminum strips so that the key word of each card is visible.

G. L. Simonds & Co., 115 S. La Salle St., Chicago, Ill. Booklet entitled "Economical Steam Production" showing the use of the "Vulcan" soot cleaner and data on economies effected.

Crescent Tool Co., Jamestown, N. Y. Circular of "Crescent" universal pliers which hold securely taper, half round, triangular, and other shapes as well as rectangular, parallel and round pieces.

F. E. Wells & Son Co., Greenfield, Mass. Card illustrating the Wells improved Stillson pattern pipe wrench in which the wooden handle is provided with double ferrules to prevent breaking.

H. W. Johns-Manville Co., 41st St., & Madison Ave., New York City. Specifications of J M asbestos roofing and waterproofing material for shops, factories, mills, office buildings and other structures.

Morrison Boiler Co., Sharon, Pa. Circular of the Morrison water tube boiler illustrated with views of a 200 H. P. boiler recently erected for the National Pulp & Turpentine Co., Green Cove Springs, Florida.

Chicago Pneumatic Tool Co., Fisher Bldg., Chicago, Ill. Bulletin No. 34 D on Chicago pneumatic Corliss compressors, steam driven, containing description of construction and mechanical details with illustrations.

Gilbert & Barker Mfg. Co., Springfield, Mass. Pamphlet on the Gilbert & Barker process for burning fuel oil under low pressure, with illustrations of apparatus and installations in large manufacturing plants.

Fox Machine Co., Grand Rapids, Mich. Sectional catalogues on hand and power feed milling machines Nos. 2, 3 and 3½; universal trimmers; bench, floor and column types, and mitering machines; tube and pipe cutting machines Nos. 1, 3, 5 and 6; adjustable dado heads.

E. L. Patten, St. Louis, Mo. Postcard illustrating and describing the "Universal" bench filing machine having adjustable work table and adjustable file carrier enabling the user to file all angles in either direction up to 5 degrees.

Flexible Steel Lacing Co., 544 W. Jackson Blvd., Chicago, Ill. Circular of "Alligator" steel lacing for machinery belting, consisting of steel hooks that can be applied with a hammer only. The hooks form a flexible joint when joined with a sectional rocker hinge pin.

Firth-Sterling Steel Co., E. S. Jackman & Co., agents, 710-714 Lake St., Chicago, Ill. Catalogue of Firth-Sterling steels, including treatise on tool steel, the selection of steel, and heat-treatment of all grades. The catalogue contains valuable information for all steel users.

Graham Mfg. Co., 94 Point St., Providence, R. I. Pamphlet entitled "The Virtues of a Vise" illustrating uses of the Graham drill vise for drilling machines, milling machines, shapers or planers. The jig vise may be used as a substitute for expensive jigs on many kinds of work.

Kasenit Co., 21 State St., New York City. Circular of "Kasenit" open fire casehardening compound which is said to be the most rapid compound for open fire hardening. It is non-poisonous, non-explosive and non-inflammable, and may be used for casehardening and carbonizing wrought iron, mild steel and tool steel.

C. H. Driver & Kerr Co., 1300 Sixteenth St., Racine, Wis. Circular of the Driver & Kerr drill racks for use in machine shops. These racks are ingeniously devised so as to prevent the drilling machine man from putting his drills into the wrong holes. Hence, the rack is a time saver, as every drill must be in its proper place.

Cincinnati Milling Machine Co., Cincinnati, Ohio. Circular of "Cincinnati" semi-automatic milling machines with intermittent feed and power quick return, 28-inch size. The circular illustrates the machine including details of construction. This is essentially a manufacturing machine, applicable to the work found in armories, sewing machine factories, etc.

Cowan Truck Co., Holyoke, Mass. Catalogue on the Cowan transveyor illustrated with views showing use in printing plants, automobile factories, electric welding shops, screw machine departments, electric manufacturing works, paper mills, etc. The catalogue gives conclusive evidence of the value of the truck or transveyor in reducing cost of handling materials in industrial plants of all kinds.

R. K. LeBlond Machine Tool Co., Cincinnati, Ohio. Pamphlet on the LeBlond belt shifting attachment for lathes, milling machines and other machine tools. This mechanically operated attachment shifts the drive belt of cone-driven machines quickly and in either direction. It not only eliminates the danger incident to changing belts, but converts an ordinary cone-driven headstock into a quick speed change mechanism.

Hannifin Mfg. Co., Chicago, Ill. Catalogue of "Aero" devices comprising air-operated chucks, countershafts, mandrels, clamping fixtures, vises, gate valve seating chucks and other air-operated tools and machinery. The use of compressed air for quick machine tool operation, especially in brass working lathes has assumed large proportions in the last few years. The catalogue is of considerable interest to all mechanics.

J. S. Bretz Co., 250 West 54th St., New York City. Booklet on F. & S. annular ball bearings (made in Germany) of the single annular type fitted with ribbon ball separator and the W. H. narrow width ball separators. The company is the sole importer of these bearings, and the booklet lists each bearing, giving the outside diameter, bore, width, ball diameter, number of balls, load in pounds, etc. The dimensions are given in millimeters and a table of inch equivalents is included.

Wells Bros. Co., Greenfield, Mass. Catalogue of gages, comprising standard cylindrical or ring and plug gages, plug and templet thread gages, screw pitch gages, pipe thread gages in sets, fork cylindrical limit gages, fork thread limit gages, "Crescent" thread limit gages, screw thread micrometers. The catalogue contains interesting and useful matter on standards of length, the use of measuring tools, how to hold screw thread micrometers and data on screw threads. It should be in the hands of every progressive mechanic.

American Swiss File & Tool Co., 24 John St., New York City. Catalogue and revised price-list of American Swiss files. A price revision was made necessary by the new tariff law, under which hand cut files and files of precision are dutiable at 25 per cent ad valorem. The company has revised its prices to meet the competition as far as possible, but states that the new prices cannot be lowered without lowering the standard of quality. Excepting a few shapes and cuts below 6 inches in length, all files will be found as low in price as any of approximately equal quality made abroad. The catalogue is of interest to all toolmakers and other users of fine files.

Titanium Alloy Mfg. Co., Niagara Falls, N. Y. Bulletin No. 3, "Rail Reports on Open Hearth Steel" containing a summary of the results of chemical and physical tests on seven standard and seven titanium-treated open hearth A rails. The work being done by the company in making comparative tests of standard and titanium-treated steel rails and publishing results of same is attracting wide attention from metallurgists and users of rails. The bulletin is profusely illustrated, showing large sulphur prints and sections of A rails and micro-photographs taken from the top of head, center of head, web, center of flange, bottom of flange and end of flange.

TRADE NOTES

Worcester Lathe Co., 134 Gold St., Worcester, Mass., is the designation under which C. E. Thwing is marketing a new eleven-inch lathe built for him by the Whitcomb-Blaisdell Machine Tool Co.

W. H. Leland & Co., Worcester, Mass., manufacturers of sensitive drilling machines, have changed the firm name to "Leland-Gifford Co.," the members of the firm remaining the same as before.

N. C. Walpole, Southern representative of the Niles-Bement-Pond Co. and the Pratt & Whitney Co., has opened a sales office and a machinery display room at 2015 First Ave., Birmingham, Ala.

J. Faessler Mfg. Co., Moberly, Mo., manufacturer of boiler tools, has removed its general sales office to rooms 1934-6 Railway Exchange Bldg., St. Louis, Mo. Charles F. Palmer remains in charge.

DeForrest Electric Welding Co., Cleveland, Ohio, has been incorporated to do an electric welding business. The following are interested: H. J. Lamb, M. M. McLaughlin, C. F. Miser, H. B. Altman and Edward Cherney.

Hoefer Mfg. Co., Freeport, Ill., has appointed the J. R. Stone Tool & Supply Co., Detroit, Mich., which has opened a Chicago branch office at 820 Ashland Block, as agent for the Hoefer auxiliary heads in Chicago territory.

James Maher Chain Tongs & Wrench Mfg. Co., of East Liverpool, Ohio has been incorporated with a capital of $25,000. James Maher, Michael Maher, Thomas Terry, H. E. Pfaff, L. L. Campbell and George Wurzell are interested.

Galion Iron Works & Mfg. Co., Galion, Ohio, has been incorporated with a capital of $10,000 to manufacture machinery and tools. W. Pelton, B. T. Meyer, C. C. Gilmore, C. D. Wise, D. G. Strother, O. P. Beck and D. C. Boyd are incorporators.

Rockford Drilling Machine Co., Rockford, Ill. S. H. Beck, secretary and treasurer has sold his interest to William Nelson, president who now becomes the sole owner of the business of manufacturing upright drills, gang drills and lathes.

Kelly Reamer Co., Cleveland, Ohio, has increased its capital stock from $25,000 to $50,000 common stock. The increase of capital stock was made to enable the company to increase its facilities and to care for the rapidly growing business in Kelly reamers, etc.

Baxter-Frick Gear Cutting & Mfg. Co., Cleveland, Ohio, has been incorporated with a capital of $25,000 to manufacture and sell gears. The following parties are interested: Archie K. Baxter, William H. Frick, Vincent A. Taylor, Oswald M. Hoch and Mrs. Grace Dartos.

THE MOVING PICTURE IN THE MACHINE TOOL BUSINESS*

BY CHESTER L. LUCAS†

The moving picture as an entertainer is rapidly making room for the moving picture as an instructor. This has been much in evidence recently in the scientific films which have been shown to illustrate plant life, biology, laws of physics and similar subjects. Another phase of moving picture activities was manifested in motion study for "scientific management" and a still later one in the moving picture as an aid to the machine tool builder in handling factory problems and selling campaigns. Several examples of the use of moving pictures in aiding the salesman will be cited in this article and suggestions offered whereby the application of the moving picture may be made of greater value in the machine tool industry.

Primarily, the service which the moving picture can render to the machine builder is instruction in the factory or the selling field. Suppose, for instance, a manufacturer of an intricate machine had trouble in getting his machines properly set up and started after they had been taken down at the factory for shipment to distant points. Although drawings and printed instructions were sent with each machine, there was often difficulty in setting up and starting. This manufacturer could have a moving picture film made to show just how the machine should be assembled and operated. It could show the sequence in which the members should be put together, graphically illustrate the important parts to be most carefully assembled, and in fact show the building up of the machine from the time it left the crate to the completed stage ready for operation. No amount of verbal or written instruction could make this process as clear as a picture could, and, moreover, the entire process of assembling the machine, unless extraordinarily long, could be carried through in a thousand feet of film, requiring about twenty minutes to show. The question will be raised as to how the man who is to set up the machine is to see the film in a case like this. If the machine is going to a point not far distant, the machine manufacturer can arrange to have the men who are to set it up come to his factory and see the film on a screen and listen at the same time to instructions. It would often be the case, however, that the film would be most valuable when the machine is going so far away that verbal instruction in the factory is impracticable. In such cases the erectors can have the film shown in the nearest moving picture theater in the morning hours and study it at leisure. It seems a safe prediction, however, to say that not many years will elapse before a small moving picture machine will be as essential a part of a manufacturing plant's equipment as the camera is at the present time. Many colleges and schools are now using moving picture machines for instruction purposes.

Depicting mechanical movements is an interesting field for the moving picture. It is practicable to slow down or speed up any movement when making a moving picture film. Suppose, for instance, the operation of a very slowly moving piece of mechanism is to be shown. In this case the moving picture camera is set up and the operating crank is turned very slowly so as to take as few pictures as possible and still show continuous movement. This is the method employed in making botanical pictures showing the growth of a plant—a process normally requiring several weeks being reproduced in a few minutes. To get this effect, the photographs are taken at the rate of one every eight hours instead of sixteen every second as for ordinary moving pictures.

The value of this possibility to the mechanical public is illustrated in an automatic machine that was made in Brooklyn, N. Y. This machine made one revolution every thirty-one

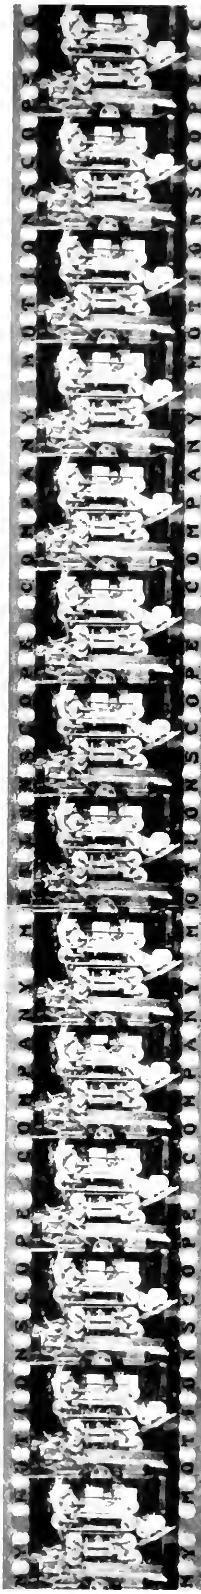

Fig. 2. Section of Film showing Operation of Automatic Machine

* For additional information on the moving picture machine and its relation to the machine shop see "The Moving Picture as an Aid to Mechanical Instruction," MACHINERY, May, 1912, engineering edition, and articles there referred to.

† Associate Editor of MACHINERY.

minutes, and as it was desired to show its operation, a moving picture was made, taking the pictures so slowly that the full revolution of the machine could be thrown on the screen in a few minutes. Conversely, a mechanism operating at high speed may be taken by accelerating the picture-taking camera speed if it is desired to show it operating at a slower speed. Then when the film is projected at the normal rate of sixteen pictures per second, the speed can be made apparently slow. Thus the movement of any kind of mechanism can be graphically illustrated to students or apprentices, who perhaps could not grasp the operation if it were running at full speed. Especially is this true of spring-actuated mechanism, such as that employed in some adding machines in which analysis of the movements of the parts is difficult. The National Cash Register Co. uses moving pictures to instruct repair men as well as salesmen in the manipulation of the different parts of the mechanism.

In the comparatively slowly operated pictures the water takes on the appearance of molasses, and its motion seems sluggish in comparison with the rotation of the ball. The experiment has been carried still further by shooting the column of water with a rifle bullet. When this is shown on the screen, the effect of the bullet is to shatter the column from top to bottom, after which it is seen to pull itself together and finally return to the former position.

Another case where the moving picture will undoubtedly prove of value as an instructor is in showing the operation of automatic machinery that has been built and shipped perhaps years before. A concern building automatic machinery might have produced a machine such as that illustrated by the film from which the print in Fig. 2 was made, the mechanism of which was especially complex. Suppose, after the machine had been built for several years, it was destroyed by fire. If a film showing the operation of this machine was at

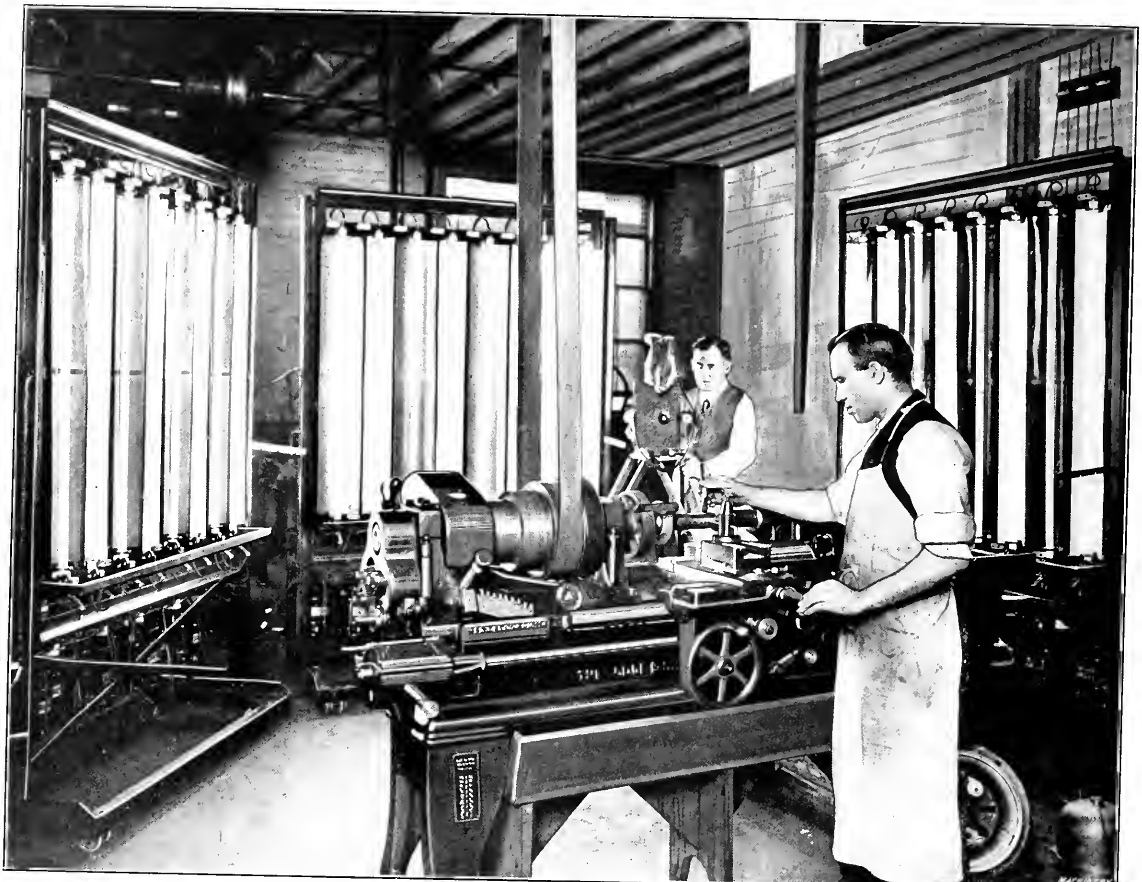

Fig. 3. Making a Moving Picture Film in a Machine Shop

Films for instruction purposes along mechanical lines can be used at much less expense than that of keeping and operating the mechanism itself. Thomas A. Edison proposes to demonstrate the elementary laws of physics to school children who would have great difficulty in understanding them from textbook descriptions, by making moving pictures of pumps having glass working parts. If the operating parts of any mechanism are inaccessible to observe or study, they are the parts that should be most clearly shown. Moving pictures of such sections make the operation of the machine clearly understood.

An instance of the aid of the moving picture to the scientist and teacher in the study of gyroscopic motion may well be cited. Why does a hollow rubber ball balance itself so perfectly at the top of a jet of water? By making moving pictures at high speed and projecting them upon the screen, the ball is shown to acquire a gyroscopic motion at the top of the column of water, tending to keep it from going off at the side.

hand, it should facilitate the building of a duplicate machine by a new set of men, for even though drawings are accessible, there is often doubt about operating points that a moving picture would clear up.

Recent Developments in High-speed Pictures

Pathe Freres are undoubtedly among the leaders in producing scientific films, and it is through their courtesy that much of this information and some of the views were obtained. They have recently developed a high frequency spark apparatus used for taking pictures of rapidly moving objects. These pictures, of course, must be taken in a dark room; the film operates continuously, that is, without the intermittent motion of the ordinary moving picture camera. The spark operates at the rate of 1200 flashes per second and this number of exposures is made on the film. By this method, they have been able to record the path of a bullet shot at a clay pipe. By projecting the film at a normal speed, the bullet could be followed slowly across the screen until it entered the clay

pipe bowl. It seemed to remain within the bowl for a few seconds and then slowly, very slowly, the bowl dropped to pieces and the sections fell to the floor. Of course this film looked unnatural, but it showed the possibility of analyzing the action of rapidly moving objects.

Of course, there is hardly any need of mentioning the value of the moving picture as an aid in instructing apprentices and unskilled workmen in their duties. One does not have to draw on the imagination to a great extent to see the advantage of the moving pictures in instructing the apprentice as to the sequence of operations to follow in performing a given operation in the approved manner.

The Moving Picture as an Aid to the Salesman

Just as the highest type of technical advertising involves showing machine tools actually at work, so the great advantage of the moving picture lies in its ability to show to the prospective customer just what the advantages of the machine in operation are. A large steel company was particularly interested in securing foreign business. It wished to show foreign prospects the equipment of the plant, the large lathes, planers and the magnitude with which the business was conducted. It was impossible to bring these men to the works, so the company decided to take the works to the men. Accordingly, moving picture films were made, showing panoramic views through the plant and detail views of some of the large machine operations. These films were sent to the company's foreign agents, who, through the aid of a projecting machine, showed them to the prospective customers. The views made such an impression that large orders from these foreign countries were soon received.

The educational film showing, for instance, the making of a typewriter or the building of an automobile is becoming quite common, and its value as an advertising attraction has been well demonstrated. Several large manufacturing companies are already exhibiting films at conventions and exhibitions showing the manufacture of their product.

Small portable projecting machines are coming to the front more rapidly than ever. One of the latest of these weighs but little more than a typewriter, and the turning of the crank also operates a magneto, thus generating electric light for illuminating the pictures. The machine is self-contained and, with its case, comprises a portable outfit which a salesman can easily take into the office of a prospective customer. Then, by drawing the shades, the moving pictures can be projected upon the blank wall to show the superintendent or manager just how the machine works. Of course, films would be selected to exploit some impressive job, showing the machine working at its full capacity, preferably on the class of work done by the prospect. The salesman can demonstrate exactly how the different movements are secured. The explanation of an automatic feed throw-off, or the action of a cam movement, could be readily made in a demonstration of this sort.
